Is discard better than return gastric residual aspirates: a systematic review and meta-analysis

Zunjia Wen†, Ailing Xie†, Mingqi Peng†, Lanzheng Bian, Li Wei and Mei Li *

Abstract

Background: The assessment of residual gastric volume is common practice in critical care units. However, the effects and safety of discarding or returning gastric aspirates remain uncertain. Therefore, we aimed to evaluate the role of discarding or returning gastric aspirates on the gastric residual volumes in critically ill patients.

Methods: A comprehensive, systematic meta-analysis of randomized controlled trials (RCTs) on the efficacy and safety of discarding or returning gastric aspirates in critical ill patients was performed. Studies were identified by searching Pubmed and other databases (from inception to 31 Sept 2018). Summary odd ratios (ORs) or mean differences (MDs) with 95% confidence intervals were calculated using fixed- or random-effects model for outcome assessment.

Results: Four RCTs, with a total number of 314 adult patients, were included in the analysis. No significant differences were found in the 48th hour residual volume (MD = 8.89, 95% CI: 11.97 to 29.74), the average potassium level (MD = 0.00, 95% CI: −0.16 to 0.16), the episodes of gastric emptying delay (OR = 0.98, 95% CI: 0.35 to 2.80), the incidence of aspiration pneumonia (OR = 0.93, 95% CI: 0.14 to 6.17), the episodes of nausea or vomiting (OR = 0.53, 95% CI: 0.07 to 4.13) and diarrhea (OR = 0.99, 95% CI: 0.58 to 1.70).

Conclusions: No evidence confirms that returning residual gastric aspirates provides more benefits than discarding them without increasing potential complications. Rigorously designed, multi-center, large-sample randomized controlled trials must be further conducted to validate the role of discarding or returning residual gastric aspirates.

Keywords: Gastric residual volume, Enteral nutrition, Nursing care, Management, Review, Meta-analysis

Background

Nutritional support is an essential part of patient management in intensive care unit (ICU) [1]. In general, a common practice of health care providers is to insert a nasogastric or orogastric tube to provide nutrition support, and nutrition delivery by the gastrointestinal tract is more economic and physiological than the parenteral route; enteral nutrition (EN) helps maintain the structure and function of intestinal mucosa, reduce the risk of infection, and avoid the potential adverse effects of parenteral nutrition (PN) [2–4]. Critically ill ICU patients with feeding tube are at a high risk for many complications, such as gastric retention, pulmonary aspiration, and feeding intolerance, considering their impaired consciousness level, unstable physiological status, and intervene of mechanical ventilation [5, 6]. Therefore, scholars must explore methods for maximizing the benefits and reducing the complications of feeding tube for nutrition support to improved outcomes of critical ill patients.

Monitoring gastric residual volume (GRV) is typically conducted to observe signs of feeding intolerance. Previous studies [7–9] have investigated the use of GRV to observe gastric tolerance during EN, the results remain inconsistent, and many clinicians [10, 11] speculate that monitoring GRV is unnecessary. Moreover, the ideal cut-off for intervention and frequency of monitoring GRV has not been established yet [12]. Further investigations must be conducted to guide the clinical practice. To date, several studies have focused on management of gastric aspirates; their results on whether to return or discard gastric
aspirates remain controversial. Despite a certain number of randomized controlled trials (RCTs) on management of gastric aspirates, the variability of intervention time, sample size, and outcomes remains large. In this regard, critical review of related studies and synthesize of data of RCTs are necessary to provide evidence for management of gastric aspirates and insights into future direction on this issue. This systematic review and meta-analysis aims to evaluate whether discarding or returning gastric aspirates can improve the outcomes of ICU patients with feeding tube.

Methods
We conducted this systematic review in compliance with the recommendations from Cochrane Collaboration and reported results in accordance with preferred reporting items for systematic reviews and meta-analyses (PRISMA) [13, 14].

