We present an approach that combines the local density approximation (LDA) and the dynamical mean-field theory (DMFT) in the framework of the full-potential linear augmented plane waves (FLAPW) method. Wannier-like functions for the correlated shell are constructed by projecting local orbitals onto a set of Bloch eigenstates located within a certain energy window. The screened Coulomb interaction and Hund’s coupling are calculated from a first-principle constrained RPA scheme. We apply this LDA+DMFT implementation, in conjunction with a continuous-time quantum Monte-Carlo algorithm, to the study of electronic correlations in LaFeAsO. Our findings support the physical picture of a metal with intermediate correlations. The average value of the mass renormalization of the Fe $3d$ bands is about 1.6, in reasonable agreement with the picture inferred from photoemission experiments. The discrepancies between different LDA+DMFT calculations (all technically correct) which have been reported in the literature are shown to have two causes: i) the specific value of the interaction parameters used in these calculations and ii) the degree of localization of the Wannier orbitals chosen to represent the Fe $3d$ states, to which many-body terms are applied. The latter is a fundamental issue in the application of many-body calculations, such as DMFT, in a realistic setting. We provide strong evidence that the DMFT approximation is more accurate and more straightforward to implement when well-localized orbitals are constructed from a large energy window encompassing Fe-$3d$, As-$4p$ and O-$2p$, and point out several difficulties associated with the use of extended Wannier functions associated with the low-energy iron bands. Some of these issues have important physical consequences, regarding in particular the sensitivity to the Hund’s coupling.

I. INTRODUCTION

This article has two purposes. The first one is to present a new implementation of dynamical mean-field theory (DMFT) within electronic structure calculation methods. This implementation is based on a highly precise full-potential linear augmented plane waves method (FLAPW), as implemented in the Wien2k electronic structure code.$^{2,3}$ The second purpose of this article is to report on DMFT calculations for the iron oxypnic
tide $\text{LaFeAsO}$, the parent compound of the ‘1111’-family of recently discovered iron-based superconductors. The strength of electronic correlations in these materials is an important issue, which has been a subject of debate in the literature.$^{2,3,4,5,6}$

The combination of dynamical mean-field theory with density-functional theory in the local density approximation (LDA+DMFT) provides a powerful framework for the quantitative description of electronic correlations in a realistic setting. A number of materials have been investigated in this framework over the past decade, such as transition metals and transition-metal oxides, rare-earth and actinide compounds, and organic conductors. These examples testify to the progress in our understanding of the key physical phenomena associated with the competition between the localized and itinerant characters of electrons belonging to different orbitals (see e.g. Refs. $^{7,8,9,10,11,12}$ for reviews).

In the past few years, a new generation of LDA+DMFT implementations have been put forward,$^{13,14,15,16,17,18,19}$ which emphasize the use of Wannier functions as a natural bridge between the band-structure and the real-space description of the solid in terms of orbitals. These functions span the subset of orbitals which are treated within the many-body DMFT framework. In this article, we present an implementation of LDA+DMFT within the full potential linear augmented plane wave (FLAPW) framework, using atomic orbitals that are promoted to Wannier functions by a truncated expansion over Bloch functions followed by an orthonormalization procedure. This is a simpler alternative to the previous implementation of DMFT within FLAPW$^{20}$, which constructed the Wannier functions following the prescription of maximal localization.$^{21}$ The choice of FLAPW is motivated by the high level of accuracy of this all-electron, full-potential...
method. In the present work, we use the Wien2k electronic structure package, and we have constructed an interface to it that allows for the construction of Wannier-like functions used in DMFT. Our implementation is described in detail in Sec. III. As a benchmark, we perform calculations on a test material, SrVO$_3$, which are presented in Appendix A and compared to previously published results for this material. Throughout this article, many-body effects are treated in the DMFT framework using the recently developed continuous-time strong-coupling Quantum Monte Carlo algorithm of P. Werner and coworkers. Because very low temperatures can be reached, and very high accuracy can be obtained at low-frequency, this algorithm represents a major computational advance in the field.

In Sec. III we address the issue of electronic correlations in LaFeAsO. The DMFT calculations which have been published soon after the experimental discovery of superconductivity in the iron oxypnictides have provided seemingly contradictory answers to this question. In Refs. [1,2], K. Haule and G. Kotliar proposed that LaFeAsO is a strongly correlated metal, rather close to the Mott metal-insulator transition, and characterized by a reduced value of the quasiparticle coherence scale, resulting in bad metallic behavior. In contrast, in Refs. [3,4], V. Anisimov and coworkers proposed that these materials are in a weak to intermediate regime of correlations.

Our LDA+DMFT calculations for LaFeAsO support the physical picture of a metal with intermediate correlations. The average value of the mass renormalization of the Fe 3d bands is about 1.6, in reasonable agreement with the picture inferred from photoemission experiments. We also find that there is no technical inconsistency between different DMFT results reported for LaFeAsO before. We show that the discrepancies in the literature are due to two causes: i) the specific value of the interaction parameters used in these calculations and ii) the degree of localization of the Wannier orbitals chosen to represent the Fe 3d states, to which many-body terms are applied.

In Sec. III we perform detailed comparisons between LDA+DMFT calculations performed with different degree of localization of the correlated orbitals, associated with different choices of energy windows for the Wannier construction (and accordingly, different degrees of screening of the interaction parameters). We point out several difficulties associated with the use of more extended Wannier functions associated with the low-energy iron bands only. Some of these issues have important physical consequences, in particular regarding the sensitivity to the Hund’s coupling.

This article ends with several appendices, reporting on more detailed aspects or technical issues. Appendix A is devoted to a benchmark of our implementation on a “classical” test compound, SrVO$_3$. Appendix B details some technical issues associated with the projection scheme used to display partial spectral functions with a given orbital character. Appendix C discusses the influence of spin-flip and pair-hopping terms on the degree of correlations, on the basis of model calculations. We conclude that while these terms are indeed important close to the Mott transition, they can safely be neglected in the regime of correlations relevant to LaFeAsO.

II. THEORETICAL FRAMEWORK

A. Implementation of LDA+DMFT in the APW framework

1. LDA+DMFT in the basis of Bloch waves

To make this article self-contained and in order to define the main notations, this subsection begins by briefly reviewing some essential aspects of the LDA+DMFT framework. The presentation is close to that of Refs. [14,15], where additional details can be found.

Dynamical mean-field theory is a quantitative method for handling electron correlations, which can be described as an “effective atom” approach. The self-energy in the solid is approximated by that of a local model, a generalized Anderson impurity model describing a specific set of atomic-like orbitals coupled to a self-consistent environment. The self-consistency requirement is that the local on-site Green’s function of the solid, calculated using this local self-energy, must coincide with the Green’s function of the effective impurity model.

In order to formulate the local effective atom problem, a set of (orthonormal) local orbitals $|\chi^\alpha_m\rangle$, and corresponding Wannier-like functions $|w_{k_m}\rangle$, must be constructed. These Wannier functions span the “correlated” subspace $C$ of the full Hilbert space, in which many-body correlations (beyond LDA) are taken into account. This set of orbitals spanning the correlated subspace must be clearly distinguished from the full basis set of the problem, in which the Green’s function of the solid can be expressed. Obviously, the basis set spans a much larger Hilbert space, involving all relevant electronic shells.

Below, we discuss in details how the $|w_{k_m}\rangle$ are constructed from the local orbitals $|\chi^\alpha_m\rangle$. The index $m$ is an orbital index within the correlated subset, $\alpha$ denotes the atom in the unit cell, and $\sigma$ is the spin degree of freedom. Projections of quantities of interest on the subset $C$ are done using the projection operator

$$ P_{\alpha,\sigma}(k) = \sum_{m \in C} |w_{k_m}^{\alpha,\sigma}\rangle \langle w_{k_m}^{\alpha,\sigma}|. $$

The effective impurity model is then constructed for the correlated subset $C$. It is defined by the Green’s function of the effective environment, $G_{mn,\sigma}^{\alpha,\beta}(i\omega_n)$ and Hubbard-Kanamori interaction parameters $U_{mnmn^{\prime}m^{\prime}}$. By solving this model in a suitably chosen manner one obtains the impurity Green’s function $G_{mntn^{\prime}}^{\alpha,\beta}(i\omega_n)$ as well.
as the impurity self-energy

$$\Sigma^{\sigma,\text{imp}}(i\omega_n) = (G^{\sigma,0}(i\omega_n))^{-1}_{mm'} - (G^{\sigma,\text{imp}}(i\omega_n))^{-1}_{mm'},$$  \tag{2}$$

