Alzheimer's disease

ABSTRACT
Signaling between the endoplasmic reticulum (ER) and mitochondria regulates a number of key neuronal functions, many of which are perturbed in Alzheimer's disease. Moreover, damage to ER-mitochondria signaling is seen in cell and transgenic models of Alzheimer's disease. However, as yet there is little evidence that ER-mitochondria signaling is altered in human Alzheimer's disease brains. ER-mitochondria signaling is mediated by interactions between the integral ER protein VAPB and the outer mitochondrial membrane protein PTPIP51 which act to recruit and “tether” regions of ER to the mitochondrial surface. The VAPB-PTPIP51 tethers are now known to regulate a number of ER-mitochondria signaling functions including delivery of Ca²⁺ from ER stores to mitochondria, mitochondrial ATP production, autophagy and synaptic activity. Here we investigate the VAPB-PTPIP51 tethers in post-mortem control and Alzheimer's disease brains. Quantification of ER-mitochondria signaling proteins by immunoblotting revealed loss of VAPB and PTPIP51 in cortex but not cerebellum at end-stage Alzheimer's disease. Proximity ligation assays were used to quantify the VAPB-PTPIP51 interaction in temporal cortex pyramidal neurons and cerebellar Purkinje cell neurons in control, Braak stage III-IV (early/mid-dementia) and Braak stage VI (severe dementia) cases. Pyramidal neurons degenerate in Alzheimer's disease whereas Purkinje cells are less affected. These studies revealed that the VAPB-PTPIP51 tethers are disrupted in Braak stage III-IV pyramidal but not Purkinje cell neurons. Thus, we identify a new pathogenic event in post-mortem Alzheimer's disease brains. The implications of our findings for Alzheimer's disease mechanisms are discussed.

1. Introduction
Signal transduction processes enable eukaryotic cells to communicate with each other and to respond to physiological stimuli. An important component of this signaling involves communications between different organelles. Such crosstalk permits organelles to respond dynamically to changes in the cellular environment in an orchestrated manner (Cohen et al., 2018;Gordaliza-Alaguero et al., 2019). Communications between the endoplasmic reticulum (ER) and mitochondria represent a particularly important component of organelle signaling since this regulates a number of fundamental cellular processes. These include bioenergetics, Ca²⁺ homeostasis, lipid metabolism, mitochondrial biogenesis and trafficking, ER stress responses, autophagy and inflammation (Csordas et al., 2018;Krols et al., 2016;Lau et al., 2018;Paillusson et al., 2016;Rieusset, 2018;Rowland and Voeltz, 2012).

ER-mitochondria signaling is facilitated by close physical contacts between the two organelles such that up to 20% of the mitochondrial surface is tightly apposed to ER membranes. These regions of ER are termed mitochondria-associated ER membranes (MAM) (Csordas et al., 2018;Krols et al., 2016;Lau et al., 2018;Paillusson et al., 2016;Rieusset, 2018;Rowland and Voeltz, 2012). The mechanisms by which ER membranes are recruited to the mitochondrial surface are not fully understood but it is widely accepted that the process involves

Abbreviations: Aβ, amyloid-β; ApoE4, ε4 allele of apolipoprotein E4; ER, endoplasmic reticulum; GSK3β, glycogen synthase kinase-3β; IP3, inositol 1,4,5-trisphosphate; MAM, mitochondria associated ER membranes; MCU, mitochondrial Ca²⁺ uniporter; PDI, protein disulphide isomerase; PLAs, proximity ligation assays; PTPIP51, protein tyrosine phosphatase interacting protein-51; RIPA, radioimmunoprecipitation assay; VAPB, vesicle-associated membrane protein-associated protein B; VDAC1, voltage dependent anion channel-1.

“tethering proteins” which act to scaffold the two organelles in close proximity. One tether involves an interaction between the integral ER protein, vesicle-associated membrane protein-associated protein B (VAPB) and the outer mitochondrial membrane protein, protein tyrosine phosphatase interacting protein-51 (PTPIP51) (De Vos et al., 2012; Staiga et al., 2014). The VAPB-PTPIP51 tethers are known to control a number of ER-mitochondria regulated functions including inositol 1,4,5-trisphosphate (IP3) receptor delivery of Ca²⁺ from ER stores to mitochondria, mitochondrial ATP production and autophagy (De Vos et al., 2012; Gomez-Suaga et al., 2017; Gomez-Suaga et al., 2019; Paillusson et al., 2017; Puri et al., 2014; Staiga et al., 2014; Staiga et al., 2016).

