We propose to use the lateral interface between two regions with different strengths of the spin-orbit interaction(s) to spin-polarize the electrons in gated two dimensional semiconductor heterostructures. For a beam with a non zero angle of incidence the transmitted electrons will split into two spin polarization components propagating at different angles. We analyze the refraction at such an interface and outline the basic schemes for filtration and control of the electron spin.

There is considerable interest in generating spin polarized current in semiconductor devices for the purposes of spintronics. The central idea is to polarize electrons using ferromagnetic materials with the subsequent injection of the polarized electrons into a semiconductor device for further applications [1]. Despite the noticeable progress in the understanding the physics of this problem, the technology of the injection of the spin polarized electrons into a semiconductor system still remains unsettled; for a review see Ref. [2].

In this letter we propose an alternative way to generate a spin polarized current in heterostructures using non magnetic semiconductor materials only, see also Ref. [3]. We exploit the effect of the spin-orbit interaction(s) [4,5,6] to polarize the electron beams. The principal element of the proposed spin polarizer contains an interface between two regions with different strengths of the spin-orbit interaction(s). As a result of the refraction at such an interface, for an electron beam with a non zero angle of incidence the transmitted electrons split into two beams with different spin polarizations propagating at different angles, and consequently, one can spatially separate the beams with different polarizations. The further applications of this effect are similar to that in optical devices exploiting the polarization of light. The proposed polarizing element can be realized in a two dimensional (2D) electron (hole) gas confined by an inhomogeneous quantum well. Such a well can be created either by manipulating the gates [4,5,6,7], or by fabricating a laterally varying heterostructure.

Typically, the potential well has the shape of an asymmetric triangle, and, consequently, there is a direction of asymmetry, \( \hat{l} \), perpendicular to the electron gas plane. This leads to the appearance of the Rashba spin-orbit interaction term \( \alpha (\hat{p} \times \hat{l}) \sigma \) in the Hamiltonian, \( \alpha (\hat{p} \times \hat{l}) \sigma \). We will study the case when the parameter \( \alpha \) varies along the \( x \)-direction, and there is an interface at \( x = 0 \). The direction of \( \hat{l} \) is chosen as \( \hat{l} = -\hat{y} \). Then the Hamiltonian has the form:

\[
H_R = p_x \frac{1}{2m(x)} p_x + \frac{1}{2m(x)} p_z^2 + B(x) + \frac{1}{2} (\alpha(x) \hat{p} + p \alpha(x)).
\] (1)

Here \( B(x) \) describes the varying bottom of the conduction band which may be controlled by gates. The current operator corresponding to this Hamiltonian contains a spin-dependent part, \( J = p / m + \alpha(x) (\hat{I} \times \sigma) \). The presence of spin in the current operator implies that in the process of scattering at the interface with varying \( \alpha \) the continuity conditions for the wave function will involve the spin degrees of freedom of the electrons. The situation is analogous to the refraction of light where the polarization of light enters the conditions determining the amplitudes of the refraction (Fresnel formulas).

To diagonalize the Hamiltonian with \( \alpha(x) = \text{const} \) one has to choose the axis of the spin quantization along the direction \( (\hat{l} \times \text{p}) \). Then the electron states are described by their chiralities (referred to as “ + ” and “ - ”). For an electron in a state with a definite chirality the spin polarization is perpendicular to the direction of motion. The dispersion relations of the two chiral modes are

\[
E^\pm = \frac{p^2}{2m} \pm \alpha p + B, \quad v = \frac{\partial E^\pm}{\partial p} = \frac{p}{m} \pm \alpha. \] (2)

Notice that for both modes the velocity depends on the energy in the same way \( \alpha \), \( v = \sqrt{2(E - B)/m} \pm \alpha^2 \) and therefore under the stationary conditions the two spin components can be separated only if they are forced to move in different directions [11].