For the formulation of the self-consistency condition relating the lattice Green’s function of the solid to the impurity model, it is convenient to choose the Bloch basis $|\psi_{k}\rangle$ as the complete basis set of the problem, since it is a natural output of any electronic structure calculation. The (inverse) Green’s function of the solid expressed in this basis set is given by:

$$G^\sigma(k, i\omega_n)_{mm'}^{-1} = (i\omega_n + \epsilon_{k\nu}^\sigma)\delta_{\nu\nu'} - \Sigma^{\sigma,\nu\nu'}(k, i\omega_n),$$  \tag{3}$$

where $\epsilon_{k\nu}^\sigma$ are the Kohn Sham eigenvalues and $\Sigma^{\sigma,\nu\nu'}(k, i\omega_n)$ is the approximation to the self-energy obtained by the solution of the DMFT impurity problem. It is obtained by “upfolding” the impurity local self-energy as

$$\Sigma^{\sigma,\nu\nu'}(k, i\omega_n) = \sum_{\alpha,mm'}P^{\alpha,\sigma\nu\nu'}_{m,m'}(k)\Delta\Sigma^{\sigma,\text{imp}}(i\omega_n)P^{\alpha\sigma\nu\nu'}_{m,m'}(k),$$  \tag{4}$$

where $P^{\alpha\sigma\nu\nu'}_{m,m'}(k) = \langle \psi_{k\nu}\alpha\psi_{k\nu'}\sigma \rangle$ are the matrix elements of the projection operator, Eq. (1) and

$$\Delta\Sigma^{\sigma,\text{imp}}(i\omega_n) = \Sigma^{\sigma,\text{imp}}(i\omega_n) - \Sigma^{\text{dc}}_{\nu\nu'}.$$  \tag{5}$$

Here, $\Sigma^{\sigma,\text{imp}}(i\omega_n)$ is the impurity self-energy, Eq. (2), expressed in the local orbitals, and $\Sigma^{\text{dc}}_{\nu\nu'}$ is a double-counting correction, which will be discussed in Sect. [11B].

The local Green’s function is obtained by projecting the lattice Green’s function to the set of correlated orbitals $m$ of the correlated atom $\alpha$ and summing over the full Brillouin zone,

$$G^{\sigma,\text{loc}}(i\omega_n) = \sum_{k,\nu\nu'}P^{\alpha\sigma\nu\nu'}_{m,m'}(k)G^{\sigma,\text{imp}}(k, i\omega_n)P^{\alpha\nu\nu'}_{m,m'}(k).$$  \tag{6}$$

Note that the local quantities $G^{\sigma,\text{loc}}_{mm'}(i\omega_n)$ and $\Delta \Sigma^{\sigma,\text{imp}}(i\omega_n)$ carry also an index $\alpha$, which we suppressed for better readability.

The self-consistency condition of DMFT imposes that the local Green’s function, Eq. (6) must coincide with the one obtained from the effective impurity problem,

$$G^{\sigma,\text{loc}}(i\omega_n) = G^{\sigma,\text{imp}}(i\omega_n).$$  \tag{7}$$

This equation implies that the Green’s function of the effective environment, $G_0$, must be self-consistently related to the self-energy of the impurity model through:

$$G_0^{-1} = \Sigma_{\text{imp}} + G^{\sigma,\text{imp}}(i\omega_n).$$  \tag{8}$$

In order to construct the set of Wannier functions, we start from a set of local atomic-like orbitals $|\chi_{m,\alpha}\rangle$ defined in the unit cell. These orbitals can be expanded over the full Bloch basis-set as:

$$|\chi_{km,\alpha}\rangle = \sum_{\nu} \langle \psi_{k\nu}\alpha | \chi_{m,\alpha} \rangle |\psi_{k\nu}\rangle$$  \tag{9}$$

This expansion is then truncated by choosing an energy window $W$, and restricting the sum to those Bloch states with Kohn-Sham energies $\epsilon_{k\nu}$ within $W$. The number of bands included in $W$ will in general depend on $k$ and $\sigma$.

We thus define the modified orbitals (which do not form an orthonormal set because of the truncation):

$$|\tilde{\chi}_{km,\alpha}\rangle = \sum_{\nu \in W} \langle \psi_{k\nu\alpha} | \chi_{m,\alpha} \rangle |\psi_{k\nu}\rangle.$$  \tag{10}$$

Let us denote the matrix elements of the projection operator for this subset as

$$\tilde{P}^{\alpha,\sigma\nu\nu'}_{m,m'}(k) = \langle \tilde{\chi}_{km,\alpha} | \psi_{k\nu}\sigma \rangle, \quad \nu \in W$$  \tag{11}$$

The matrix $\tilde{P}^{\alpha,\sigma\nu\nu'}_{m,m'}(k)$ is not unitary, except when the sum in (10) is carried over all Bloch bands. It is also important to note that the matrices $\tilde{P}^{\alpha,\sigma\nu\nu'}_{m,m'}$ are in general non-square matrices. They reduce to square matrices only in the case when the number of Kohn-Sham bands included in the chosen window equals at every $k$-point the number of correlated local orbitals to be constructed.

The orbitals $|\tilde{\chi}_{km,\alpha}\rangle$ can be orthonormalized, giving a set of Wannier-like functions:

$$|\psi_{km,\alpha}\rangle = \sum_{\alpha',m'} S^{\alpha\alpha',m\sigma}_{m',m'} |\tilde{\chi}_{km',\alpha'}\rangle,$$  \tag{12}$$

where $S^{\alpha\alpha',m\sigma}_{m',m'} = \{O(k, \sigma)^{-1/2}|\chi_{m,\alpha}\rangle_{m'} \langle \chi_{m',\alpha'}|O(k, \sigma)^{-1/2}\}$ the overlap matrix elements.

The overlap $O^{m\alpha\alpha',m'}(k, \sigma)$ finally reads

$$O^{m\alpha\alpha',m'}(k, \sigma) = \sum_{W} \tilde{P}^{\alpha,\sigma\nu\nu'}_{m,m'}(k)\tilde{P}^{\alpha',\sigma\nu\nu'}_{m',m'}(k),$$  \tag{13}$$

while the orthonormalized projectors are then written as

$$P^{\alpha,\sigma\nu\nu'}_{m,m'}(k) = \sum_{\alpha',m'} \{O(k, \sigma)^{-1/2}|\chi_{m,\alpha}\rangle_{m'} \langle \chi_{m',\alpha'}|O(k, \sigma)^{-1/2}\}^{\alpha,\sigma\nu\nu'}_{m,m'}(k).$$  \tag{14}$$

2. Augmented plane waves

In this work, the Bloch basis $|\psi_{k\nu}\sigma\rangle$ are expanded in augmented plane waves (APW/LAPW), which will be briefly described in the following. As was first pointed out by Slater, near atomic nuclei the crystalline potential in a solid is similar to that of a single atom, while in the region between nuclei (in the interstitial) the potential is rather smooth and weakly-varying. Hence, one
may introduce a set of basis functions, augmented plane waves, adapted to this general shape of the potential. First the crystal space is divided into non-overlapping muffin-tin (MT) spheres centered at the atomic sites and the interstitial region in between. In the interstitial region (I) the APW $\phi^k_G(r)$ is simply the corresponding plane wave for given reciprocal lattice vector $G$ and crystal momentum $k$:

$$\phi^k_G(r) = \frac{1}{\sqrt{V}} e^{i(k+G)r}, \quad r \in I,$$  \hspace{1cm} (15)

where $V$ is the unit cell volume. This plane wave is augmented inside each of the MT-spheres by a combination of the radial solutions of the Schrödinger equation in such way that the resulting APW is continuous at the sphere boundary. The APW are then employed to expand the Kohn-Sham (KS) eigenstates $\psi^0_{k\nu}(r)$ for the full Kohn-Sham (KS) potential, (without any shape approximation). In the original formulation of the APW method the radial solutions expanding a KS eigenstate inside MT-spheres had to be evaluated at the corresponding eigenenergy leading to an energy-dependent basis set and, hence, to a non-linear secular problem. In order to avoid this complication, linearized versions of the APW method have been proposed. There are two widely-used schemes for the APW linearization. In the first, the linear APW (LAPW) method, the plane wave is augmented within MT-spheres by a combination of the radial solutions, evaluated at chosen linearization energies $E_{1I}$, and their energy derivatives. The resulting linear augmented plane wave then reads:

$$\phi^k_G(r) = \begin{cases} \frac{1}{\sqrt{V}} e^{i(k+G)r} & r \in I \\ \sum_{lm} \left[ A_{lm}^{\alpha,k+G} u_{l}^{\alpha,\sigma}(r, E_{1I}^\alpha) + B_{lm}^{\alpha,k+G} \hat{u}_{l}^{\alpha,\sigma}(r, E_{1I}^\alpha) \right] Y_m(\hat{r}) & r \in R_{MT}^\alpha \end{cases}$$  \hspace{1cm} (16)

