Abstract

The partition function on the three-sphere of ABJM theory and its generalizations has, at large $N$, a universal, subleading logarithmic term. Inspired by the success of one-loop quantum gravity for computing the logarithmic corrections to black hole entropy, we try to reproduce this universal term by a one-loop calculation in Euclidean 11-dimensional supergravity on $\text{AdS}_4 \times X_7$. We find perfect agreement between the results of ABJM theory and the 11-dimensional supergravity.

Keywords: Ads/CFT correspondence, ABJM model, supergravity, partition function, expansion $1/N$

PACS numbers: 04.60.Cf, 11.25.Tq, 11.25.Yb

1. Introduction

Recently, various exact results have been obtained on the partition function on the three-sphere of supersymmetric Chern–Simons–matter (CSM) theories generalizing ABJM theory [1]. Typical examples are quiver $\mathcal{N} = 3$ CSM theories [2]. These theories are parametrized by the rank $N$ of the $U(N)$ gauge group, the CS levels $k_a$, and the number of flavors in each node, $N_{fa}$. Here, $a = 1, \ldots, p$ is an index labeling the node. For these theories, the partition function at all orders in $1/N$ was computed in [3, 4] by generalizing earlier work in [5–8]. The result is given by an Airy function

\begin{equation}
Z_{\text{CFT}}(N, \{k_a\}, \{N_{fa}\}) \propto \text{Ai}[C(\{k_a\}, \{N_{fa}\})]^{-1/3}(N - B(\{k_a\}, \{N_{fa}\})).
\end{equation}

(1.1)

In this expression, $C(\{k_a\}, \{N_{fa}\})$ is a known function of the parameters $k_a$ and $N_{fa}$. The function $B(\{k_a\}, \{N_{fa}\})$ can be computed by a precise algorithm in a case-by-case basis [4]. The proportionality coefficient in (1.1) is independent of $N$, but it is a non-trivial function of $k_a$ and $N_{fa}$ (see [4, 9] for explicit results on this coefficient in ABJM theory).

If we recall the asymptotic expansion of the Airy function,

\begin{equation}
\text{Ai}(x) \sim \frac{e^{\frac{x}{3} + \frac{2}{3}\sqrt{x}}}{2\sqrt{\pi}x^{1/4}}, \quad x \gg 1,
\end{equation}

(1.2)
we find the large $N$ expansion of the free energy $F \equiv \ln Z$

$$F_{\text{CFT}}(N, \{k_a\}, \{N_{fa}\}) = -\frac{2}{3} C((k_a), \{N_{fa}\})^{-1/2} N^{3/2} + C((k_a), \{N_{fa}\})^{-1/2} B((k_a), \{N_{fa}\}) N^{1/2}$$

$$-\frac{1}{4} \log N + \text{constant} + O\left(\frac{1}{\sqrt{N}}\right).$$

(1.3)

These CSM theories are conjecturally dual to M-theory compactifications on manifolds of the form $\text{AdS}_4 \times X_7$, where $X_7$ is a tri-Sasaki Einstein manifold whose geometry is specified by the data of the quiver $k_a, N_{fa}$. In particular, the function $C((k_a), \{N_{fa}\})$ is given by [4, 7, 10]

$$C((k_a), \{N_{fa}\}) = \frac{6 \text{vol}(X_7)}{\pi^6},$$

(1.4)

where in the definition of $\text{vol}(X_7)$ we have taken out a factor of $(2L)^7$, $L$ being the ‘radius’ of $\text{AdS}_4$. With this convention $\text{vol}(X_7)$ is a purely numerical factor. The leading term of the free energy is then

$$-\sqrt{\frac{2\pi^6}{27 \text{vol}(X_7)}} N^{3/2}.$$  

(1.5)

If we use the dictionary relating $N$ to the AdS radius $L$

$$(2\pi \ell_p)^N = 6 (2L)^6 \text{vol}(X_7)$$

(1.6)

it can be shown that (1.5) is (minus) the regularized, gravitational action on-shell, as expected from the AdS/CFT correspondence (see for example [11] for a review). This provides a non-trivial, quantitative check of the correspondence at leading order in $N$.