Let us analyze the kinematical aspects of the scattering at the interface between the two regions with different \( \alpha \).
All the waves participating in scattering have the same energy $E$ which determines their momenta as follows:

$$p^\pm = m(\sqrt{2(E - B)}/m + \alpha^2 + \alpha) = mv_F(\sqrt{1 + \alpha^2} \mp \alpha).$$

Here we introduce a small dimensionless parameter $\tilde{\alpha} = \alpha/\gamma v_F$ which we will use throughout the paper. The conservation of the projection of the momentum on the interface together with Eq. (3) determine the angles of the transmitted and reflected beams (Snell’s law). Figure 1 illustrates the scattering for the simplest case when $\alpha(x < 0) = 0$. The region without (or suppressed) spin-orbit term is denoted as N while the region with a finite $\alpha$ is denoted as SO, and the directions of spin polarizations are indicated by the small arrows. In Fig. 1(a) an incident (unpolarized) beam split into the N-region and when transmitted into the SO-region splits into two beams of different chirality that propagate at different angles. Thus the interface acts as a spin polarizer. In

$$\Psi^+ = e^{ip_x z} \left\{ e^{ip_x x} \chi^+_N + e^{-ip_x x} \chi^+_N r_{++} + e^{-ip_x x} \chi^-_N r_{--}, \; x < 0 \right\}$$

$$e^{ip_x x} \chi^+_N f_{++} + e^{ip_x x} \chi^-_N f_{--}, \; x > 0$$

where $\chi^\pm_{N/SO}$ are spinors corresponding to the ± chiral modes in the N/SO-regions, and $r$ and $t$ are the amplitudes of the reflected and the transmitted waves. A

Correspondingly, the + mode is refracted to larger angles than the − one. Moreover, the + mode exhibits a total reflection for an angle of incidence in the interval $\varphi^- < \varphi < \pi/2$ when $\varphi^-$ is a critical angle for total internal reflection. We will use this fact in the discussion of spin filtration devices (see Figs. (3) and (4)).

Another important fact for the spin filtration is that the − mode has a limited aperture in the SO-region. Hence, there exists an interval of outgoing angles, $\pi/2 > \theta > \theta^c$, where only the + component can penetrate. If it is possible to collect electrons from this interval, one will have an ideal spin filter. Potentially promising for spin filtration is an interval of incident angles $\varphi^f < \varphi < \varphi^c$. For an angle of incidence within this interval the transmitted beams of different chirality do not overlap. Namely, the + mode scatters into the interval $\theta^c < \theta < \pi/2$, while the − mode fills the interval $\theta^f < \theta < \theta^c$, where $\theta^c$ is the angle of separation of the two polarizations [see Fig. (1b) for a graphical definition of the angles $\varphi^f, \theta^f$ and $\theta^c$].

Remarkably, all angle intervals indicated in Fig. (1b) are not so narrow as their widths have a square root dependence on $\tilde{\alpha}$. It follows from Snell’s law that $(\pi/2 - \varphi^f) \approx (\pi/2 - \theta^c) \approx \sqrt{\delta B}$. Actually one can reduce $\theta^c$ even further. With the gates acting selectively on the different regions of the electron gas, $\delta B = B(-\infty) - B(+\infty) \neq 0$, one can alter the position of the bands relative to the Fermi level in the N- and SO-regions. A simple analysis based on Eq. (3) shows that with an increase of $\delta B$ (i.e., lowering $p_F$ in the normal region) the angle interval $(\pi/2 - \theta^c)$ grows and reaches $2\sqrt{\delta B}$. However, at that moment, which is optimal for spin filtration, the angle for total internal reflection reaches $\pi/2$. Starting from this point the angle interval suitable for spin filtration narrows and eventually becomes $\sim \tilde{\alpha}$, instead of $\sim \sqrt{\delta B}$.