Data sources and search strategies
Two authors independently searched the databases for appropriate studies. Related articles were identified and selected by searching in Pubmed, EMBASE, Web of Science, Science Direct, Cochrane Central Register of Controlled Trials, China National Knowledge Infrastructure, Wanfang Database, and the Chinese Biomedical Literature Database (from inception to 31 August 2018) with the following search terms: (nasogastric tube OR gastric tube OR gastric feeding OR enteral nutrition OR EN) AND (gastric residual volume OR GRV OR gastric residual aspirate OR aspirate) AND (discard OR return or management). Searching was conducted through strategies used in Pubmed and the instructions and rules of each database. The reference lists of the retrieved studies and previous reviews and meta-analyses were manually search for potential RCTs. No language limits were set for the identification of related publications.

Study selection
Studies were selected on the basis of the first screening of the identified titles or abstracts and the second check-up of full-text articles. Studies were considered eligible if the following criteria were met: the study design was RCT; the study subjects included critical ill adult patients with feeding tube; the intervention was to return or discard gastric aspirates with orogastric tube; we made no restrictions on the timing of starting and ending of the intervention; and related outcomes, such as GRV, gastric emptying delay, aspiration pneumonia, and feeding intolerance, were reported and data could be retrieved. Case reports, series, qualitative studies, and review articles were excluded. All studies were screened independently by the two authors (Z W and A X) according to the selection criteria. The studies were selected when the two reviewers consented. Any disagreement on the studies for inclusion was settled with resort to a third reviewer (M L).

Data extraction
A standardized data collection form was designed to extract important information. Any discrepancies in the extraction process were resolved by consents. We also attempted to contact authors to obtain original data or missing details. Two reviewers (Z W and A X) independently extracted the following information: first author, year of publication, study location, target population, details of discarding and returning residual gastric aspirates, main outcomes, and conclusions.

The following outcomes were extracted: the primary outcome was the gastric residual volume: the volume of gastric residuals at different time-point after the first return or discard of the gastric residual. The second outcomes included the blood test of electrolyte level, and related complications including the number of patients with episodes of gastric emptying delay, aspiration pneumonia, vomiting, diarrhea.

Quality assessment
Two reviewers independently used Cochrane Collaboration’s risk of bias tool to evaluate the methodological quality and risk of bias of the included RCTs. This tool includes seven specific domains: sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective outcome reporting, and other issues. Each domain is classified as low risk of bias, high risk of bias, or unclear risk of bias according to the judgment criteria. Furthermore, we assessed the quality of evidence using the GRADE criteria [15]. Any disagreements in the quality assessment were resolved by discussion and consents.

Data synthesis and analysis
All of the extracted data were processed and analyzed with Review Manager version 5.3 [16]. Data were extracted and double-checked by two reviewers independently. Data syntheses and interpretations were performed by two authors (Z W and M P) to ensure the accuracy of the results. Binary outcomes were presented as Mantel–Haenszel-style odds ratios (ORs) with 95% confidence intervals (CIs). Continuous outcomes were reported as mean differences (MDs). A fixed-effect model was adopted in case of homogeneity ($P$-value of $\chi^2$ test $> 0.10$ and $I^2 < 50\%$). A random-effect model was used in case of significant heterogeneity ($P$-value of $\chi^2$ test $> 0.10$ and $I^2 \geq 50\%$). We planned to do subgroup analysis if there are evident heterogeneity, and the source of heterogeneity was analyzed according to patients’ age, the threshold of discarding or returning gastric residuals among trials. Publication bias was evaluated with funnel plots, and asymmetry was
Results

Figure 1 indicates the PRISMA flow chart of study selection. Briefly, 91 relevant publications were identified through the initial comprehensive search. After screening the titles and abstracts of the citations, we included 12 potentially related studies for another round of full-text review. These studies were further screened and subjected to quality appraisal. We then included four RCTs [17–20] for final analysis.