Many of the functions regulated by ER-mitochondria signaling are perturbed in Alzheimer’s disease. These include mitochondrial biogenesis and ATP production, ER stress responses, Ca²⁺ signaling, lipid metabolism, autophagy, protein and organelle trafficking (especially axonal transport), and inflammatory responses (Area-Gomez et al., 2018; Krols et al., 2016; Paillusson et al., 2016). Moreover, synaptic activity has recently been shown to be regulated by ER-mitochondria signaling and synaptic damage is a prominent early feature of Alzheimer’s disease (Gomez-Suaga et al., 2019; Hirabayashi et al., 2017). Such links have prompted investigations of ER-mitochondria contacts and signaling in Alzheimer’s disease (Area-Gomez et al., 2018; Krols et al., 2016; Paillusson et al., 2016).

Mutations in the amyloid precursor protein (APP) and Presenilins (Presenilin-1 and -2) cause some familial forms of Alzheimer’s disease (Schellenberg and Montine, 2012). APP is processed to produce amyloid-β (Aβ) that is deposited as a pathology in Alzheimer’s disease and the Presenilins form part of the γ-secretase complex that cleaves APP to produce Aβ (Schellenberg and Montine, 2012). APP and the Presenilins all localise to ER-mitochondria contact sites, and MAM are a site of APP processing and Aβ production (Area-Gomez et al., 2009; Del Prete et al., 2017; Pera et al., 2017; Schreiner et al., 2015). Also both mutant Presenilins, APP and Aβ affect ER-mitochondria contacts and related functions (Area-Gomez et al., 2012; Hedskog et al., 2013; Martino Adami et al., 2019; Sepulveda-Falla et al., 2014; Zampese et al., 2011). Finally, the ε4 allele of apolipoprotein E (ApoE4) which is a major risk factor for Alzheimer’s disease has been shown to affect MAM function (Tambini et al., 2015). Together, these studies support the notion that damage to the ER-mitochondria axis is part of the pathogenic process in Alzheimer’s disease. Such findings also provide a plausible route for explaining many of the seemingly disparate pathological features of Alzheimer’s disease (Area-Gomez et al., 2018; Krols et al., 2016; Paillusson et al., 2016).

However, to date these studies have focussed on cell and transgenic mouse models of Alzheimer’s disease and as yet there is little evidence that ER-mitochondria contacts and signaling are affected in Alzheimer’s disease brain. This represents a fundamental omission especially since APP and Presenilin transgenic mice only partially model Alzheimer’s disease phenotypes (Puzzo et al., 2015; Sasaguri et al., 2017). Here, we address this issue by examining the ER-mitochondria tethering proteins VAPB and PTPIP51 in post-mortem Alzheimer’s disease and control brains.

2. Materials and methods

2.1. Antibodies

The following primary antibodies were used in this study:

- Rabbit anti-PTPIP51 antibody (Anti-RMDN3, HPA009975) and rabbit anti-Sigma-1 receptor (Anti-SIGMAR1, HPA018802) were from Atlas Antibodies. Mouse anti-protein disulfide isomerase (PDI) (RL77, MA3–018) was from Thermo Fisher Scientific. Rabbit anti-voltage-dependent anion channel-1 (VDAC1) (4866) and rabbit anti-mitochondrial Ca²⁺ unipporter (MCU) (D2Z23B, 14,997) were from Cell Signaling Technology. Rabbit anti IP3 receptor type-1 (117003) was from Dynaptic Systems. Mouse anti-neuron specific enolase (NSE) (BBS/NC/VI-H14) was from Dako.

F = female; M = male.
homogenates in ice-cold radioimmunoprecipitation assay (RIPA) buffer (50 mM Tris-HCl, pH 7.4; 150 mM NaCl; 1 mM EDTA; 1% (v/v) Triton X-100; 0.5% (v/v) sodium deoxycholate; 0.1% (v/v) SDS) with protease and phosphatase inhibitor cocktails (Complete and PhosStop, Roche) using a Bio-Gen PRO200 rotor-stator homogeniser (Pro Scientific) for 20 s. Following homogenisation, each sample was sonicated three times for 3 s before being centrifuged at 13,000 xg for 20 min at 4 °C. Supernatants were collected and protein concentrations determined using a bicinchoninic acid protein concentration assay kit (Pierce) according to the manufacturer's instructions. Protein concentrations were adjusted to the same concentration in each sample by adding RIPA and SDS-PAGE sample buffers comprising 2% (w/v) SDS, 100 mM dithiothreitol, 10% (w/v) glycerol, 0.1% (w/v) bromophenol blue and protease inhibitors (Complete Roche) in 50 mM Tris-HCl pH 6.8 and heated to 96 °C for 10 min. Samples were stored at −80 °C.