where the index $\alpha = 1, \ldots, N_a$ runs over all $N_a$ atomic sites in the unit cell, the coefficients $A_{lm}$ and $B_{lm}$ are determined from the requirement for the linear APW to be continuous and differentiable at the sphere boundary, $r$ and $\hat{r}$ are the radial and angular parts of the position vector, respectively. The energy-independent basis set [10] leads to a linear secular problem, however, compared to the energy-dependent APW, a larger number of the LAPW in the basis set is generally required to attain the same accuracy. In order to decrease the requirement for the number of APW another linearization scheme, APW+lo/b has been proposed. The APW+lo basis set consists of the augmented plane waves evaluated at a fixed energy $E_{1I}$:

$$\phi^k_G(r) = \begin{cases} \frac{1}{\sqrt{V}} e^{i(k+G)r} & r \in I \\ \sum_{lm} A_{lm}^{\alpha,k+G} u_{l}^{\alpha,\sigma}(r, E_{1I}^\alpha) Y_m(\hat{r}) & r \in R_{MT}^\alpha \end{cases}$$  \hspace{1cm} (17)

where the coefficient $A_{lm}$ are determined from the requirement for $\phi^k_G(r)$ to be continuous at the sphere boundary. To increase the variational freedom of the APW+lo basis set the fixed-energy APW [17] are supplemented for the physically important orbitals (with $l \leq 3$) by the local orbitals (lo) that are not matched to any plane wave in the interstitial and are defined only within the muffin tin spheres ($r \in R_{MT}^\alpha$)

$$\phi_{lm,\alpha}^{lo}(r) = \left[ A_{lm}^{\alpha,lo} u_{l}^{\alpha,\sigma}(r, E_{1I}^\alpha) + B_{lm}^{\alpha,lo} \hat{u}_{l}^{\alpha,\sigma}(r, E_{1I}^\alpha) \right] Y_m(\hat{r})$$  \hspace{1cm} (18)

with the coefficients $A_{lm}$ and $B_{lm}$ chosen from the requirement of zero value and slope for the local orbital at the sphere boundary.

Additional local orbitals (usually abbreviated with the capital letters as $LO$, $\phi_{lm,\alpha}^{LO}$) can be introduced to account for semicore states. They have a similar form as Eq. (18) with the redefined $A_{lm}^{\alpha,LO}$ and a second term with a coefficient $C_{lm}^{\alpha,LO}$ and the radial function evaluated at a corresponding energy $E_{2I}^\alpha$ for the semicore band. The coefficient $B_{lm}$ is set to 0 in the APW+lo framework. Generally, in the full potential augmented plane wave method the LAPW, APW+lo and $LO$ types of orbitals can be employed simultaneously. The Kohn-Sham eigenstate is expanded in this mixed basis as:

$$\psi^\sigma_{k\nu}(r) = \sum_{i=1}^{N_b} c_{i\nu}^\sigma \phi_i^\sigma(r),$$  \hspace{1cm} (19)

where $N_b$ is the number of the orbitals in the basis set. The LDA+DMFT framework introduced in the present work can also be used in conjunction with any mixed APW+lo/LAPW/LO basis set.

3. Local orbitals and Wannier functions in the APW basis

Having defined the basis set we may now write down the expression for the Bloch eigenstate expanded in the general APW basis [19]. For $r$ in the interstitial region, it reads:

$$\psi^\sigma_{k\nu}(r) = \frac{1}{\sqrt{V}} \sum_{G} c_{\sigma}^{\nu,G}(k) e^{i(k+G)r},$$  \hspace{1cm} (20)
while for the region within the MT-spheres $r \in R_{MT}^\alpha (\alpha = 1, ..., N_{\alpha})$, we have:

\[
\psi_{\nu,\nu'}^{\rm lo}(r) = \sum_{n=1}^{N_{\nu}} c^{\nu,\sigma}_{\nu,\nu'}^{\alpha}(k) \sum_{lm} A^{\alpha,\nu}_{lm} \phi^{\alpha,\sigma}_{l}(r) Y_{m}^{l}(\hat{r}) + \sum_{n=1}^{N_{\nu}} c^{\nu,\sigma}_{\nu,\nu'}^{\alpha}\left[ A^{\alpha,\nu}_{lm} \phi^{\alpha,\sigma}_{l}(r) + B^{\nu}_{lm} \phi^{\nu,\sigma}_{l}(r) \right] Y_{m}^{l}(\hat{r}) + \\
+ \sum_{n=1}^{N_{\nu}} c^{\nu,\sigma}_{\nu,\nu'}^{\alpha} \left[ A^{\alpha,\nu}_{lm} \phi^{\alpha,\sigma}_{l}(r) + B^{\nu}_{lm} \phi^{\nu,\sigma}_{l}(r) \right] Y_{m}^{l}(\hat{r}),
\]

where $N_{PW}$ is the total number of plane waves considered in the interstitial which in turn is augmented inside each MT-sphere, $N_{\nu}$ is the number of $\phi_{\nu}^{\alpha,\nu}(r)$ orbitals of Eq. (13) and $N_{LO}$ the corresponding number of auxiliary orbitals for semicore states $\phi_{LO}^{\alpha,\nu}(r)$.

In the framework of the APW method one has several choices for the ‘initial’ correlated orbitals $|\chi_m^{\alpha,\sigma}\rangle$. Any suitable combination of the radial solution of the Schrödinger equation and its energy derivative for a given correlated shell $\{\alpha, l\}$ can be employed, for example, the $lo$-orbital (18). In the present paper we simply chose $\{\alpha, l\}$ as the solutions of the Schrödinger equation within the MT-sphere $|\phi_{\nu}^{\alpha,\sigma}(E_{11})Y_{m}^{l}\rangle$ at the corresponding linearization energy $E_{11}$.

Inserting $|\chi_m^{\alpha,\sigma}\rangle = |\phi_{\nu}^{\alpha,\sigma}(E_{11})Y_{m}^{l}\rangle$ and the expansion (21) of the Bloch eigenstate in terms of APWs into Eqs. (10 11), and making use of the orthonormality of the radial solutions and their energy derivatives: 

\[
\langle \phi_{\nu}^{\alpha,\sigma}(E_{11})Y_{m}^{l} | \phi_{\nu'}^{\alpha,\sigma}(E_{11})Y_{m'}^{l} \rangle = \delta_{\nu'\nu} \delta_{mm'}
\]

(22) one obtains the following expression for the projection operator matrix element:

\[
\tilde{P}_{m\nu}^{\alpha,\sigma}(k) = \langle \phi_{\nu}^{\alpha,\sigma}(E_{11})Y_{m}^{l} | \psi_{\nu,\nu'}^{\alpha,\sigma}(k) \rangle = A_{m\nu}^{\alpha,\nu}(k, \sigma) + \sum_{l=1}^{N_{LO}} C_{m\nu}^{\alpha,LO}(k, \sigma),
\]

(24)

In this expression, the first term in the right hand side of (24) is due to the contribution from the LAPW and/or APW+lo orbitals

\[
A_{m\nu}^{\alpha,\nu}(k, \sigma) = \sum_{G} c_{\nu,\nu'}^{\alpha}(k) A_{m\nu,\nu'}^{\alpha,k,G}
\]

(25)

and the contribution due to the $LO$ (semicore) orbitals that arises due to mutual non-orthogonality of the radial solutions of the Schrödinger equation for different energies

\[
C_{m\nu,LO}^{\alpha,\nu}(k, \sigma) = c_{\nu,\nu'}^{\alpha,\nu} C_{m\nu}^{\alpha,LO} \tilde{O}_{m\nu,LO}^{\alpha,\nu},
\]

(26)

where $\tilde{O}_{m,\nu,\nu'}^{\alpha,\nu}$ is the corresponding overlap:

\[
\tilde{O}_{m\nu,\nu'}^{\alpha,\nu} = \langle \phi_{\nu}^{\alpha,\sigma}(E_{11})Y_{m}^{l} | \phi_{\nu'}^{\alpha,\sigma}(E_{11},LO)Y_{m'}^{l} \rangle \neq 0
\]

(27)

Then we orthonormalize the obtained local orbitals to form a set of Wannier-like functions, Eq. (12). The corresponding projection operator matrix elements (24) are orthonormalized accordingly using Eq. (14).