Study characteristics

Table 1 shows the basic characteristics of the four included RCTs, which involved 314 adult patients, comprising 156 patients who underwent discard intervention and 158 patients who underwent return intervention. All of the four RCTs were conducted in different countries, namely, Egypt [19], the USA [18], Spain [17], and China [20]. The follow-up period varied from 2 days [17, 18] to 7 days [19]. Two RCTs [17, 19] returned gastric aspirates up to 250 mL, one RCT [20] returned gastric aspirates up to 150 mL, and one RCT [18] returned all gastric aspirates. Three RCTs [17–19] reported the number of patients with episodes of gastric emptying delay in discard and return groups, and the delayed gastric emptying is reckoned as there are more GRV than the nominated GRV in those studies.

Risk of bias assessment

Figures 2 and 3 represent the risk of bias of included in the four RCTs. All of the RCTs mentioned the randomization, yet the method of randomization of two RCTs [18, 19] remained unclear, and none reported allocation blinding. Significant exposure of allocation was observed in one RCT [17], whereas the allocation concealment of resting three RCTs [18–20] remained unclear. Given the nature of interventions, blinding participants and personnel is difficult; therefore, no study reported the blinding design on participants and personnel. Only one RCT [18] was rated with low risk of bias considering their blinding design on the assessment process. No other significant biases were found among the included RCTs.
Outcome analysis

**Forty-eight hour residual volume**

Two RCTs [17, 18] reported the 48th hour residual volume in discard and return groups. The summary MD on the 48th hour residual volume was 8.89 (95% CI: −11.97 to 29.74), and no evident heterogeneity was found ($P = 0.52$, $I^2 = 0\%$) (Fig. 4a).

**Average potassium level**

Two RCTs [17, 18] reported the average potassium level in discard and return groups. The summary MD on the average potassium level was 0.00 (95% CI: −0.16 to 0.16), and no evident heterogeneity was found ($P = 1.00$, $I^2 = 0\%$) (Fig. 4b).

**Episodes of gastric emptying delay**

Three RCTs [17–19] reported the episodes of gastric emptying delay in discard and return groups. The summary OR on the episodes of gastric emptying delay was 0.98 (95% CI: 0.35 to 2.80), and heterogeneity was evident ($P = 0.05$, $I^2 = 66\%$) (Fig. 4c).

**Incidence of aspiration pneumonia**

Three RCTs [18–20] reported the incidence of aspiration pneumonia in discard and return groups. The summary OR on the incidence of aspiration pneumonia was 0.93 (95% CI: 0.14 to 6.17), and no evident heterogeneity was found ($P = 0.47$, $I^2 = 0\%$) (Fig. 5a).

### Table 1 The characteristics of included studies

| Study (author year) | Country | Sample (discard / return) | Population | Intervention | Outcomes | Conclusions |
|---------------------|---------|--------------------------|------------|--------------|----------|-------------|
| Behairy 2014 [19]   | Egypt   | 44 (20/24)               | Adult patients connected with EN within first 24 h and for 7 consecutive days | Discarded all gastric aspirate before feeding, Returned the gastric aspirate up to 250 ml | The GRV, gastric emptying delay, the aspiration pneumonia, feeding intolerance (vomiting & diarrhea), the electrolytes & glucose level, comfort outcomes (vital signs and oxygen saturation) on 1st and 7th day. | It is recommended to return gastric aspirate up to 250 ml to the patients. |
| Booker 2000 [18]    | USA     | 18 (10/8)                | Critically ill adult ICUs patients with expected EN > 48 h. | Discarded all the residual volumes before feeding, Had all the residuals returned through the feeding tube. | Weight changes; serum level of electrolytes; complications such as diarrhea, nausea, vomiting et al. | It’s tempting to encourage nurses to discard the residual volumes. |
| Juvé-Udina 2009 [17]| Spain   | 122 (61/61)              | Critically ill ICU adult patient with estimated length of stay > 48 h | Any aspirate was discarded. Returned the gastric aspirate up to 250 ml | Nasal gastric tube obstructive complication episodes; pulmonary aspiration episodes; intolerance episodes (nausea, vomiting, diarrhoea and abdominal distension); enteral feeding delays; hyperkalaemia, hyperglycaemia episodes; discomfort episodes | Re-introduce gastric content aspirated to improve GRV management is favored |
| Wang 2017 [20]      | China   | 130 (65/65)              | Surgical ICU adult patients with total or part EN | All the aspirates were discarded. Returned the gastric aspirate up to 150 ml | The incidence of gastric emptying delay; the serum level of blood sugar, potassium, blood sodium; related complications (the incidence of gastric retention, tube blockage, diarrhea and aspiration) | Re-transfusion of gastric retention fluid is recommended. |