Let us analyze the scattering of electrons at the interface between two regions with different magnitudes of the Bychkov-Rashba term. The problem will be considered for the two cases of sharp and smooth interfaces (12). For the clarity of the presentation we limit ourselves to the case of the interface between the N- and SO-regions only, and it will be assumed in what follows that $B(x) = const$. The scattering states of an electron coming from the N-region in the incident state $e^{i(p_x x + p_z z)} \chi^+_N$ is given by

$$\Psi^+ = e^{ip_z z} \left\{ e^{ip_x x} \chi^+_N + e^{-ip_x x} \chi^+_N r_{++} + e^{-ip_x x} \chi^-_N r_{--}, \; x < 0 \right\}$$

$$e^{ip_x x} \chi^+_N f_{++} + e^{ip_x x} \chi^-_N f_{--}, \; x > 0$$

similar expression holds also for $\Psi^-$ which evolves from the incident state $\chi^-_N$.

For the sharp interface the amplitudes $r, t$ can be
found from the continuity conditions that follow from the Schrödinger equation:

\[
\left[ \frac{p_x}{m(x)} - \alpha(x) \sigma_z \right] \Psi \bigg|^{SO}_{N} = 0; \quad \Psi \bigg|^{SO}_{N} = 0 \quad (5)
\]

where \( F \bigg|^{SO}_{N} \) denote \( F(x = +0) - F(x = -0) \). Analysis of Eq. (3) shows that in the course of refraction at the interface with \( \alpha \ll 1 \) transitions between waves with different chiralities are strongly suppressed. Namely, the amplitude \( t_{++} \sim \alpha \langle \chi_{SO} | \Psi(x) \rangle \sim \alpha^2 \tan \varphi \), and similarly for \( t_{--} \). An extra factor of \( \alpha \tan \varphi \) in the off-diagonal amplitudes is a consequence of the fact that angles of deviation of the refracted electrons are small, and therefore the overlap of the spinors of different chiralities tends to vanish. The amplitudes \( t_{--} \) and \( t_{+-} \) reach their maximal values \( \sim \alpha^{3/2} \) at \( \varphi \approx \varphi_c \) where deviation angles are maximal and \( \langle \chi_{SO} | \chi_{SO} \rangle \sim \alpha^2 \). The intensities of the transmitted electrons without change of their chirality are plotted in Fig. 2. The drop of the intensities occurs practically only due to the reflection which becomes decisive for \( \varphi \gtrsim \varphi_c \). Similar to \( t_{+-} \) and \( t_{--} \), the amplitudes of the reflection with a change of the chirality, \( r_{+-} \) and \( r_{--} \), are negligible at any angle. These amplitudes get their maximal value \( \sim \alpha^{3/2} \) at \( \varphi = \varphi_c \). Therefore, when total reflection occurs for the \( + \) mode at \( \varphi \geq \varphi_c \) its intensity is left mostly in the same mode.

At angles \( \varphi \geq \varphi_c \) the amplitude \( r_{+-} \) is close to unity, while \( r_{--} \) is still small (as well as \( r_{-+} \)). It appears that for the angle of incidence equal to \( \varphi_c \) the ratio \( |r_{--}/r_{+-}|^2 \) has a cusped minimum. For small \( \alpha \) this ratio has a limiting value \( \approx 0.03 \) at the minimum. Therefore, an unpolarized electron beam, when reflected, acquires a significant level of spin polarization at \( \varphi \approx \varphi_c \) (see the dashed line in Fig. 2). The situation is analogous to the Brewster angle in the reflection of light. An angular interval around \( \varphi_c \) where the degree of polarization of the reflected beam remains large enough is not so narrow, see Fig. 2. This fact opens an opportunity to use reflection for the purposes of spin polarization.