The first subleading correction of order $N^{1/2} \sim L^3$ originates from a local eight-derivative correction to the effective action that modifies the relation between $N$ and $L$ by shifting $N$ by $-B((k_a), \{N_{fa}\})$ [12, 13]. A similar shift in the context of five dimensional black hole entropy has been discussed in [14].

What about the subleading, logarithmic correction appearing in (1.3)? When expressed in terms of the AdS radius, it leads to a term of the form

$$-\frac{1}{2} \log L.$$  

(1.7)

Notice that this term is universal: it is the same for all compactifications, irrespectively of the $X_7$ manifold. In fact, there is some evidence that, even for theories with $N = 2$ supersymmetry, the partition function is also an Airy function [15], and therefore one finds the same type of logarithmic correction.

A natural question is: can one test the result of this ‘microscopic’, gauge theory computation of the partition function, in terms of a ‘macroscopic’ computation in AdS gravity?

Recently, a similar question has been answered in the affirmative in a related context. In string theory there are by now many exact formulae for the microscopic entropy of extremal black holes, as a function of the charges. In the limit of large charges, this entropy agrees with the Bekenstein–Hawking entropy (or, more generally, with Wald’s entropy). However, there are subleading corrections in the asymptotic expansion of the exact microscopic entropy. These include in particular logarithmic corrections. In [16–20] it has been shown that these logarithmic corrections can be obtained by a one-loop calculation in Euclidean quantum gravity. The field theory background for this calculation is taken to be the near-horizon geometry of the black hole.

A general argument showing why the logarithmic corrections are not affected by higher loop corrections can be found in section 2.5 of [21]. Even though the argument was given in the context of black hole entropy, it holds for the partition function of quantum gravity in any background characterized by a large overall length scale.

3 A general argument showing why the logarithmic corrections are not affected by higher loop corrections can be found in section 2.5 of [21]. Even though the argument was given in the context of black hole entropy, it holds for the partition function of quantum gravity in any background characterized by a large overall length scale.
Our problem is very similar, structurally, to the problem of computing extremal black hole entropy. The CFT partition function can be regarded as the ‘microscopic’ result for the partition function. The leading large \( N \) result (1.5) is the analogue of the Bekenstein–Hawking or Wald entropy. We then expect the subleading logarithmic correction (1.7) to be reproduced by a one-loop correction in Euclidean quantum gravity on \( \text{AdS}_4 \times X_7 \), as in [16–20].

In this note we describe a one-loop calculation in 11-dimensional supergravity (11D SUGRA) leading to a log correction of the form (1.7). The only contribution to the log corrections in 11D SUGRA comes from the analysis of zero modes. This is due to the fact that in odd dimensions the heat kernel expansion does not contain constant terms; an analogous situation occurs in the analysis of five-dimensional black holes [19]. The only source of zero modes in the \( \text{AdS}_4 \times X_7 \) background is the two-form anticommuting ghost which appears in the quantization of the SUGRA three-form. Since this does not depend on \( X_7 \), this would explain the universality of the result (1.7). Our goal will be to check that the contribution from the zero modes gives us the same coefficient of \( \log L \) that appears in (1.7).

2. General strategy

The general strategy for computing the logarithmic term in the one-loop corrections in Euclidean quantum gravity has been explained in [16–20], building on previous results (see for example [22, 23]).

The contribution of a free field to the free energy \( F \) is divided into two parts: the contribution of non-zero modes, and the contribution of zero modes. Let us start with the contribution of non-zero modes. This is given by the logarithm of the one-loop determinant of the kinetic operator \( A \), sans the zero modes, and takes the form

\[
\pm \frac{1}{2} \ln \det' A = \pm \frac{1}{2} \sum_{n} \ln \kappa_n, \tag{2.1}
\]

where the ‘\( \cdot \)’ denotes sum over non-zero modes, \( \kappa_n \) are the eigenvalues of the kinetic operator, and the sign \( \mp \) corresponds to Grassmann even/odd fields, respectively. Information about the spectrum of an operator \( A \) is encoded in its heat kernel operator, defined as

\[
K(\tau) = e^{-\tau A} = \sum_{n} e^{-\kappa_n \tau} |\phi_n \rangle \langle \phi_n|, \tag{2.2}
\]