Wen et al. BMC Gastroenterology (2019) 19:113  Page 4 of 9
Episodes of nausea or vomiting
Two RCTs [17, 18] reported the episodes of nausea or vomiting in discard and return groups. The summary OR on the episodes of nausea or vomiting was 0.53 (95% CI: 0.07 to 4.13), and no evident heterogeneity was found ($P = 0.52$, $I^2 = 0\%$) (Fig. 5b).

Episodes of diarrhea
Three RCTs [17, 18, 20] reported the episodes of diarrhea in discard and return groups. The summary OR on the episodes of diarrhea was 0.99 (95% CI: 0.58 to 1.70), and no evident heterogeneity was found ($P = 0.42$, $I^2 = 0\%$) (Fig. 5c).

Subgroup and sensitivity analyses
No subgroup analyses were performed in our study because of the small heterogeneity and limited number of the included RCTs. We attempted to evaluate publication bias by using a funnel plot. However, publication bias was
not determined because of the limited number of the included RCTs (less than 10).

Sensitivity analyses are used to investigate the influence of one study on the overall risk estimate by removing one study in each turn for every included results. The results suggested that the overall risk estimates were not substantially changed by any single study.

**Discussion**

To return or discard gastric residual volume is an important question that warrants discrete verification. Gastric residues may increase the risk of tube blockage and infection, whereas discarding gastric residues may increase the risk of fluid and electrolyte imbalance in patients [21, 22]. The three included RCTs [17, 19, 20] indicated that the return of gastric residues provided more benefits on the balance of fluid and electrolyte but did not increase the gastric intolerance; these studies supported the return of gastric residues to improve the outcomes of critically ill adult patients. However, our synthesized results indicate no significant differences in the 48th hour residual volume, the average potassium level, the episodes of gastric emptying delay, the incidence of aspiration pneumonia, and the episodes of vomiting and diarrhea for adult patients. Even when including a larger sample size, we still did not detect differences in the benefits of discarding and returning residual gastric aspirates, and the quality of evidence was generally moderate (Table 2). A previous systematic review and meta-analysis [23] in Chinese patients included two RCTs [17, 18]; consistent with our present finding, this work did not provide evidence that returning gastric residual aspirates can effectively improve the management of gastric retention without increasing potential complications. Therefore, more rigorous, multi-center, large-sample RCTs are needed to validate the effects of discarding or returning residual gastric aspirates and provide solid evidence and guidance to clinical practice.

At present, the amount of gastric residues to be taken as gastric retention has not been clearly defined yet. Based on literature review, most studies [9] regarded gastric retention as 150–400 mL, but the values vary greatly. A computer simulation of nutrient solution infusion and

