Avalanche phenomena use steeply nonlinear dynamics to generate disproportionately large responses from small perturbations, and are found in a multitude of events and materials. Photon avalanching enables technologies such as optical phase-conjugate imaging, infrared quantum counting and efficient upconverted lasing. However, the photon-avalanching mechanism underlying these optical applications has been observed only in bulk materials and aggregates, limiting its utility and impact. Here we report the realization of photon avalanching at room temperature in single nanostructures—small, Tm3+-doped upconverting nanocrystals—and demonstrate their use in super-resolution imaging in near-infrared spectral windows of maximal biological transparency. Avalanching nanoparticles (ANPs) can be pumped by continuous-wave lasers, and exhibit all of the defining features of photon avalanching, including clear excitation-power thresholds, exceptionally long rise time at threshold, and a dominant excited-state absorption that is more than 10,000 times larger than ground-state absorption. Beyond the avalanching threshold, ANP emission scales nonlinearly with the 26th power of the pump intensity, owing to induced positive optical feedback in each nanocrystal. This enables the experimental realization of photon-avalanche single-beam super-resolution imaging with sub-70-nanometre spatial resolution, achieved by using only simple scanning confocal microscopy and without any computational analysis. Pairing their steep nonlinearity with existing super-resolution techniques and computational methods, ANPs enable imaging with higher resolution and at excitation intensities about 100 times lower than other probes. The low photon-avalanching threshold and excellent photostability of ANPs also suggest their utility in a diverse array of applications, including sub-wavelength imaging and optical and environmental sensing.

The primary advantage of photon avalanching (PA) is its combination of extreme nonlinearity and efficiency, achieved without any periodic structuring or interference effects. PA was first observed over 40 years ago in Pr3+-doped bulk crystals, which exhibited a sudden increase in upconverted luminescence when excited beyond a critical pump laser intensity. Its discovery quickly led to the development of other lanthanide-based bulk PA materials—used, for example, in efficient upconverted lasers—and its unique properties continue to spark interest over diverse fields.

PA is a positive-feedback system analogous to the second-order phase transition of ferromagnetic spin systems—a comparison that has proved to be useful for modelling the process. In lanthanide-based PA, a single ground-state absorption (GSA) event initiates a chain reaction of excited-state absorption (ESA) and cross-relaxation events between lanthanide (Ln3+) ions, resulting in the emission of many upconverted photons. The sensitivity of Ln3+ photophysics to local material properties has precluded the realization of PA in nanomaterials. Avalanche-like behaviour in previous nanoparticle designs was ultimately the result of the formation of larger aggregate materials, non-PA thermal mechanisms or pre-avalanche energy looping, with nonlinear order ranging from 2 to 7. There remains strong motivation for developing PA in nanoparticles, given that the ability to process these colloidal...
nanomaterials in solution allows them to be incorporated into various device platforms, nanotechnologies and environments using bio-compatible surface chemistries and materials.

To design nanocrystals that may be capable of PA, we combined four key elements: (1) the recent design paradigm for upconverting nanoparticles, which emphasizes high Ln 3+ content and energy confinement; (2) the choice of Tm 3+ (Fig. 1a), with its slow radiative lifetime of the intermediate state, up to seconds; (3) the delivery of the core Tm 3+ concentration; (4) the selection of excitation wavelengths in the second near-infrared window (NIR-II) (either 1,064 nm or 1,450 nm; Fig. 1c) optimized for resonant ESA, in contrast to the usual Tm 3+ ground-state pumping wavelengths (800 nm, or 980 nm with Yb 3+ sensitization; Fig. 1j); and (4) the use of CdSe nanoparticles, which emphasizes high Ln 3+ content and energy looping.

To determine whether PA occurs, we examined the nanoparticles for three definitive criteria: (i) stronger pump-laser-induced ESA compared to GSA, with the ratio of ESA to GSA rates exceeding 10^4 (Supplementary Table 4); (ii) a clear excitation-power threshold, above which a large nonlinear increase in excited-state population and emission is observed; and (iii) a slowdown of the excited-state population rise time at threshold. For PA, rise times typically reach more than 100 times the lifetime of the intermediate state, up to seconds. Together, these criteria delineate PA from other nonlinear multiphoton processes, including conventional energy-transfer upconversion (ETU) process, in which Yb 3+ ions sensitize ground-state absorption, precluding PA.