where \( |\phi_n \rangle \) are the corresponding eigenstates (here, for simplicity, we are assuming that the spectrum is discrete and non-degenerate; the formulae can be easily modified for more general cases). As emphasized in for example section 2 of [24], the heat kernel contains information about both zero and non-zero modes. Let us denote by \( n^0_A \) the number of zero modes of the operator \( A \). Then, one has the following equation

\[
-\frac{1}{2} \ln \det A = \frac{1}{2} \int_{\epsilon}^{\infty} \frac{d\tau}{\tau} \left( \text{Tr} K(\tau) - n^0_A \right), \tag{2.3}
\]

where \( \epsilon \) is an ultraviolet (UV) cutoff. On the other hand, the trace of the heat kernel has the following well-known expansion at small \( \tau \), called the Seeley–De Witt expansion\(^4\),

\[
\text{Tr} K(\tau) = \frac{1}{(4\pi)^{d/2}} \sum_{n=0}^{\infty} \frac{\tau^{d/2}}{n!} \int d^d x \sqrt{g} u_n(x, x). \tag{2.4}
\]

\(^4\) The coefficients \( a_n \) given here were called \( a_{2n} \) in [20].
As explained in [16–20], one can extract from the Seeley–De Witt expansion the contribution to $\ln \det A$ proportional to $\log L$. To see this, notice that since the non-zero eigenvalues of a standard Laplace type operator $A$ scale as $L^{-2}$, the heat kernel is a function of
\[
\tau = \frac{\tau}{L^2}.
\]
and we can write
\[
-\frac{1}{2} \ln \det A = \frac{1}{2} \int_{\epsilon/L^2}^{\infty} \frac{d\tau}{\tau} \left( \sum_{n=0}^{\infty} \frac{1}{(4\pi)^{d/2}} \tau^{d/2} \int d^d x \sqrt{g} a_n(x, x) - n_n^0 \right). \tag{2.6}
\]

The logarithmic contribution to $\ln \det A$ comes from the term $n = d/2$ in (2.6), and we get
\[
-\frac{1}{2} \ln \det A = \left( \frac{1}{(4\pi)^{d/2}} \int d^d x \sqrt{g} a_{d/2}(x, x) - n_n^0 \right) \log L + \cdots, \tag{2.7}
\]
where $\cdots$ denote non-logarithmic contributions. In odd–dimensional spacetimes, as it will be in our case, the coefficient $a_{d/2}$ vanishes\(^5\), and the only contribution comes from $n_n^0$. Combining (2.1) and (2.7) we get the net contribution to the free energy from the non-zero modes.

Note that the $\log L$ term comes from the region of integration $\epsilon / L^2 \ll \tau \ll L^2$. This is the infrared region and hence is not affected by the details of the UV cut-off $\epsilon$, which only affects the contribution to the integral from the region $\tau \sim \epsilon$. This is important since 11-dimensional supergravity is known to have UV divergences [25]. The reader may nevertheless worry about the fact that the UV divergent terms could give contributions which dominate over the logarithmic corrections, e.g. a term involving $a_0$ will give a one-loop contribution of order $L^{d-2n}$. Thus for example, the $a_0$ term, if non-zero, would have produced a contribution of order $L^{11}$ in $d = 11$. To avoid this worry we could consider, instead of the free energy $F$, the quantity $(Ld/dL) - 1)(Ld/dL - 3) \cdots (Ld/dL - 11)F$. In this all polynomials in $L$ up to order $L^{11}$ cancel, and the dominant term is proportional to $\log L$, whose coefficient we are calculating. A similar trick was used in [27] for extracting the universal part of entanglement entropy in quantum field theories.

Let us now look at the contribution coming from zero modes. As in [16–20], these arise due to asymptotic symmetries. To understand the dependence on $L$ of this integration, one evaluates the Jacobian from the coefficients of the zero modes, to the parameters labeling the supergroup of asymptotic symmetries. Let us suppose that there is a factor of $L^\pm \beta_0 a_0$ for each zero mode. Then, the total contribution to the partition function from the zero modes is
\[
L^\pm \beta_0 a_0 n_n^0, \tag{2.8}
\]
and hence to the free energy is
\[
\pm \beta_0 n_n^0 \log L. \tag{2.9}
\]

Notice that our conventions for the Grassmannian case are slightly different from the ones used in [18, 19].