gastric emptying was performed using a combination of nine gastric emptying speeds and six infusion rates; the results showed that for healthy people, if intestinal feeding is performed at 0–125 mL per hour, then the gastric residue will be rapidly stabilized at 225–900 mL at the beginning of enteral feeding for 3 to 13 h [24]. That is, different critically ill patients have different levels of gut dysfunction dependent on their pathology, shock states or therapies applied that reduce/impaired gut motility, spanning from 225 mL to 900 mL. Therefore, the numerical range of gastric retention in different populations must be determined. Previous studies [10, 25] reported that for children, if the gastric residual amount exceeds 5 mL/kg, then gastric emptying delay and gastric retention occur. However, one previous study [26] has found that the bedside EN tolerance assessments, particularly GRV, do not predict delayed GE or rate of EN advancement. One of our included studies [19] has divided gastric emptying delay into three levels based on an amount of more than 150 mL: 151–250 mL as light delay, 251–350 mL as moderate delay, and over 350 mL as severe delay; however, the return of residual gastric aspirates was not evaluated based on the severity of gastric emptying delay. The return of residual gastric aspirates should be based on the discrete consideration of gastric retention degree [27]. With greater gastric residual volume, the return of gastric residual aspirate is suspected to cause higher risks in gastric retention. Two of the included RCTs [17, 19] returned gastric aspirates up to 250 mL, one RCT [20] returned gastric aspirates up to 150 mL, and one RCT [18] returned all gastric aspirates. Future studies should address the advantages and disadvantages of GRV monitoring to potentially identify the cutoffs of GRV in different populations and provide recommendations on return of residual gastric aspirates.

The potential advantages and disadvantages of discarding and returning residual gastric aspirates should be considered. Discarding aspirates may reduce the handling of feed delivery systems for medical staff and the risk of potential contamination, but it exposes staff to splash injury [27]. However, whether discarding residual gastric aspirates reduces the level of gastric retention remains unclear. In the present meta-analysis, the result of the 48th hour residual volume indicate no difference in discarding and returning aspirates; the result is similar to that of the 7th day residual volume [19]. Discarding residual gastric aspirates may result in insufficient nutritional supplement for the patient and higher risk of fluid and electrolyte disturbance [28]. Meanwhile, returning residual gastric aspirates can improve the management of nutrition delivery and balance of fluid and electrolyte; however, this process is prone to higher risk of tube blockage and contamination [9, 29]. It’s well-known that discarding the residual gastric aspirates can increase the risk of reducing energy intake, however, the very abnormal looking aspirates such as bloody, fecal or very bilious aspirates are virtually always discarded since it’s a sign of gastric bleeding or intolerance [30]. The present study did not found any difference between the return and discard intervention in terms of the average potassium level, the episodes of gastric emptying delay, and related adverse complications. The discard or return of residual gastric aspirates should be highly individualized and appropriately used after careful assessment of the potential benefits and risks of such therapy, considering specific short- and long-term goals.

This meta-analysis has several limitations that should be considered. First, although this study did not found effect and safety differences between discard and return intervention, the rather small sample size of the pooled studies may be insufficient to detect significant difference. Given the limited number and outcome differences, subgroup analyses and funnel plot evaluation were not conducted. Second, some of the included RCTs recruited patients who received EN and PN. PN may result in impaired bowel function, and its inclusion may confuse the results. Further evidence should be obtained using a rigorous

| Outcomes                          | Number of included studies | Number of participants contributing data to this outcome | Summary MD/OR | 95% CI       | Heterogeneity (I²) | Quality of evidence (GRADE) |

Table 2 The summary of synthesized findings
standardized nutrition regimen to investigate the effects and safety of discarding or returning aspirates in patients with EN or PN. Third, the randomization procedures are well explained in all of the included RCTs. However, the process of allocation, blindness, and assessment is unclear, although it is essential to the adequacy and reliability of the results, we have attempted to contact the original authors to get the related information on their own studies, yet no reply has been received. Future studies with rigorous design and large sample sizes are warranted to identify the role of discarding and returning residual gastric aspirates.

Conclusions
In conclusion, this meta-analysis failed to determine effect and safety differences between discarding or returning residual gastric aspirates. The optimal strategy for management of residual gastric aspirates in critically ill patients has yet to be determined. To date, management of GRV and residual gastric aspirates varies greatly. Limited lines of evidence are available to guide the practice, especially in the population of children. Further studies on this area must be conducted to evaluate the role of discarding or returning residual gastric aspirates.