Plots of Tm 3+ emission at 800 nm versus 1,064 nm pump intensity measured on nanoparticle ensembles drop-casted onto glass substrates show that as Tm 3+ content is increased from 1% to 4%, the degree of nonlinearity s also increases, but resides firmly in the energy looping regime, with s ≤ 7 (Fig. 2a). At these Tm 3+ concentrations, the chain reaction of ESA and cross-relaxation is too slow to compensate for radiative and multiphonon relaxation from the F 2 level of the 3H 6 state, which occurs with a rate of W 2. However, at 8% Tm 3+ doping, a clear threshold is observed at pump intensity of about 20 kW cm^-2 (Supplementary Fig. 3 and Table 3), beyond which the combination of cross-relaxation and ESA act as a gain, and a nonlinear slope of s > 22 is achieved (Fig. 2a, grey circles), surpassing the maximum value of 7 observed in the existing pre-avalanching systems. Up- and down-scans of excitation intensity display no measurable photobleaching nor hysteresis, thus showing no detectable contribution from excitation-induced thermal avalanching (Supplementary Information Fig. 4). Critically, all three PA criteria are met at room temperature for these 8% Tm 3+ ANPs (Fig. 2).

To understand why 8% Tm 3+ doping gives rise to such nonlinear emission, we modelled the PA process in ANPs using coupled nonlinear differential rate equations (DREs; see Supplementary Information and Supplementary Tables 4–8). Fitting the model to the experimental data for 8% Tm 3+ ANPs (Fig. 2a, grey dash-dotted line) yields an ESA-GSA rate (R 2/R 1) ratio of more than 10,000 (Supplementary Table 6), satisfying the R 2/R 1 > 10^4 criterion for PA.

To observe the signature slow-down in the excited-state population rise times expected for PA, the time-dependent luminescence from the 3H 6 level (800 nm emission) was measured (Fig. 2b; Methods and Supplementary Figs. 6–8). The rise time is defined as the time needed to reach 95% of the asymptotic value (Supplementary Fig. 7). We observe that a substantial lengthening of the luminescence rise time emerges near the PA threshold intensity, reaching a maximum of approximately 608 ms (Fig. 2b)—nearly 400 times the lifetime of the 3F 4 state—further verifying that the PA mechanism prevails in these nanoparticles.

Our modelling also predicts PA for even longer-wavelength excitation near 1,450 nm, resonant with ESA between F 2 and H 4, but not with GSA (Fig. 1c). This is a technologically attractive wavelength range because
Emission intensity (a.u.)

Fig. 2 | Demonstration of nanoparticle PA. a, 800-nm emission intensity versus excitation intensity for ensemble films of 1%, 4% and 8% Tm³⁺-doped nanocrystals. Excitation at 1,064 nm excitation is used, except where noted. See Supplementary Tables 1, 2 for ANP sizes. PA is also achieved in the 8% Tm³⁺ nanocrystals. Excitation at 1,064 nm excitation is used, except where noted. b, 800-nm emission rise times versus excitation intensity for the 8% Tm³⁺ ANPs in a, showing a large increase, up to 608 ms, near the PA threshold.

it is beyond the absorption cut-off of Si-based detectors and leads to emission that is easily detected by Si, and is also useful for deep-tissue imaging, including through-skin fluorescence imaging of live mouse brain at depths greater than 2 mm (ref. 14). Using 1,450-nm excitation, we indeed observe PA, with the emission–intensity curve showing a threshold at about 40 kW cm⁻² and a maximum nonlinearity of s = 14.9 (Fig. 2a, brown stars). More generally, the ANPs demonstrate PA for wavelengths between 1,400 nm and 1,470 nm (Supplementary Fig. 9), with the lowest threshold occurring at 1,450 nm in this range.