Now we discuss the case of a smooth interface when \( \alpha \) changes weakly on the scale of the electron wavelength \( \lambda \). One can conduct the analysis of the refraction at a smooth interface using a small parameter \( \eta = (d \alpha / dx) / \alpha p_F \sim \lambda / d \ll 1 \), where \( d \) is a characteristic scale of the variation of \( \alpha \) (i.e., an effective width of the interface). Due to the smoothness of the interface the electron spin will adjust itself adiabatically to the momentum keeping its polarization in the direction perpendicular to the momentum. In addition, for \( \eta \ll 1 \) the reflected wave can be neglected if \( \varphi < \varphi_c \). Having these arguments in mind, we seek a solution which evolves from the state \( \chi^+ \) in the form which generalizes the WKB ansatz to include the spin degrees of freedom:

\[
\Psi^+ = \phi_{++}(x) \frac{\chi^+(x)}{\sqrt{v_x}} e^{i \int p_x^x dx} + \phi_{--}(x) \frac{\chi^-(x)}{\sqrt{v_x}} e^{i \int p_x^x dx}
\]

with \( \phi_{++}(x = -\infty) = 1 \) and \( \phi_{--}(x = -\infty) = 0 \).

To obtain an admixture of the wave with the opposite chirality, \( \phi_{--} \) and \( \phi_{++} \neq 0 \), one has to analyze the Schrödinger equation up to first order in \( \eta \). This equation is similar to the one describing transitions in a two-level system subjected to an oscillating perturbation (the Rabi problem 13). The latter arises due to the phase difference of the two WKB waves in Eq. (6). The analysis shows that the admixture of a wave with different chiralities due to a smooth interface is very small, \( \phi_{--} \sim |\sin^2 \varphi (\eta \alpha_{SO}/v_F)^2| \ll 1 \) or \( \sin^2 \varphi (\alpha_{SO}/v_F)^4 \), whichever is smaller. In addition, the shape of the \( \pm \) lines on Fig. 2 becomes more rectangular.

Summarizing the above consideration, one can state that for both the discussed cases each of the spin chiralities propagates along its own trajectory, while the change of the chiralities is very inefficient. Hence, the construction of spin filtering devices should be based on the kinematical separation of the trajectories of different chiralities. The N-SO interface analyzed so far for any kind \([4, 5]\) will result in splitting of the trajectories which can be used for the purpose of spin polarization and filtration.

We now consider a spin polarization device presented schematically in Fig. 3. The geometry of the device is analogous to the Glan style optical polarizers made of uniaxial crystals. A stripe with a reduced strength of the Bychkov-Rashba term is imposed across the SO conductor (SO-“N”-SO junction). The direction of the stripe is chosen in such a way that the angle of incidence of the electron beam exceeds the angle for total internal reflection for the – mode. (It is the – mode that can be totally reflected at the SO-“N” interface.) The + mode will pass through the junction mostly unaffected, while

![FIG. 2: A sharp N-SO interface; \( \alpha = 0.1 \). The intensities per unit outgoing angle of the electrons transmitted without change of their chirality \( \sim (d \theta^2 / d \varphi)^{-1} \left| t_{++} \right|^2 \) and \( \sim (d \theta^2 / d \varphi)^{-1} \left| t_{--} \right|^2 \) as a function of an angle of incidence. The dashed line indicates the level of spin polarization, \( \left| r_{--}/r_{++} \right|^2 \), of the reflected electrons for an unpolarized incident beam.](image)
the spin components. The kinematical construction is explained in the text.

In Fig. 3, the kinematics of the refracted electrons is illustrated. The concentric circles represent spin split Fermi surfaces in each of the regions of the junction. The dashed lines are directed perpendicular to the stripe. They show that the projection of momenta on the direction of the interfaces is conserved. The kinematically allowed wave vectors in each of the regions are given by the intersection of the dashed lines with a circle. This distance should be shorter than a spin relaxation length.

Finally, we would like to point out the potential advantages of the proposed method. The spin polarized current can be comparable with the incoming unpolarized current. The compactness of the proposed setup makes it not very sensitive to the spin relaxation and disorder. The present experience of control of ballistic electrons (spin filters) makes the proposed method of spin manipulations feasible.

The authors gratefully acknowledge the discussions with M. Heiblum and Y. Levinson.