B. Implementation and computational methods

1. FLAPW code

For the electronic structure calculation we use the full potential APW+lo/LAPW code as implemented in the Wien2k package. We have built an interface that constructs the projectors to the correlated orbitals $(P_{m\nu}^{\alpha,\sigma}(k))$ out of the eigenstates produced by the Wien2k code, as described in Sect. II A 3. In order to obtain the local Green’s function, the summation over momenta, Eq. (4), is done in the irreducible Brillouin zone (BZ) only, supplemented by a symmetrization procedure which is standard in electronic structure calculations, 

\[
\sum_{k=1}^{\text{BZ}} A(k) = \sum_{s=1}^{N_{s}} \sum_{s=1}^{\text{IBZ}} O_{s}A(k)O_{s}^{\dagger},
\]

(28)

where $A(k)$ is any $k$-dependent matrix, $N_{s}$ the number of symmetry operations and $O_{s}$ the symmetrization matrices. Furthermore, we construct the local orbitals in the local coordinate system of the corresponding atom. This means that the equivalent atoms in the unit cell for which the DMFT should be applied, e.g. the two Fe atoms in the oxypnictides, are exactly the same and the impurity problem has to be solved only once. Afterward, the Green’s function and self-energies are put back to the global coordinate system of the crystal in which the Bloch Green’s function, Eq. (3) is formulated.
2. Continuous-time quantum Monte-Carlo

For the solution of the impurity problem we use the strong-coupling version of the continuous-time quantum Monte Carlo method (CTQMC). It is based on a hybridization expansion and has proved to be a very efficient solver for quantum impurity models in the weak and strong correlation regime. It allows us to address room temperature \((\beta \equiv 1/kT \approx 40\text{eV}^{-1})\) without problems. In our calculations, we used typically around \(5 \cdot 10^6\) Monte-Carlo sweeps and 1000 \(k\)-points in the irreducible BZ. Since the CTQMC solver computes the Green’s function on the imaginary-time axis, an analytic continuation is needed in order to obtain results on the real-frequency axis. Here, we choose to perform a continuation of the impurity self-energy using a stochastic version of the Maximum Entropy method, yielding real an imaginary parts of the retarded self-energy \(\text{Re}\Sigma(\omega + i0^+),\text{Im}\Sigma(\omega + i0^+)\) which can be inserted into Eq. \(33\) in order to obtain the lattice spectral function and density of states.

3. Many-body interactions

The CTQMC strong-coupling algorithm can deal with the full rotationally invariant form of the interaction Hamiltonian. However, most calculations presented in this article will consider only the Ising terms of the Hund’s coupling, yielding the interaction Hamiltonian:

\[
H_{\text{int}} = \frac{1}{2} \sum_{m,n,m',\sigma} U_{mm',\sigma}^\sigma n_{m\sigma} n_{m'\sigma} + \frac{1}{2} \sum_{m,m'} U_{mm'}^{\sigma\sigma} (n_{m\uparrow} n_{m'\downarrow} + n_{m\downarrow} n_{m'\uparrow}), \tag{29}
\]

with \(U_{mm',\sigma}^\sigma\) and \(U_{mm'}^{\sigma\sigma}\) the reduced interaction matrices for equal and opposite spins, respectively. This enables us to take advantage of a maximal amount of conserved quantum numbers and, hence, perform the CTQMC calculation without any truncation of the local basis. The effects of spin-flip and ‘pair-hopping’ terms in the Hund’s interaction are discussed in Appendix C.

In our approach, the interaction matrices are expressed in terms of the Slater integrals \(F^0, F^2, F^4\), where for \(d\)-electrons these parameters are related to the Coulomb and Hund’s coupling via \(U = F^0, J = (F^2 + F^4)/14\), and \(F^2/F^4 = 0.625\). Using standard techniques the four-index \(U\)-matrix is calculated, and the reduced interaction matrices are then given by \(U_{mm',\sigma}^{\sigma\sigma} = U_{mm'\sigma\sigma} = U_{mm'\sigma\sigma}\) and \(U_{mm'}^{\sigma\sigma} = U_{mm'mm'} - U_{mm'mm'}\). With the above definitions, the Coulomb parameters \(U\) and \(J\) are related to the matrices via

\[
U = \frac{1}{N^2} \sum_{mm'}^N U_{mm'}^\sigma, \tag{30}
\]
\[
J = U - \frac{1}{N(N-1)} \sum_{m\neq m'}^N U_{mm'}^{\sigma\sigma}. \tag{31}
\]

As mentioned above, the LDA+DMFT scheme (as the LDA+U one) involves a double-counting correction \(\Sigma^{dc}_{mm'}\) in Eqs. \(16\). Indeed, on-site Coulomb interactions are already treated on mean-field level in LDA. Several forms of the double-counting correction term have been proposed and investigated. In this work we follow Ref. \(33\) and use the following double-counting correction:

\[
\Sigma^{dc}_{mm'} = \delta_{mm'} \left[ U \left( N_c - \frac{1}{2} \right) - J \left( N^\sigma_c - \frac{1}{2} \right) \right], \tag{32}
\]

where \(U\) is the average Coulomb interaction, \(J\) the Hund’s rule coupling, \(N^\sigma_c\) the spin-resolved occupancy of the correlated orbitals, and \(N_c = N^\uparrow_c + N^\downarrow_c\). We compared the results obtained with Eq. \(32\) also with the double-counting correction given in Ref. \(36\) which gave very similar results.

C. Choice of energy window, localization of Wannier functions, and screening

The Wannier functions defining the correlated subspace of orbitals for which a DMFT treatment is performed, are constructed by truncating the expansion of the initial atomic-like local orbitals to a restricted energy window \(W\), as described above. The choice of this energy window is an important issue, which deserves further discussion. Indeed, it will determine the shape and the degree of localization of the resulting Wannier-like functions.

Let us consider first the case of a rather small energy window, containing only those bands that have dominantly an orbital character which qualifies them as “correlated” (e.g., the Fe-3d orbitals in LaFeAsO or the V-3d-t_{2g} orbitals in SrVO_3). In that case, the dimension of the Kohn-Sham Hamiltonian used in Eq. \(4\) coincides with that of the correlated subspace \(C\) (i.e. with the number of orbitals involved in the effective impurity model, for a single correlated atom per cell). The Wannier-like functions are then quite extended in real space, and resemble strongly the Wannier orbitals constructed within other schemes, such as the maximally localized Wannier construction of Ref. \(20\), or the \(N\)-th order muffin-tin basis set downfolded to that set of bands. In such a situation, hybridization of the correlated orbitals with states that lie outside the energy window is neglected at the DMFT level. Some information about the hybridization, e.g., of the \(d\)-states with ligand orbitals is of course taken into account through the leakage of the Wannier orbitals on neighboring ligand sites (see, e.g., Ref. \(10\)).
In contrast, if a larger energy window is chosen, it will in general contain states treated as correlated as well as states on which no Hubbard interactions are imposed. In this case, the dimension of the Kohn-Sham Hamiltonian used in the LDA+DMFT calculation of the local Green’s function \( \Sigma \) exceeds the number of correlated orbitals involved in the effective impurity model. The Wannier functions are more localized in space, and the information about the hybridization of the correlated orbitals with other states within this larger window is carried by the off-diagonal blocks of the Hamiltonian between correlated and uncorrelated states.

An instructive case occurs when the correlated bands are well separated from the uncorrelated bands at all \( k \)-points, but the bands overlap in energy. This situation is realized for instance for the \( t_{2g} \) bands in SrVO\(_3\) that extend into the energy region of the \( e_g \) bands. In order to strictly pick the three correlated \( t_{2g} \) bands at each \( k \)-point, one would in that case have to introduce a \( k \)-dependent energy window. For a \( k \)-independent energy window, one will in general have more than three bands at some \( k \)-points, corresponding to some \( e_g \) contribution in the chosen window. This can then be expected to result in slightly more localized orbitals. An example is given in Appendix A.

D. Local Coulomb interactions, screening and constrained RPA calculations

The choice of the energy window influences the value of the interaction parameters \( U_{mm'm''m'''} \) in a crucial manner, which can be traced back to two main reasons.

First, the interaction parameters are related to matrix elements of a screened interaction between the chosen Wannier functions. The more bands are included in their construction, the more localized they become and, hence, the matrix elements increase. Second, screening effects themselves affect the value of \( U \). The more states are excluded from the screening process, the larger \( U \) becomes. In what follows we distinguish carefully between these two effects.

In the present work, we apply the present LDA+DMFT implementation to one of the new high-\( T_c \) superconductors, LaFeAsO. For constructing the Wannier functions, we focus on an energy window that contains the 10 bands around the Fermi level with dominantly Fe-3\( d \) character and also the bands coming from the \( p \)-bands of O and As, which are mainly located in the energy region \([-6,-2]\) eV, resulting in a “\( dpp \)”-Hamiltonian. In addition, we performed calculations also for a smaller energy window containing only the Fe-3\( d \) bands, yielding a “\( d \)-Hamiltonian”, as well as for a very large window including around 60 Bloch bands.