Recent theoretical treatments show that achieving PA with a large nonlinearity involves a complex balance between several coexisting phenomena within the material. However, in the limiting case in which the cross-relaxation rate s₂ₛ₃ is much greater than W₂, the DRE model predicts that threshold intensity is determined entirely by W₂ (refs. 15,16). In ANPs, s₂ₛ₃ is controlled by the Ln³⁺ concentration, whereas the non-radiative decay component of W₂ is dominated by losses at surfaces and interfaces17. To determine whether rebalancing these factors would reduce threshold intensity, we synthesized two 8% Tm³⁺ core–shell structures designed to reduce surface losses, and thus W₂. These designs include thicker shells, as well as larger core size than the 8% ANPs in Fig. 2, to further reduce the surface-to-volume ratio. The changes indeed result in a distinct reduction in threshold, to <10 kW cm⁻² at room temperature (Fig. 3a, Supplementary Fig. 5).

We further hypothesized that increasing the Tm³⁺ content should change s₂ and W₂, and therefore the PA excitation threshold intensity. To study this effect, core–shell ANPs with 20% and 100% Tm³⁺ were synthesized (including two sizes of 20% Tm³⁺ ANPs; Supplementary Fig. 1), and the threshold intensity was found to increase with increasing Tm³⁺ content (Fig. 3a). This is consistent with recent studies showing that at these pump intensities, excited-state lifetimes are reduced (W₂ is increased) as Ln³⁺ content increases within nanoparticles, with the resulting increase in ion–ion energy transfer opening many potential relaxation pathways that act collectively to depopulate and repopulate the levels18,19.

Models predict a linear dependence between PA threshold intensity and W₂, with a slope that is determined by s₂ₛ₃, W₂ (the excited-state decay rate; see Fig. 1c) and the excited-state relaxation branching ratio20. These dependencies are shown in Fig. 3b for three different Tm³⁺ concentrations. As s₂ₛ₃ increases, W₂ and the branching ratio become less important, leading to a slight reduction in slope in the threshold-intensity–W₂ curves. The presence of the 20% and 100% Tm³⁺ data points on nearly the same line demonstrates that by the time the Tm³⁺ content reaches 20%, s₂ₛ₃ dominates, and the relative effects of W₂ and the branching ratio become almost negligible. This well defined relationship between the PA threshold and W₂ shown in Fig. 3b has important implications for sensing applications, in which W₂ can be modulated by environmentally dependent energy transfer to the ANP surface, with small changes in W₂ (and thus threshold) resulting in large changes in luminescence for a given pump intensity.

To evaluate the efficiency and relative brightness of ANPs, we used a kinetic computational model of energy transfer within Ln³⁺-doped nanoparticles, similar to those used to reproduce the experimental upconverting quantum yields of Er³⁺/Yb³⁺ co-doped upconverting nanoparticles21,22, as well as energy-looping nanoparticles23 (Supplementary Information). Our calculations reveal that for fully passivated core–shell nanoparticles, the quantum yield can reach about 40% for ANPs excited beyond the threshold at 10⁵ W cm⁻² (Fig. 3c). Although the model has known limitations—in particular, the absence of higher-energy excited states—we note that calculated quantum yields are consistent with both previous quantum yield calculations for energy-looping nanoparticles22 and quantum yield measurements of PA-induced upconversion in fibres at room temperature23. In our calculations, we find that whereas the 8% Tm³⁺ ANPs are somewhat more efficient than the 20% ANPs at this pump fluence, the 20% ANPs are brighter (Fig. 3c). This is because brightness is a function of quantum yield, but also of the total number of emitters within the ANP (brightness is defined as the product of the wavelength-dependent Tm³⁺ ion absorption cross-section, the Tm³⁺ concentration and the quantum yield). The emission intensity shows a more nonlinear dependence on pump fluence than does quantum yield, given that the extreme nonlinearity of PA emission is a function of both intensity-dependent quantum yield and excited-state populations.