SDS-PAGE and immunoblotting was performed as described previously (Morrotz et al., 2019a; Morrotz et al., 2019b). Briefly, samples were separated on Novex 4–12% Tris-Glycine Plus Midi Protein gels (Invitrogen) using the XCell4 Sureloc Midi-Cell system (Invitrogen). Separated proteins were transferred to BioTrace NT nitrocellulose membrane (0.2 μm pore size; Pall Corporation) using a Midi Trans-Blot electrophoretic transfer cell (Bio-Rad) for 2 h. Membranes were blocked with Odyssey blocking buffer, probed with primary antibodies in TBS containing 0.1% Tween 20 (wash buffer) and following washing, incubated with IRDye-conjugated secondary antibodies in wash buffer. Proteins were visualised using an Odyssey CLx near infrared imaging system (Li-Cor Biosciences). Protein signals were normalised to NSE signals.

2.4. Proximity ligations assays

VAPB-PTPIP51 PLAs were performed on 7 μm thick sections of paraffin wax embedded post-mortem human temporal cortex and cerebellum using rabbit VAPB and rat PTPIP51 antibodies with Duolink PLA reagents (Sigma). Donkey anti-rabbit in situ PLA probes were purchased directly; donkey anti-rat PLA probes were prepared using Duolink PLA reagents (Sigma). Donkey anti-rabbit in situ PLA probes were added to the manufacturer’s instructions. Brieﬂy, samples were separated on Novex 4–12% Tris-Glycine Plus Midi Protein gels (Invitrogen) using the XCell4 Sureloc Midi-Cell system (Invitrogen). Separated proteins were transferred to BioTrace NT nitrocellulose membrane (0.2 μm pore size; Pall Corporation) using a Midi Trans-Blot electrophoretic transfer cell (Bio-Rad) for 2 h. Membranes were blocked with Odyssey blocking buffer, probed with primary antibodies in TBS containing 0.1% Tween 20 (wash buffer) and following washing, incubated with IRDye-conjugated secondary antibodies in wash buffer. Proteins were visualised using an Odyssey CLx near infrared imaging system (Li-Cor Biosciences). Protein signals were normalised to NSE signals.

2.5. Statistical analyses

Statistical analysis was performed using Excel (Microsoft Corporation) and Prism software (version 8; GraphPad Software Inc.). Statistical significance was determined as described in the figure legends.

3. Results

3.1. VAPB and PTPIP51 levels are reduced in post-mortem Alzheimer’s disease cortex but not cerebellum

We first enquired whether expression of key ER-mitochondria signalling proteins might be altered in post-mortem Alzheimer’s disease brain tissues. We studied VAPB and PTPIP51 since they function to tether ER domains with mitochondria, and a number of proteins involved in the delivery of Ca2+ from ER stores to mitochondria. This is because ER-mitochondria Ca2+ exchange controls several functions damaged in Alzheimer’s disease such as mitochondrial ATP production, apoptosis and autophagy (Cardenas and Foskett, 2012; Coradas et al., 2018; Gomez-Suaga et al., 2017; Krols et al., 2016; Paullussen et al., 2016; Rowland and Voeltz, 2012). Delivery of Ca2+ from ER stores to mitochondria involves its release from ER located IP3 receptors and subsequent uptake into mitochondria via VDAC1 and the mitochondrial Ca2+ unipporter (MCU) (Coradas et al., 2018; Krols et al., 2016; Paullussen et al., 2016; Rowland and Voeltz, 2012). There are 3 subtypes of IP3 receptor (type-1, −2 and −3) all of which function in delivery of Ca2+ to mitochondria (Bartok et al., 2019). However, they display differences in expression patterns within the nervous system; IP3 receptor type-1 is highly expressed in neurons in the cortex, hippocampus and cerebellum, IP3 receptor type-2 in mainly expressed in glia, and IP3 receptor type-3 is the major isoform in brain stem and spinal cord including motor neurons but is largely absent in cortex and hippocampus (De Smedt et al., 1994; Sharp et al., 1999; Watanabe et al., 2016). We therefore studied IP3 receptor type-1, VDAC1 and MCU levels. We also studied expression of the Sigma-1 receptor since it is a MAM protein that regulates several ER-mitochondria signalling functions (Hayashi, 2019; Su et al., 2016). Finally, we monitored expression of protein disulphide isomerase (PDI) which a major ER protein that is commonly used as a marker for changes to the ER in neurodegenerative diseases (Perri et al., 2015).