The values of the Coulomb interactions \( U \) and \( J \) are calculated from the constrained random phase approximation (cRPA)\(^{41,42}\) using the recently developed scheme for entangled band structures\(^{43}\). cRPA calculations for LaFeAsO have been performed before in Refs. 44,45. In Ref. 47 the screened Coulomb parameters are obtained for three different situations: (i) by constructing Wannier functions from an energy window comprising the Fe-\( d \) bands only, and screening calculated excluding the Fe-\( d \) channels only, (ii) by considering a larger window which also includes the As and O-\( p \) states, so that the screening processes, for instance, from the As-\( p \) states to the Fe-\( d \) ones are also excluded, (iii) and finally, a hybrid situation (dubbed ‘\( dpp \)’ in Ref. 47), in which the Wannier functions are calculated from an energy window including Fe-\( d \), O-\( p \), and As-\( p \), but only the Fe-\( d \) states are excluded from the screening. In other words, the screening is calculated as in (i) and the Wannier functions as in (ii). As discussed in Ref. 47 this third option should be appropriate in a situation in which a full \( dpp \)-Hamiltonian is used but Hubbard interactions are only applied to the \( d \) states.

Here, we follow the same approach as in the “\( dpp \)” case of Ref. 47, but using the new disentanglement scheme of Ref. 43. First, a partially screened Coulomb interaction \( W_r \) is constructed as follows: Wannier functions for the Fe-\( d \) states are calculated, and a basis for the complementary subspace (containing in particular the ligands, but also higher lying \( f \)-states) is constructed. Based on the interpolating \( d \)-band structure, the \( P_d \) polarization is computed, and the partially screened Coulomb interaction \( W_r \) is obtained by screening the bare Coulomb interaction by all RPA screening processes except \( P_d \). Finally, according to the cRPA procedure the Hubbard \( U \) matrix is composed of the matrix elements of \( W_r \) in the basis of \( dpp \)-Wannier functions. As argued in Ref. 47 this procedure is suitable for calculations that deal with the full \( dpp \)-Hamiltonian in the many-body calculations while explicitly retaining Coulomb interactions on the \( d \)-submanifold only. In particular, we stress that to the extent that our projection method produces Wannier functions for the \( dpp \)-window, the Hubbard \( U \) parameters are expressed in the same basis as the impurity quantities.

It is important to note that we keep the screening channels in cRPA, i.e. \( P_d \), unchanged when the energy window in our calculation is varied. Thus, the different energy windows affect only the localization of the Wannier functions, but not the screening process of the bare Coulomb interaction, and therefore the effective interactions are increasing with increasing energy window. Keeping the screening channels fixed is fully consistent with the fact that correlations are only included for the \( d \) electrons, but not for the ligand states.

For our purposes, we calculate the average Coulomb interaction \( U \) and Hund parameter \( J \) from the matrices calculated by cRPA. With this \( U \) and \( J \), the interaction matrices in the spherical symmetric approximation used in our calculation are obtained as discussed above. As we will discuss in more detail below, the comparison of the resulting \( U_{\sigma \sigma}^{m'm'} \) and \( U_{\sigma \sigma}^{m'm} \) with the cRPA matrices shows that for the \( dpp \)-Hamiltonian, the approximation using atomic values for the ratios of Slater integrals \( F_k \)
is well justified, whereas for the $d$-hamiltonian the cRPA matrices show strong orbital anisotropies.

III. RESULTS FOR THE IRON OXYPNICTIDE LAFEASO

A. Construction of the $dpp$-Hamiltonian

Let us start the discussion of correlation effects in LaFeAsO with our results for the $dpp$-hamiltonian, for which Wannier functions are obtained from cRPA, as described in the previous section. They read:

$$U^{\sigma\sigma}_{\text{cRPA}} = \begin{pmatrix}
0.00 & 1.61 & 1.55 & 2.26 & 2.26 \\
1.61 & 0.00 & 2.50 & 1.82 & 1.82 \\
1.55 & 2.50 & 0.00 & 1.70 & 1.70 \\
2.26 & 1.82 & 1.70 & 0.00 & 1.74 \\
2.26 & 1.82 & 1.70 & 1.74 & 0.00
\end{pmatrix}$$

$$U^{\nu\nu}_{\text{cRPA}} = \begin{pmatrix}
3.77 & 2.35 & 2.21 & 2.71 & 2.71 \\
2.35 & 3.94 & 2.87 & 2.44 & 2.44 \\
2.21 & 2.87 & 3.31 & 2.29 & 2.29 \\
2.71 & 2.44 & 2.29 & 3.48 & 2.29 \\
2.71 & 2.44 & 2.29 & 2.29 & 3.48
\end{pmatrix}$$

The ordering of orbitals in those matrices is $d_{z^2}$, $d_{x^2-y^2}$, $d_{xy}$, $d_{xz}$, $d_{yz}$.

According to the conventions of the formulae Eqs. (30), (31), these matrices correspond to the values: $U = 2.69$ eV and $J = 0.79$ eV. Using these values of $U$ and $J$, we construct the spherically symmetric interaction matrices,

$$U^{\sigma\sigma}_{\text{cRPA}} = \begin{pmatrix}
0.00 & 1.49 & 1.49 & 2.30 & 2.30 \\
1.49 & 0.00 & 2.57 & 1.76 & 1.76 \\
1.49 & 2.57 & 0.00 & 1.76 & 1.76 \\
2.30 & 1.76 & 1.76 & 0.00 & 1.76 \\
2.30 & 1.76 & 1.76 & 1.76 & 0.00
\end{pmatrix}$$

$$U^{\nu\nu}_{\text{cRPA}} = \begin{pmatrix}
3.59 & 2.19 & 2.19 & 2.73 & 2.73 \\
2.19 & 3.59 & 2.91 & 2.37 & 2.37 \\
2.19 & 2.91 & 3.59 & 2.37 & 2.37 \\
2.73 & 2.37 & 2.37 & 3.59 & 2.37 \\
2.73 & 2.37 & 2.37 & 2.37 & 3.59
\end{pmatrix}$$

It is obvious, that the approximation of the cRPA matrices by using spherical symmetrisation is well justified in this case, with the largest absolute deviation being $\Delta U \approx 0.35$ eV, corresponding to a relative error of around 0.09. The reason for this good agreement is that in the present case the Wannier functions are already very close to atomic-like orbitals. We also checked that cRPA yields a significantly larger value of $U$ for iron-oxide (FeO), as expected physically.

B. LDA+DMFT Results ($dpp$ hamiltonian)

We carried out LDA+DMFT calculations for the $dpp$-hamiltonian using the above matrices at an inverse temperature $\beta = 40$ eV$^{-1}$ (room temperature $T = 300$K), using the experimental crystal structure of LaFeAsO. In Fig. 1 we display the resulting total densities of states (DOS) together with the corresponding LDA DOS. The total densities of states were computed from the lattice Green’s function, Eq. (3), traced over all $\nu \in W$ and integrated over BZ. In order to obtain the corresponding LDA densities of states $\Sigma^{\sigma}_{\nu\nu}(\mathbf{k},\omega_n)$ in Eq. (3) was set to zero.

One sees in Fig. 1 that the LDA+DMFT DOS near the Fermi level displays characteristic features of a metal in an intermediate range of correlations. Both occupied and empty states are shifted towards the Fermi level due to the Fermi-liquid renormalizations. No high-energy fea-
The partial LDA+DMFT DOS for the $x^2-y^2$ and $y_z,z_x$ orbitals are shifted upwards relative to the $xy$. Indeed, we found that the crystal field (CF) splitting between the Fe 3d orbitals is somewhat affected by correlations. The splitting between the lowest $xy$ and highest $z^2$ orbitals remains unchanged ($\approx 0.3$ eV), while the $x^2-y^2$ and $y_z,z_x$ CF levels are shifted upwards by 0.15 and 0.08 eV relative to their positions in LDA. In LDA+DMFT they are located at 0.25 and 0.18 eV, respectively, above the $xy$ orbital.

It is also instructive to look at the momentum-resolved spectral function $A(k,\omega)$ of the crystal. It is obtained from the lattice Green’s function, Eq. (4), using the real-frequency self-energy and tracing over the orbital degrees of freedom. The result for the $dpp$-model is shown in Fig. 4 for an energy range including Fe-$d$, As-$p$, and O-$p$ states. In agreement with the Fermi-liquid picture of moderately-correlated quasiparticles discussed above, one can see well-defined excitations around the Fermi level, which get more diffuse at higher binding energies. The bands above the Fermi level are less affected, since the self-energies are quite asymmetric and smaller for positive frequencies, see Fig. 4. Additionally, it is easy to see that the As-$p$ states, dominantly in the energy range $[-3.5,-2]$ eV, hybridize stronger with the Fe-$d$ states and get, thus, affected by correlations. This effect is almost absent for the O-$p$ states, since they hybridize much less with Fe-$d$.