A compelling application for ANPs is single-particle super-resolution imaging, as elucidated by the recently proposed photon-avalanche single-beam super-resolution imaging (PASSI) concept, which exploits the extreme nonlinear response of PA. The size of the imaging point spread function in scanning confocal microscopy (SCM) scales inversely with the square root of the degree of nonlinearity s (as in multiphoton microscopy)24, with the full-width at half-maximum (FWHM) of an imaged nonlinear emitter in SCM given by:

\[
\text{FWHM} = \frac{\lambda}{2\text{NA}\cdot s^{3/2}}
\]

in the Gaussian optics approximation25 (where NA is the numerical aperture and \(\lambda\) is the wavelength). Therefore, deeply sub-wavelength...
resolution would be realized automatically with ANPs during standard SCM. The imaging requires no complex instrumentation, excitation beam shaping or patterning, image post-processing, or alignment procedures.

We performed single-ANP imaging, measuring a PASSI image spot of ≤75 nm average FWHM when excited at 1,064 nm at the optimal pump intensity for PASSI, which corresponds to emission intensity at the top of the steep segment of the response curve (see Methods). More specifically, the image of the 8% Tm3+ ANP from the batch with s = 26 (Fig. 3a), shows a short-axis FWHM of 65 ± 7 nm and a long-axis FWHM of 81 ± 9 nm (Fig. 4b and Supplementary Fig. 10), with its elliptical shape due to a slightly elliptical excitation spot. This spot size agrees well with PASSI simulations (Fig. 4e). The comparison with a diffraction-limited excitation spot size of 357 nm FWHM clearly shows the advantage of the extreme nonlinearity of PA (Fig. 4c). In Fig. 4a, the spot size is ~220 nm FWHM when excited closer to the saturation regime, where the degree of nonlinearity s is considerably lower, as predicted (Fig. 4d). The theoretical resolution limit considering s = 26 is 70 nm, in excellent agreement with the measured values. PASSI super-resolution and its unique power dependence is readily apparent, with two ANPs separated by 300 nm being just resolvable when excited near saturation, but easily resolvable for intensities in the steep-slope region of the PA emission–pump intensity curve (Fig. 4g, h). The resolution is fully determined by the slope of the power-dependent emission (Fig. 4f) curve, allowing us to select the optimal intensity for imaging for a given ANP architecture once that curve is measured. Beyond PASSI, there are also notable advantages for combining the steeply nonlinear ANPs with existing super-resolution approaches (Supplementary Table 11).

For example, the extreme nonlinearity and anti-Stokes luminescence should improve the achievable signal-to-noise and resolution limits of methods such as nonlinear structured illumination microscopy and near-infrared emission saturation46 nanoscopy for a given photon budget47. Additionally, applying the photon localization accuracy concept to PASSI imaging (Fig. 4b), which already exhibit sub-100-nm resolution, yields a localization accuracy of <2 nm for only 7,600 collected photons, compared to the 10–40 nm accuracies typically achieved. Realizing that the longer rise times might limit scan rates50, we also calculated a multi-point excitation scheme (Supplementary Figs. 11–13) that suggests that possible scan rates of approximately 4 s or less per frame are achievable and reasonable using multi-point PASSI.

Finally, we note that in characterizing this PA system, we measure -500–10,000-fold increases in emission intensity when the pump intensity is increased from the threshold (Ith) to twice the threshold value, which takes us beyond the steep-slope region of the ANP response curve (Figs. 2a, 3a). This enhancement, which we define as the parameter ΔIav = I2/Ith,Iav = I2/Ith, is substantially larger than in reported energy-looping systems (for example, ΔIav ≤ 50)11,22 and suggests a simpler empirical method of identifying PA using a single measurable ratio. ΔIav captures the complex balance between R/R0, cross-relaxation, and radiative versus non-radiative relaxation. We find that all nanoparticles with ≥8% Tm3+ content reported here meet this criterion (Supplementary Table 9; with a maximum ΔIav of ~10,000 attained with 20% Tm3+ ANPs, whereas a borderline value of ~500 is seen in the 100% Tm3+ ANPs, where the large increase in cross-relaxation rates leads to faster non-radiative depopulation of 3H4 (ref. 46). In conclusion, we report steeply nonlinear nanomaterials, realizing PA in engineered nanocrystals at room temperature with continuous wave pumping. We observe that core–shell architectures doped with only Tm3+ ions exhibit avalanching behaviour for Tm3+ concentrations ≥8%,
and that the PA excitation threshold intensity is fully determined by the $^3F_4$ intermediate-state lifetime at higher concentrations. Further, we show that PA is achieved for excitation in the range 1,400–1,470 nm in addition to 1,064 nm. Along with emission intensities that scale non-linearly with pump intensity up to the 26th power—enabling sub-70-nm SCM imaging resolution and $<2$-nm photon localization—these results can enable applications in local environmental, optical and chemical reporting and in super-resolution imaging.