We quantified the levels of these proteins by immunoblotting of post-mortem temporal cortex and cerebellum in control, Braak stage III-IV (mid-dementia) and Braak stage VI (severe dementia) cases. Temporal cortex is a region of the brain that is most susceptible to Alzheimer’s pathology whereas the cerebellum is the least affected brain region; analyses of the cerebellum is therefore often included for comparison and as an internal control in studies of Alzheimer’s disease pathology (Andersen et al., 2012; Morrotz et al., 2019a; Tavares et al., 2013; Tiwari et al., 2015). The levels of each protein were normalised to the levels of neuron specific enolase (NSE) as described by others (Kurbatskaya et al., 2016; Lau et al., 2016; Morrotz et al., 2019b; Tavares et al., 2013; Tiwari et al., 2015). Compared to controls, VAPB, PTPIP51 and IP3 receptor type-1 levels were all significantly reduced in cortex in Braak stage VI cases (Fig. 1). The levels of VDAC1, MCU, the Sigma-1 receptor and PDI were unaffected (Fig. 1). By contrast, we detected no changes in expression of any of these proteins in cerebellum (Fig. 2). Thus, compared to control cases, the levels of VAPB, PTPIP51 and IP3 receptor type-1 are all reduced in Braak stage VI Alzheimer’s disease cortex but not cerebellum.

We also enquired whether the loss of VAPB in Braak stage VI temporal cortex correlated with the reductions in PTPIP51 amounts in these cases. To do so, for each sample the NSE-normalised VAPB and PTPIP51 signals from immunoblots of control, Braak stage III-IV and Braak stage VI cases were correlated. These analyses revealed a highly significant overall correlation (Fig. 3A). On subgroup analyses, the control group showed positive correlation but the correlation was lost in both Braak stage III-IV and Braak stage VI groups (Fig. 3A). In a similar fashion, we also correlated VAPB levels with the ER protein PDI and PTPIP51 levels with the mitochondrial protein MCU. These analyses revealed a positive
Fig. 1. Expression of MAM related proteins in post-mortem control and Alzheimer's disease temporal cortex. Representative immunoblots show levels of MAM related proteins in control, Braak stage III-IV and Braak stage VI brains. Graphs show quantification of MAM related protein levels in the different samples following normalisation to NSE levels in the same sample. Data were analysed by ANOVA and Tukey post hoc test; error bars are s.e.m., *p < .05 **p < .01.
Fig. 2. Expression of MAM related proteins in post-mortem control and Alzheimer's disease cerebellum. Representative immunoblots show levels of MAM related proteins in control, Braak stage III-IV and Braak stage VI brains. Graphs show quantification of MAM related protein levels in the different samples following normalisation to NSE levels in the same sample. Data were analysed by ANOVA; error bars are s.e.m.
correlation between levels of VAPB and PDI in control cases but this was lost in Braak stage III-IV and Braak stage VI pyramidal cells (Fig. 5). By contrast, we detected no changes in VAPB-PTPIP51 PLA signal numbers in Purkinje cells between the control and Alzheimer’s disease cases (Fig. 6).

4. Discussion

A number of studies support the notion that ER-mitochondria signaling is damaged in Alzheimer’s disease (Area-Gomez et al., 2012; Del Prete et al., 2017; Hedskog et al., 2013; Leal et al., 2018; Martino Adami et al., 2019; Pera et al., 2017; Schreiner et al., 2015; Sepulveda-Falla et al., 2014; Tambini et al., 2015; Zampese et al., 2011). However, these studies largely focused on experimental models and to date, there is little evidence that ER-mitochondria contacts and signaling are altered in Alzheimer’s disease brain. Here, we utilised PLAs to study the VAPB-PTPIP51 interaction in post-mortem temporal cortex and cerebellum in control, Braak stage III-IV and Braak stage VI Alzheimer’s disease cases.