In Fig. 5 we show a comparison between the LDA band structure and the LDA+DMFT $k$-resolved electronic structure in a low-energy range around the Fermi level. This again reveals the coherent quasiparticles at the Fermi level, as well as more diffuse bands at higher energies. The crossover between long-lived quasiparticles and more diffuse states with a shorter lifetime is around $-0.4$ eV, in qualitative agreement with existing ARPES data. A point to mention here is the effect of the CF...
splitting on the band structure. For example, a difference between the LDA and DMFT results can be seen for the excitation with predominantly \( xy \) character. In LDA it forms a hole-pocket with an excitation energy of \(+0.08\,\text{eV}\) at the \( \Gamma \) point. Due to correlations, however, this band is shifted down significantly to the Fermi level, and the third hole pocket stemming from the \( d_{xy} \) orbital could eventually vanish upon electron doping.

One has to keep in mind that a direct comparison to experimental data is difficult for this compound, since (i) the experiments where done at low temperatures in the SDW phase, whereas our calculations are done at room-temperature using the tetragonal crystal structure, and (ii) ARPES experiments on the 1111 family of pnictide superconductors are difficult to perform because of difficulties with single-crystal synthesis. Nevertheless, on a qualitative level, there is a satisfactory agreement between LDA+DMFT and experiments.

![Comparison of the momentum-resolved spectral function of LaOFeAs at low energies. Upper panel: LDA. Lower panel: LDA+DMFT dpp hamiltonian.](image)

**FIG. 5:** Comparison of the momentum-resolved spectral function of LaOFeAs at low energies. Upper panel: LDA. Lower panel: LDA+DMFT dpp Hamiltonian.

We also studied the dependence of the results on the values of the interaction parameters \( U \) and \( J \). The resulting quasi-particle renormalizations \( Z_m \) are listed in Table II. Comparing the first two rows, one can see that a smaller value of \( J \) decreases the degree of correlations. The third line correspond to values similar to the ones used in Ref. 4, giving very similar results. We also increased \( U \) to the (unphysically) large value of \( U = 5.0\,\text{eV} \), and the system still displays metallic behavior, although more correlated. Hence, our calculations strongly suggest that LaFeAsO is not close to a Mott metal-insulator transition.

In order to check the robustness of our results, we also investigated the effect of increasing even further the spatial localization of the Wannier functions, corresponding to a very large energy window \( W = [-5.5, 13.6]\,\text{eV} \). We did several calculations for different parameter sets, and the resulting quasi-particle renormalizations \( Z_m \) of all these calculations are listed in Table II. For this case, no cRPA calculations for the interaction matrices were performed, but it is expected that \( U \) and \( J \) will slightly increase with more localised Wannier orbitals. In that sense, the first row of Table II corresponds to interaction parameters that could be realised for these Wannier functions. It is very satisfying to see the calculations gave almost identical quasi-particle renormalizations. Also the dependence on \( U \) and \( J \) is very similar to the one we found for the dpp Hamiltonian. In that sense we consider our calculations to be converged in terms of the number of Bloch bands that are included for the construction of the Wannier functions and the local Hamiltonian.

### C. Remarks on calculations using the \( d \)-Hamiltonian and extended Wannier functions

In this section, we address the LDA+DMFT calculations performed with the so-called \( d \)-Hamiltonian, where only the 10 Fe-\( d \) bands around the Fermi level are used for the construction of the Wannier orbitals. In doing so, we shall shed light on the discussion which has appeared in the literature regarding the results of LDA+DMFT calculations by different authors, and the degree of correlations of the 1111 family of pnictide superconductors.

| Interactions | \( z^2 \) | \( x^2 - y^2 \) | \( xy \) | \( yz \) | \( zx \) |
|-------------|-----------|----------------|------|------|------|
| \( U = 2.69, J = 0.79 \) | 0.61 | 0.66 | 0.61 | 0.60 |
| \( U = 2.69, J = 0.60 \) | 0.72 | 0.76 | 0.73 | 0.71 |
| \( U = 3.70, J = 0.80 \) | 0.52 | 0.57 | 0.53 | 0.52 |
| \( U = 5.00, J = 0.80 \) | 0.41 | 0.45 | 0.43 | 0.42 |

TABLE II: Quasiparticle weights for different interaction parameters, with the Wannier orbitals constructed for a very large window \( W = [-5.5, 13.6]\,\text{eV} \).
clearly that the spherical approximation is highly questionable when using only the $d$-bands for the Wannier construction. Of course, the full anisotropic interaction matrices can in principle be used in the LDA+DMFT calculation, but this raises the very delicate issue of a reliable orbital-dependent double-counting correction.

Another consequence of using delocalized Wannier functions is that they lead to significant non-local interactions $V_{id}$, which we found to be (from cRPA) of order $0.23U$ to $0.32U$. These interactions are completely neglected in the single-site local DMFT approach, suggesting the need for a cluster extension in that case. For these various reasons, we have reservations against using a $d$-only Hamiltonian with extended Wannier functions for DMFT calculations on LaFeAsO, as also previously emphasized Ref. 40.

2. Consistency with previous calculations

Nevertheless, in order to clarify apparent discrepancies between previously published LDA+DMFT results2,3,4, we performed calculations within the $d$-hamiltonian, for several interaction parameters reported in the literature. For the values $U = 4.0\text{eV}$ and $J = 0.7\text{eV}$ used in Ref. 2 we do confirm that the results then display very strong correlations with quasiparticle renormalizations ranging from $Z = 0.11$ ($xy$ orbital) to $Z = 0.34$ ($x^2-y^2$ orbital). One may note that within the $d$-model there is a substantial orbital dependence of $Z_m$, with a stronger renormalization predicted for the $xy$, $yz$, and $zx$ orbitals. This is a clear consequence of the Wannier functions being much more delocalized and anisotropic.

The scattering rate at this inverse temperature of $\beta = 40\text{eV}^{-1}$ is quite sizable ($\text{Im}\Sigma(\omega^z = 0) \approx -0.4 \ldots -0.6$, depending on the orbital), showing that the system is on the verge of a coherence-incoherence crossover and a bad metal. The impurity spectral function is plotted in Fig. 6. It resembles very much the one shown in Fig. 3 of Ref. 2, showing clear signatures of lower and upper Hubbard bands. There are, though, some discrepancies with the total weight and the positions of the Hubbard bands, but given the differences in the calculation (underlying electronic structure method, temperature, interaction vertex which here is only density-density), this agreement with Ref. 2 is quite satisfactory.

Furthermore, using the parameters $U = 0.8\text{eV}$ and $J = 0.5\text{eV}$ from Ref. 4, we find renormalizations in the range $Z \approx 0.7 \ldots 0.8$. This is somewhat smaller than reported in Ref. 4, although not in drastic disagreement.

Finally, we investigated the dependence on the Hund’s rule coupling of calculations performed with the $d$-only hamiltonian. Decreasing $J$ to the much lower value $J = 0.2\text{eV}$ but keeping $U = 4\text{eV}$, we find the system to be much less correlated ($Z$ between 0.63 and 0.73). We thus confirm, for those calculations, the great sensitivity to the Hund’s coupling reported in Ref. 2. We note
however that, although reducing $J$ does make the system somewhat less correlated in this case too, this sensitivity is much weaker when calculations are performed with the full $dpp$ hamiltonian, as reported above.

3. Origin of the sensitivity to the Hund’s coupling: level crossings

In order to understand the origin of the remarkable sensitivity of the correlation strength to the value of $J$ observed with the $d$-Hamiltonian we have studied the evolution of the ground state of the Fe 3d atomic shell as function of $J$. We obtained the 3d level positions corresponding to two different choices of the energy window: the ”small” one corresponding to the $d$-Hamiltonian and comprising 10 Fe 3d bands and the very large one comprising all As 4p, O 2p and Fe 3d bands as well as all unoccupied bands up to 13 eV above $E_F$. The non-interacting level positions $\epsilon_{\alpha,\sigma}^{\gamma,\sigma'}$ are then obtained as

$$\epsilon_{\alpha,\sigma}^{\gamma,\sigma'} = \sum_{k,\nu} P_{\alpha,\nu}^{\gamma,\sigma} P_{\nu,\sigma'}^{\gamma,\sigma'} - \tilde{\Sigma}_{\alpha,\gamma,\sigma}^{\sigma',\sigma}, \quad (33)$$

where the double counting term $\tilde{\Sigma}_{\alpha,\gamma,\sigma}^{\sigma',\sigma}$ is calculated in Eq. (22) but with the ”atomic” occupancy $N = 6$ of the Fe 3d shell. We used the same values of $U = 2.14$ and $2.69$ eV for the ”small” and ”very large” window choices, respectively, while the value of $J$ was varied from 0.1 to 0.5 eV. With $\epsilon_{\alpha,\sigma}$ corresponding to the $d$-Hamiltonian we observed a level crossing at $J \approx 0.2 \text{ eV}$ with the atomic ground state changing from the one with spin moment $S = 1$ to the one with $S = 2$. In the case of the ”very large” window the ground state always corresponds to $S = 2$, and the splitting between the ground state and first excited level is constant. It is obvious that a drastically different behavior of those two ”atomic” models is related to the corresponding level positions $\epsilon_{\alpha,\sigma}$, which are computed using different choices for the Wannier orbitals. The observed change of the Fe 3d atomic ground state, induced by increasing $J$, hints on a possible strong dependence of correlation strength on the Hund’s rule coupling for LaFeAsO, which is indeed observed in our LDA+DMFT calculations with the $d$-Hamiltonian. However, this sensitivity stems from a particular choice of delocalized and anisotropic Wannier functions and is much less pronounced when the energy window for the Wannier function construction is increased.