Synthesis of core ANPs
The synthesis of NaY$_{1-x}$Tm$_x$F$_4$ ANP cores with average diameters ranging from d = 10 nm to 18 ± 1 nm (see Supplementary Table 1) was based on reported procedures. For the case of x = 0.01 (meaning 1% Tm$^{3+}$ doping), YCl$_3$ (0.99 mmol, 193.3 mg) and TmCl$_3$ (0.01 mmol, 2.8 mg) were added into a 50-ml three-neck flask, followed by an addition of 6 ml OA and 14 ml ODE. The solution was stirred under vacuum and heated to 100 °C for 1 h. During this time, the solution became clear. After that, the flask was subjected to three pump–purge cycles, each consisting of refilling with N$_2$ and immediately pumping under vacuum to remove water and oxygen. Afterwards, sodium oleate (2.5 mmol, 762 mg) and NH$_4$F (4 mmol, 148 mg) were added to the flask under N$_2$ flow. Subsequently, the resealed flask was placed under vacuum for 15 min at 100 °C, followed by three pump–purge cycles. Subsequently, the flask was quickly heated from 100 °C to 320 °C (the approximate ramp rate was 25 °C min$^{-1}$). The temperature was held at 320 °C for 40–60 min, after which the flask was rapidly cooled to room temperature using a stream of compressed air.

To isolate the nanoparticles, ethanol was added to the solution in a 1:1 volume ratio, and the precipitated nanoparticles were isolated by centrifugation (5 min at 4,000 rpm). The pellet was suspended in hexanes and centrifuged to remove large and aggregated particles. The nanoparticles remaining in the supernatant were washed two additional times by adding ethanol, isolating by centrifugation and dissolving the pellet in hexanes. The nanoparticles were stored in hexanes with two drops of oleic acid to prevent aggregation.

Shell growth
A 0.1 M stock solution of 20% GdCl$_3$ and 80% YCl$_3$ was prepared by adding YCl$_3$ (2 mmol, 390.5 mg), GdCl$_3$ (0.5 mmol, 131.8 mg), 10 ml OA and 15 ml ODE to a 50-ml three-neck flask. The solution was stirred and heated to 110 °C under vacuum for 30 min. After that, the flask was filled with N$_2$ and heated to 200 °C for about 1 h, until the solution became clear and no solid was observed in the flask. Subsequently, the flask was cooled to 100 °C and placed under vacuum for 30 min. A 0.2 M solution of Na-TFA was prepared by stirring Na-TFA (4 mmol, 544 mg), 10 ml OA and 10 ml ODE in a flask under vacuum at room temperature for 2 h, ensuring that all chemicals were dissolved. Using a nanoparticle synthesis robot, the Workstation for Automated Nanocrystal Discovery and Analysis (WANDA), 3–9 nm Na$_{1-x}$Gd$_x$O$_2$F$_2$ shells (see Supplementary Table 1) were grown on ANP cores using a layer-by-layer protocol similar to that deployed in Levy et al. Briefly, for a shell thickness of 3 nm, 6 ml ODE and 4 ml OA were added to the dried ANP cores and heated to 280 °C at 20 °C min$^{-1}$ in the WANDA glove box. The automated protocol alternated between injections of a 0.2 M Na-TFA stock solution and a 0.1 M stock solution of 20% gadolinium and 80% yttrium oleate solution. One injection was performed every 20 min for a total of 12 injections (6 injections for each precursor). Following the last injection, each reaction was annealed at 280 °C for an additional 30 min and then cooled rapidly by nitrogen flow. The particles were isolated and purified according to the purification protocol described for ANP cores.