Our studies involved 14 control, 14 Braak stage III-IV and 14 Braak stage VI Alzheimer’s disease cases and we analysed between 95 and 270 pyramidal neurons per case. For comparison, we also quantified the VAPB-PTPIP51 interaction in cerebellar Purkinje cells in the same cases since these neurons are relatively less affected in Alzheimer’s disease (Andersen et al., 2012; Mann, 1996). Compared to controls, we detected a significant decrease in VAPB-PTPIP51 PLA signals in cortical pyramidal cells in the Braak stage III-IV but not Braak stage VI cases; we detected no changes in PLA signals in Purkinje cells. These findings suggest that the VAPB-PTPIP51 tethers are disrupted in pyramidal but not Purkinje cells in Braak stage III-IV but not late-stage Alzheimer’s disease.

We also detected fewer VAPB-PTPIP51 PLA signals in the control
Purkinje cell neurons compared to control pyramidal cells. These results suggest differences in ER-mitochondria contacts and signaling between these two neuronal cell types. Indeed, Purkinje cell have unique Ca\(^{2+}\) handling mechanisms and there are marked differences in mitochondrial makeup between different neuronal cell types (Fecher et al., 2019; Meera et al., 2016).

The mechanisms that underlie breaking of the VAPB-PTPIP51 tethers in the Braak stage III-IV pyramidal cells are not clear. The expression levels of VAPB and PTPIP51 have been shown to affect ER-mitochondria contacts and linked functions; loss of VAPB and/or PTPIP51 disrupts tethering whereas overexpression increases tethering (De Vos et al., 2012; Gomez-Suaga et al., 2019; Paillusson et al., 2017; Stoica et al., 2014). We detected decreased levels of both VAPB and PTPIP51 in cortex but not cerebellum in the Braak stage VI cases. However, the PLA data revealed breaking of the VAPB-PTPIP51 tethers in Braak stage III-IV but not Braak stage VI tissues. Thus, disruption of VAPB-PTPIP51 tethering may not be due to changes in expression of these proteins. Indeed, the reduced levels of VAPB and PTPIP51 that we detect in total Braak stage VI temporal cortex do not mean that the levels of these proteins are altered in in-situ human tissues and mammalian organisms.

An alternative possibility is that the disruption is linked to activation of glycogen synthase kinase-3β (GSK3β). GSK3β is a favoured kinase for phosphorylating Tau in Alzheimer’s disease and GSK3β has been shown to inhibit the VAPB-PTPIP51 interaction and reduce ER-mitochondria contacts (Lovestone et al., 1994; Stoica et al., 2014; Stoica et al., 2016). However, the activity of GSK3β in post-mortem human Alzheimer’s disease tissues has proved to be controversial. For example, increased tyrosine-216 phosphorylation (which is required for activity) but no change in serine-9 phosphorylation (which inhibits activity) has been reported in Alzheimer’s disease (Leroy et al., 2007).

By contrast, another study reported no change in tyrosine-216 phosphorylation but an increase in inhibitory serine-9 phosphorylation in Alzheimer’s disease (Swatton et al., 2004). Finally, a third study reported increased serine-9 phosphorylated GSK3β in affected neurons in Alzheimer’s disease indicating reduced activity (Ferrer et al., 2002). Such data have led to the conclusion that “it is technically difficult, if not impossible, to measure (GSK3β) enzymatic activity in post-mortem brain tissue” (Hooper et al., 2008). One route to address this issue in human samples in future studies would be to correlate levels of GSK3β activity with changes in the VAPB-PTPIP51 interaction in neurons derived from induced pluripotent stem cells from Alzheimer’s disease patients carrying familial pathogenic mutations; some studies of such neurons reveal activation of GSK3β via altered serine-9 phosphorylation (Israel et al., 2012).

Recently, ER-mitochondria contacts have been analysed by electron microscopy in human brain biopsy cases from idiopathic normal pressure hydrocephalus patients. Of the 14 cases analysed in this study, three patients presented comorbidity with dementia; one with Alzheimer’s disease, one with Alzheimer’s disease and vascular dementia, and one with Lewy body dementia (Leal et al., 2018). Clearly, firm conclusions on any changes in ER-mitochondria contacts in Alzheimer’s disease and any linkage of such changes to Braak staging cannot be made from these studies, especially since the primary disease was not dementia. Also, these studies did not discriminate between ER-mitochondria contacts in neurons or glia (Leal et al., 2018). However, these biopsy studies are important in that they formally reveal the presence of ER-mitochondria contacts similar to those found in other human tissues and mammalian organisms.