The bottom-line of this investigation is that all previously published calculations seem to be technically correct. However, as discussed above, one introduces several severe approximations when dealing with the $d$-hamiltonian only, and the justification of these approximations (restriction to local interactions, single-site DMFT, etc...) is questionable. This is especially true in this compound, due to the strong covalency between iron and arsenic states.

IV. CONCLUSION AND PROSPECTS

In the first part of this work, we present an implementation of LDA+DMFT in the framework of the full-potential linearized augmented plane waves method. We formulate the DMFT local impurity problem in the basis of Wannier orbitals, while the full lattice Green’s function is written in the basis of Bloch eigenstates of the Kohn-Sham problem. In order to construct the Wannier orbitals for a given correlated shell we choose a set of local orbitals, which are then expanded onto the KS eigenstates lying within a certain energy window. In practice, we employ the radial solutions of the Schrödinger equation for a given shell evaluated at the corresponding linearization energy as local orbitals. By orthonormalizing the obtained set of basis functions we construct a set of true Wannier orbitals as well as projector operator matrices relating the Bloch and Wannier basis sets. We derive explicit formulas for the projected operator matrices in a general FLAPW framework, which may include different types of augmented plain waves, lo and LO orbitals. Our new implementation is benchmarked using the test case of SrVO$_3$, for which we have obtained spectral and electronic properties in very good agreement with results of previous LDA+DMFT calculations.

In the second part of this work we apply this LDA+DMFT technique to LaFeAsO in order to assess the degree of electronic correlations in this compound and clarify the ongoing controversy about this issue in the literature. We solved the DMFT quantum impurity problem using a continuous-time quantum Monte Carlo approach. The Wannier functions are constructed using an energy window comprising Fe 3d, As 4p and O 2p. The resulting Wannier orbitals are rather well localized and isotropic. We take the average values of $U = 2.69$ eV and $J = 0.79$ from constrained RPA calculations, where the Wannier functions and screening channels are consistent with our setting of the LDA+DMFT scheme. We have checked the robustness of these results by increasing the size of the energy window, what resulted in a very similar physical picture.

Our LDA+DMFT results indicate that LaFeAsO is a moderately correlated metal with an average value for the mass renormalization of the Fe 3d bands about 1.6. This value is in reasonable agreement with estimates from photoemission experiments.

We also consider a smaller energy window that includes Fe-d states only. The resulting Wannier functions in this case are quite extended, leading to anisotropic and non-local Coulomb interactions. We take different values for $U$ and $J$, including the ones used in previous theoretical LDA+DMFT approaches. We demonstrate that different physical pictures ranging from a strongly correlated compound on the verge of the metal insulator transition to a moderately to weakly correlated one can emerge depending, in particular, on the choice of the Hund’s rule coupling $J$ as observed in Ref. 3. However, there are conceptual difficulties when constructing a local Hamil-
tonization from rather delocalized Wannier orbitals. The interactions are very anisotropic and orbital dependent, and non-local interactions could also become important.

In summary, we demonstrate that the discrepancies in the results of several recent theoretical works employing the LDA+DMFT approach stem from two main causes: i) the choice of parameters of the local Coulomb interaction on the Fe 3d shell and ii) the degree of localization of the Wannier orbitals chosen to represent the Fe 3d states, to which many-body terms are applied. Regarding the first point, the calculated interaction parameters employed in the present work are significantly smaller than the values hypothesized in Refs. \[2,3\]. Regarding the second point, we provide strong evidence that the DMFT approximation is more accurate and more straightforward to implement when well-localized orbitals are constructed from a large energy window encompassing Fe-3d, As-4p and O-2p. This issue has fundamental implications for many-body calculations, such as DMFT, in a realistic setting.

APPENDIX A: BENCHMARK: SrVO$_3$

For benchmarking purposes, we present in this appendix LDA+DMFT results for an oxide that has become a classical test compound for correlated electronic structure calculations, namely the cubic perovskite SrVO$_3$. As a paramagnetic correlated metal with intermediate electron-electron interactions, it is in a regime that is neither well described by pure LDA calculations nor by approaches such as LDA+U that are geared at ordered insulating materials. From the experimental side, SrVO$_3$ has been characterized by different techniques (angle-resolved and angle-integrated photoemission spectroscopy, optics, transport, thermodynamical measurements etc)\[17,23,49,50,51,52,53,54,55,56,57\].

LDA+DMFT calculations have been performed both for an effective low energy model that comprises the three degenerate bands of mainly \(t_{2g}\) character that are located around the Fermi energy — taking advantage of the cubic crystal field that singles out this group of bands — and for a bigger energy window comprising also the oxygen \(p\)-states \[13,17,19,22,23,25,26,55,56\].

In the low-energy effective \(t_{2g}\) model a quasi-particle renormalization of \(Z \sim 0.6\), compatible with experiments, is obtained for \(U\) values around 4 eV. The remaining spectral weight is shifted toward lower and upper Hubbard bands. The lower Hubbard band, located around \(-1.5\) eV binding energy has indeed been observed in photoemission; the high energy satellite of the \(t_{2g}\) model is located around \(2.5\) eV.\[23\]

Concerning calculations taking into account also the ligand states, it should be noted that possible LDA errors on the separation of \(p\)- and \(d\)-states are not corrected by DMFT, since only the \(d\)-states are treated as correlated.

In the present work, we use SrVO$_3$ as a benchmark for our projector orbitals implementation of LDA+DMFT, with results very similar to previous theoretical studies. We performed two kinds of calculations: (i) We used as an energy window the range from \(-1.35\) eV to \(1.90\) eV which comprises the \(t_{2g}\) bands, and – at some k-points – one or both of the \(e_g\) bands. This is closest in spirit to a \(t_{2g}\) model within a Wannier function formalism, though not exactly the same due to the inclusion of some \(e_g\) contribution. To recover a Wannier prescription one would in fact have to choose a k-dependent window, such as to include exactly three bands at each k-point, corresponding to the three-fold degenerate manifold of dominantly \(t_{2g}\) bands. (ii) We used an energy window of \(-8.10\) eV to \(1.90\) eV, spanning both, the bands used in (i) and the oxy-
gen $p$ dominated bands located between $-8$ and $-2$ eV.

Please note that, in order to be consistent with existing literature, we use a different parametrisation of the interaction matrix compared to Sect. 3. Here we define $U$ to be the onsite intraorbital Coulomb interaction, $U - 2J$ to be the inter-orbital interaction for electrons with opposite spin, and $U - 3J$ the inter-orbital interaction between electrons with equal spin.

The results for the first case are shown in Fig. 7. The upper panel, Fig. 7(a), displays the total spectral function of the thus defined model within LDA and LDA+DMFT. Our results recover previously published results, with a quasiparticle renormalisation of around $Z = 0.60$ for a values $U = 4.0$ eV and $J = 0.65$ eV. The contribution of the $e_g$ band to the total DOS can easily be identified from the LDA+DMFT spectra, where an additional hump between the quasiparticle peak and the upper Hubbard band appears.

Fig. 7(b) shows the local orbitals used for the DMFT calculations, together with the corresponding impurity spectral function $A(\omega)$ and the vanadium $t_{2g}$ partial DOS. The latter one is obtained by projecting the lattice Green’s function to $t_{2g}$ character using the partial projectors to be introduced in App. B. The main difference to panel (a) is the absence of the additional $e_g$ character.

Finally, Fig. 8 shows the LDA+DMFT spectral function compared to the LDA density of states, as calculated within the larger energy defined in (ii) above. Since the Wannier function are more localised, as compared to case (i), the value for the Coulomb interactions has to be adjusted accordingly, and we chose a value of $U = 6.0$ eV. As can be seen in the figure, ligand states are barely modified by the correlations, and the results for the $t_{2g}$-derived bands are very close to what is seen in the effective low energy model. The quasiparticle renormalisation is $Z = 0.57$, in good agreement with the pure $t_{2g}$ treatment discussed before.