Core–shell Na$_{1-x}$Y$_x$F$_4$ nanoparticles doped with Tm$^{3+}$ (1–100%) were synthesized using analogous methods.

Preparation of nanocrystal film samples
Nanoparticles (40 μl of a 1 μM suspension in hexane) were either drop-cast or spin-coated on a coverslip. Atomic force microscopy measurements (Bruker Dimension AFM) were performed to measure the thicknesses of the films.

Optical characterization of ANPs
For single-ANP imaging, a dilute dispersion of nanoparticles was deposited on a glass coverslip and placed on an inverted confocal microscope (Nikon, Eclipse Ti-S inverted microscope). A 1,064-nm continuous-wave diode laser (Thorlabs, FEHL750) or a Ti:sapphire pulsed laser (Coherent, Chameleon OPO Vis, 1,390–1,510 nm, 80 MHz) were directed into the back aperture of an NA = 1.49 100× immersion-oil objective (Olympus) and focused directly onto the sample on a three-dimensional (XYZ) nanoscopy piezo stage (Physik Instrumente, P-545.X88S Planos).

For measurements on film samples, an NA = 0.95 100× air objective lens (Nikon) was used. Emitted light was collected back through the same objective, filtered by 850-nm short-pass (Thorlabs, FESH 850) and 750-nm long-pass (Thorlabs, FEHL750) filters, and sent to a spectrometer equipped with an electron-multiplying charge-coupled device (Princeton Instruments, ProEM: 1600 × 3 eXcelon3) or a single-photon avalanche diode (Micro Photon Device, PDM series). For power dependence measurements, a neutral density wheel with a continuously variable density was used, synchronized with the collection system and automatically rotated by an Arduino-controlled rotator. Powers were simultaneously recorded by a Thorlabs power meter by using a glass coverslip to reflect ~10% of the incoming flux. Average excitation power densities were calculated using measured laser powers and the 1/e$^2$ area calculated from the imaged laser spot.

PA mechanism in our ANPs
As discussed in the main text, a single GSA event in lanthanide-based PA initiates a chain reaction of ESA and cross-relaxation events between Ln$^{3+}$ ions, resulting in the emission of many upconverted photons. This mechanism amplifies the population of excited states, such as the 800-nm-emitting Tm$^{3+}$ 3H$_6$ level (Fig. 1c), through a positive-feedback loop of ESA from an intermediate state (3F$_4$), followed by cross-relaxation (an energy-transfer process) back down to the same intermediate state while promoting a second ground-state Tm$^{3+}$ ion up to its intermediate state (we note that the cross-relaxation process is accompanied by the emission of phonons to compensate an energy mismatch of about 1,200 cm$^{-1}$). This process can effectively double the 3F$_4$ population on every iteration of the loop, and the repeated looping results in nonlinear amplification of excited-state populations.

The ESA is effective because the absorption peak for the electronic 3F$_2$–3F$_4$ transition is close to the 1,064-nm excitation wavelength. However, the 1,064-nm photons have an energy mismatch of ~1,200 cm$^{-1}$ for the electronic 3H$_6$–3H$_4$ transition, which decreases the GSA
cross-section at that wavelength. Owing to the energetic mismatch, GSA is a phonon-assisted process in this case, which makes its oscillator strength very small, ~10⁻⁴ times weaker than for excitation resonant with the purely electronic $f−f$ transitions.