Other studies of ER-mitochondria contacts and signaling in models of Alzheimer’s disease have provided conflicting data (Altmann et al., 2012; Del Prete et al., 2017; Hedskog et al., 2013; Martino Adami et al., 2019; Pera et al., 2017; Schreiner et al., 2015; Sepulveda-Falla et al., 2014; Tambini et al., 2015; Zampese et al., 2011). For example, it is not clear whether mutant Presenilin-1 and/or – 2 affect ER-mitochondria signaling nor whether these mutants increase or decrease...
contacts (Area-Gomez et al., 2012; Sepulveda-Falla et al., 2014; Zampese et al., 2011). Likewise, there is conflicting data on the effects of APP and Aβ on ER-mitochondria contacts and signaling (Del Prete et al., 2017; Hedskog et al., 2013; Martino Adami et al., 2019). The reasons for these differing results are not clear but may be due to the different experimental systems, assays and methods of analyses used to quantify ER-mitochondria contacts and signaling. There is also evidence that different expression levels of neurodegenerative disease linked mutant proteins can generate opposing effects on ER-mitochondria signaling in experimental systems (Cali et al., 2019). Finally, although the apolipoprotein E4 (ApoE4) allele (which is a major risk factor for Alzheimer’s disease) has been shown to upregulate MAM activity, treatment of cells with ApoE4 does not significantly alter ER and mitochondria co-localisation compared to ApoE3 (Tambini et al., 2015).

Here, we present the first study of the VAPB-PTPIP51 ER-mitochondria tethers in post-mortem Alzheimer’s disease brain and reveal that the tethers are disrupted in Braak stage III-IV pyramidal cells i.e. relatively early in the disease process. The VAPB-PTPIP51 tethers are now known to regulate a number of fundamental physiological processes that are likewise damaged relatively early in Alzheimer’s disease. These include Ca²⁺ homeostasis, energy metabolism, autophagy and synaptic activity (De Vos et al., 2012; Gomez-Suaga et al., 2017; Gomez-Suaga et al., 2019; Paillusson et al., 2017; Paillusson et al., 2016). Disruption of the VAPB-PTPIP51 tethers may therefore contribute to such damage.

Both mitochondria and MAM proteins can be isolated biochemically and such purifications permit analyses of protein content in these fractions; such analyses revealed that VAPB is a MAM protein and that PTPIP51 is an outer mitochondrial membrane protein (De Vos et al., 2012). It would therefore be interesting to compare MAM protein content in human control and Alzheimer’s disease brains. However, robust analyses of such purified MAM proteins requires fresh (non-frozen) tissues (Wieckowski et al., 2009), ideally with short post-mortem times. Such studies are therefore beyond the scope of this

Fig. 5. The VAPB-PTPIP51 interaction is reduced in temporal cortex pyramidal neurons in Braak stage III-IV but not Braak stage VI Alzheimer’s disease. Representative images of VAPB-PTPIP51 PLAs in pyramidal cells of control, Braak stage III-IV and Braak stage VI Alzheimer’s disease brains. Top panel shows low magnification and bottom panel shows zoom of boxed area at higher magnification. Graph shows mean number of VAPB-PTPIP51 PLA signals per pyramidal neuron for each case. VAPB-PTPIP51 signal numbers were normalised to the size of each cell so as to correct for any changes in neurons size in the Alzheimer’s disease cases. The numbers of neurons analysed per case were: N = 103–265 (control cases), N = 95–240 (Braak III-IV cases), N = 100–270 (Braak VI cases). N = 14 cases for each. Data were analysed by Welch’s ANOVA and Dunnett post hoc test; Error bars are s.e.m., *p = .0136. Scale bars; 25 μm (top panel) and 7 μm (bottom panel).
Interestingly however, a recent investigation examined inflammatory microRNAs in MAM in Alzheimer’s disease brain (Wang et al., 2020). For these studies, fresh human tissues (less than 4 h post-mortem) were collected and utilised. Similar analyses of MAM proteins would be of value in future studies.

In conclusion, we show that the levels of the key ER-mitochondria tethering proteins VAPB and PTPIP51 are reduced in temporal cortex but not cerebellum in late stage Alzheimer’s disease. Using PLAs, we also show that the VAPB-PTPIP51 tethers are disrupted in affected pyramidal neurons in post-mortem Alzheimer’s disease cortex and that this disruption occurs at a relatively early stage of disease. Our results reveal a new pathological phenotype in Alzheimer’s disease.

**Authors’ contributions**

CCJM, WN and DHWL planned the study. DHWL, SP, NH, GMM, PG-S and HR performed experiments and analysed data. CT provided input for post-mortem tissues and provided expertise. All authors edited the manuscript.