The results of these calculations correspond to what can be expected on the basis of previously published work, and thus validate our new implementation.

APPENDIX B: PROJECTORS FOR PARTIAL DOS

In order to calculate the partial density of states for a given atomic site and particular orbital character (correlated or not) we construct a different type of projectors, which we call $\Theta^{\nu,\sigma}$.

The Wannier operators of Eq. (14) project onto a given Wannier-like orbital. On the other hand, the new set $\Theta^{\nu,\sigma}$, as we will show, project onto a given orbital of certain character for which we do not apply any orthonormalization process as in the first. Unlike the Wannier projectors, the $\Theta^{\nu,\sigma}$’s can also project to other orbitals atoms apart from the correlated set.

A given orbital character contributes in the eigenstates through the solutions of the Schrödinger equation inside the sphere $u_{\nu}^\sigma(r, E_{\nu 1})Y_{\nu 1}^\sigma \chi_\sigma$, $u_{\nu}^\sigma(r, E_{\nu 2})Y_{\nu 2}^\sigma \chi_\sigma$ and $u_{\nu}^\sigma(r, E_{\nu 2})Y_{\nu 2}^\sigma \chi_\sigma$ which do not form an orthonormalized basis set. It is more convenient to construct these projectors if the wave function is rewritten in an orthonormal basis set.

In a general form, inside a given sphere we can express $\psi_{\nu,\sigma}^\nu(r)$ as

$$\psi_{\nu,\sigma}^\nu(r) = \sum_{lm} A_{\nu,lm} u_{\nu l} + \sum_{lm} B_{\nu,lm}^\nu \hat{u}_l + \sum_{lm} C_{\nu,lm}^\nu u_{\nu l}, \quad (B1)$$

where we simplify the notation by omitting the angular and spin parts and defining $A_{\nu,lm}$, $B_{\nu,lm}^\nu$, and $C_{\nu,lm}^\nu$ as combined coefficients which are generally $k$-dependent and contain the sum over the plane waves and local orbitals. We also define $u_{\nu 1} \equiv u_\nu(r, E_{\nu 1})$, $u_{\nu 1} \equiv \hat{u}_l(r, E_{\nu 1})$, and $u_{\nu 2} \equiv u_\nu(r, E_{\nu 2})$.

We then rewrite $\psi_{\nu,\sigma}^\nu(r)$ as a function of a set of orthogonal orbitals $\phi_j(r)$, $j=1,2,3$ as follows

$$\psi_{\nu,\sigma}^\nu(r) = \sum_{lm} \sum_j (A_{\nu,lm}^{\nu j} + B_{\nu,lm}^{\nu j} + C_{\nu,lm}^{\nu j}) \phi_j(r). \quad (B2)$$

The coefficients $\phi^{lm}_{ij}$ are the matrix elements of the square root of the corresponding overlap matrix

$$C = \begin{pmatrix} 1 & 0 & \langle u_{\nu 1} | u_{\nu 2} \rangle \\ 0 & \langle \hat{u}_l | \hat{u}_l \rangle & \langle \hat{u}_l | u_{\nu 2} \rangle \\ \langle u_{\nu 2} | u_{\nu 1} \rangle & \langle \hat{u}_l | u_{\nu 2} \rangle & \langle \hat{u}_l | \hat{u}_l \rangle \end{pmatrix}^{\frac{1}{2}}. \quad (B3)$$

In this way, rewriting Eq. (B2) as

$$\psi_{\nu,\sigma}^\nu(r) = \sum_{lm} \sum_j \phi^{lm}_{ij} \phi_j(r). \quad (B4)$$

the matrix elements of the projector to a given atom with $lm$ character finally reads,

$$\Theta_{m,\nu,\sigma}^{i,\nu,\sigma}(k) = \phi^{lm}_{ij} \quad (B5)$$

The spectral function of a given atom $i$ with orbital character $m$, is obtained as

$$A_{\nu,\sigma}^{i,\nu,\sigma}(k,\omega) = -\frac{1}{\pi} Im \left[ \sum_{\nu,\nu',j} \Theta_{m,\nu,\sigma}^{i,\nu,\sigma}(k) G_{\nu,\nu'}^{\sigma}(k,\omega^+) \Theta_{\nu',m,\sigma}^{i,\nu,\sigma}(k) \right].$$

APPENDIX C: INFLUENCE OF THE ROTATIONAL INVARIANCE OF HUNDS-RULE COUPLING IN MULTI-ORBITAL SYSTEMS

In our DMFT calculations using CTQMC as impurity solver, we restricted the Hund’s rule interaction to
Ising-type interactions only, although there is no conceptual limitation of the algorithm to this type of interactions. The reason for doing this is of purely technical nature, since in this case one can diagonalize the local problem very efficiently, and furthermore, it enables us to use the so-called segment-picture update scheme, which increases the efficiency of the CTQMC method a lot.

One may now ask how results change if the fully rotational-invariant Hund’s rule exchange is taken into account. For this purpose, we study a multiband model Hamiltonian, assuming degenerate bands, no interband hybridizations, and a semicircular density of states of the local Hamiltonian,

\[
H_{sf} = -\frac{J}{2} \sum_{m m'} \left( c^\dagger_m c^\dagger_{m'} c_{m'} c_m + \text{h.c.} \right) \quad \text{(C1)}
\]

\[
H_{ph} = -\frac{J}{2} \sum_{m m'} \left( c^\dagger_m c^\dagger_{m'} c_{m'} c_m + \text{h.c.} \right). \quad \text{(C2)}
\]

We do calculations at \( T = 0 \), and choose the reference system for the SFT framework to consist of one bath degree of freedom for each correlated orbital. Hence, going up to \( M = 5 \) orbitals, we have to diagonalize a local problem consisting of at most 10 orbitals.

The upper panel of Fig. 9 shows \( Z \) for a 3-orbital model at half-filling, \( n = 3 \), for \( J = 0.1 U \). A tremendous reduction of the critical \( U_c \) of the metal-to-insulator transition (MIT) is observed, already for Ising-like interactions. This is a well known fact that for multi-orbital systems at or close to half-filling, the effect of \( J \) should be strongest.\(^{60,61,62}\) The inclusion of spin-flip and pair-hopping terms gives raise to two effects. (i) For moderate correlations, \( Z \approx 0.6 \), these terms lead to a slight reduction of \( Z \), but (ii) the critical \( U \) for the MIT is shifted upwards. This qualitatively holds also away from half-filling, which can be seen in the lower panel of Fig. 9, where we plotted \( Z \) for \( n = 2 \). Although the transition is not of first order any more, one can again identify two regimes. For moderate correlations, \( Z \) decreases, whereas close to the transition the spin-flip and pair-hopping terms increase the renormalization \( Z \) and the critical \( U_c \) is pushed to higher values. This is consistent with a numerical renormalization group study for the 2-orbital Hubbard model.\(^{61}\)

This is consistent with a numerical renormalization group study for the 2-orbital Hubbard model.\(^{61}\)

We also considered the case relevant for pnictide materials, i.e., \( M = 5, n = 6 \), and \( Z \) around 0.5. This regime could be realize by setting (i) \( U = 3.5t \) and \( J = 0.35t \), which shows a reduction of \( Z \) from 0.52 to 0.47 due to spin-flip and pair-hopping, or (ii) \( U = 2t \), \( J = 0.4t \), giving a reduction from 0.61 to 0.57. In conclusion, this analysis shows that the picture of a moderately-correlated metal as argued in Sect. III holds also when a fully rotational-invariant Hund’s exchange is considered. For systems close to a MIT, this is no longer true and the spin-flip and pair-hopping terms become crucial.

**ACKNOWLEDGMENTS**

We are grateful to Vladimir Anisimov, Ryotaro Arita, Gabriel Kotliar, Igor Mazin, Frank Lechermann, Alexander Lichtenstein and, especially, Kristjan Haule for useful discussions and correspondence. M.A. is grateful to F. Assaad for enlightening discussions on the stochastic Maximum Entropy method. We acknowledge the support of the Agence Nationale de la Recherche (under project CORRELMAT), and of GENCI and IDRIS (under project 091393) for supercomputer time. M.A. acknowledges financial support from the Austrian Science Fund (FWF), grant J2760-N16.

Even though comparisons with x-ray absorption spectroscopy have been attempted it is not clear that the low-energy description by a pure $t_{2g}$ model is still valid at these energies. Note in particular that in this energy region overlaps with the $e_g$ states, split off by the cubic crystal field, could come into play.