**Materials considerations for achieving PA in nanoparticles**

PA was first observed at low temperatures—as is often the case—although several room-temperature demonstrations have been reported in bulk systems (for example, refs. 5–9, 40). In nanomaterials, however, the sensitivity of Ln³⁺ photophysics to local material properties has precluded the realization of PA and has hindered room-temperature operation. As noted in the main text, four key features were combined to design nanocrystals that may be capable of PA. The first is the recent design paradigm for Ln³⁺-based upconverting nanoparticles, in which high Ln³⁺ content, engineered energy confinement and reduced surface losses result in exceptional efficiencies and brightness 51–55. A second feature is the choice of Tm³⁺ (Fig. 1a), an ion with a particularly slow intermediate-state decay rate $\tau_I$, which strongly influences PA behaviour 56 (see below). The third critical aspect exploits the compositional strategy employed previously for energy-looping nanoparticles 57, in which typical Yb³⁺ sensitizers are omitted and high concentrations of Tm³⁺ ions are doped into a $\beta$-phase YAlF₄ matrix, enhancing Tm³⁺−Tm³⁺ cross-relaxation and ESA while reducing GSA (Fig. 1). The fourth key element, also shared with energy-looping nanoparticles, is the selection of excitation wavelengths in the NIR-II transparency window (either 1.064 nm or 1.450 nm; Fig. 1), which are optimized for resonant ESA while maintaining non-resonant GSA, in contrast to the usual wavelength-ordered GSA for pumping Tm³⁺ (800 nm, or 980 nm when combined with Yb³⁺ sensitization; Fig. 1).

To determine whether these design criteria enable nanocrystals to host PA, we synthesized Tm³⁺-doped β-NaYF₄ core–shell structures 16–33 nm in total diameter 29,33. As described in Methods sections ‘Synthesis of core ANPs’ and ‘Shell growth’, the Tm³⁺-doped core in each ANP is surrounded by an optically inert shell to minimize surface losses 11,21,31 (Figs. 1, Supplementary Figs. 1, 2 and Supplementary Tables 1, 2). These nanocrystals may be excited in the NIR-II region to emit in the NIR-I region at 800 nm (ref. 22). Both spectral windows are valuable for imaging with limited photodamage through living systems or scattering media 57. More generally, the near-infrared operation and exceptional photostability, along with the unique combination of steep nonlinearity and efficiency offered by PA suggest the utility of ANPs in a diverse array of applications, including sub-wavelength bioimaging 21,11,12, photonics and light detection 46–50, temperature 13,14,59 and pressure 53 transduction, neuromorphic computing 54 and quantum optics 55,62.

**Data availability**

All data generated or analysed during this study, which support the plots within this paper and other findings of this study, are included in this published article and its Supplementary Information. Source data are provided with this paper.

**Code availability**

The code for modelling the PA behaviour using the differential rate equations described in the Supplementary Information are freely available at https://github.com/nawgnahc/Photon_Avalanche_DRE_calculation.git.

Work at the Molecular Foundry was supported by the Office of Science, Office of Basic Energy Sciences, of the US Department of Energy under contract number DE-AC02-05CH11231. K.Y. acknowledges support from Programmable Quantum Materials, an Energy Frontier Research Center funded by the US Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES), under award DE-SC0019443. A.B. acknowledges financial support from NCN, Poland, grant number UMO-2018/31/B/ST5/01827. A.B. acknowledges financial support from MOTIE, Korea. E.Z.X. gratefully acknowledges support from the NSF Graduate Development Program (number 10077582) funded by the Ministry of Trade, Industry, and Energy (MOTIE), Korea (NRF) funded by the Ministry of Science and ICT (number 2016R1A5A2930035). KRICT Global Research Laboratory (GRL) Program through the National Research Foundation of Korea (NRF).

**Author contributions**

P.J.S., Y.D.S., S.H.N. and C.L. conceived the study. Experimental measurements and associated analyses were conducted by C.L., E.Z.X., Y.L., A.T., K.Y., A.F.-B., P.J.S., E.M.C., B.E.C., C.L. and Y.D.S. theoretical modelling and simulations of PA photophysics were carried out by A.M.K. and A.B. All authors contributed to the preparation of the manuscript.

**Competing interests**

The authors declare no competing interests.

**Additional information**

Supplementary information is available for this paper at https://doi.org/10.1038/s41586-020-03039-9.

**Correspondence and requests for materials**

should be addressed to Y.D.S., A.B., B.E.C., E.M.C. or P.J.S.

**Peer review information**

Nature thanks Xueyuan Chen, Andries Meijerink and the other, anonymous, reviewer(s) for their contribution to the peer review of this work. Peer reviewer reports are available.

Reprints and permissions information is available at http://www.nature.com/reprints.