At this point, there is an important remark to be made about the computation of the number of zero modes $n_n^0$. Often in non-compact spaces the number of zero modes, $n_n^0$, is infinite. Let us first suppose that our space is compact. If we call $\phi_0^0(x)$ the normalized eigenfunctions corresponding to the zero modes, where $\ell = 1, \ldots, n_n^0$, we have the equation
\[
n_n^0 = \sum_{\ell=1}^{n_n} \int d^d x \sqrt{g} |\phi_0^0(x)|^2. \tag{2.10}
\]

\(^5\) Since AdS$_4$ is a manifold with boundary, there could be half integer powers of $\tau$ in the expansion of $\text{Tr} K(\tau)$ from the boundary (see e.g. [26]). However these are given by integrals of local terms over the boundary of AdS$_4$ and can be cancelled by boundary counterterms.
In a non-compact space this expression is often divergent, leading to an infinite value of \( n_0^A \). Thus in order to make sense of this equation, one has to find a suitable regularization of this expression. In homogeneous spaces of constant curvature, like Euclidean AdS4 or AdS2 \( \times S^2 \), the sum

\[
\sum_\ell |\phi^{(0)}_\ell(x)|^2
\]

is a constant. Thus we can express (2.10) as

\[
n_0^A = \left( \sum_\ell |\phi^{(0)}_\ell(x)|^2 \right) \int d^4x \sqrt{g}.
\]

(2.11)

Even though the sum over \( \ell \) runs over an infinite number of zero modes, \( \sum_\ell |\phi^{(0)}_\ell(x)|^2 \) is finite in cases of interest. Thus the divergence comes from the infinite volume of space-time, and evaluation of (2.10) only involves finding a suitable regularization of the volume of space-time. This will be discussed for AdS4 space in section 3.2.

3. The calculation

Our goal now is to perform a ‘macroscopic’ calculation of the log \( L \) correction to the free energy of 11D SUGRA on a background of the form AdS4 \( \times X_7 \), and compare it to the microscopic prediction (1.7) from AdS/CFT.

The most important simplification in our case is the fact that, since we are in odd dimensions, the contributions coming from the Seeley–De Witt expansion in (2.7) vanish. Therefore, we only have to take into account the zero mode contribution (2.9). We are then led to the question of which fields lead to discrete zero modes in the background we are considering. Fields with zero modes play of course a crucial role in the calculations of [16–20]. There, the background is AdS2 \( \times S^2 \) or AdS2 \( \times (\text{squashed})S^3 \), and the zero modes arise from the ‘exceptional’ zero modes of one-forms, metric and gravitinos on AdS2 described in [28].

3.1. Expression for the logarithmic correction

In (Euclidean) AdS4, the only bosonic fields which might possibly have discrete zero modes are actually two-forms, as explained in [29] (in general, \( N \)-forms have discrete zero modes on Euclidean AdS2\(N \)). For fermionic fields, it can be shown that neither spinors (of spin 1/2) nor gravitinos (of spin 3/2) have zero modes.

Now, there is a source of two-forms in the quantization of 11D SUGRA. This is because the quantization of the SUGRA three-form \( C_{MNP} \) needs a generalized ghost field which is a Grassmannian two-form. In general, the quantization of a \( p \)-form \( A_p \) requires \( p \) generalized ghost fields \( A_{p-j} \) which are \( p-j \) forms, \( j = 1, \ldots, p \) [30–32]. They are Grassmann even if \( j \) is even, and Grassmann odd if \( j \) is odd. The action for the original \( p \)-form and the ghost fields, after gauge fixing, is given by

\[
S = \frac{1}{2} \sum_{j=0}^{p} (p-j)! (A_{p-j}, (\Delta_{p-j})^{j+1} A_{p-j}).
\]

(3.1)

where \((\cdot, \cdot)\) is the standard inner product of forms induced by the Riemannian metric, and \( \Delta_k \) is the Hodge–Laplace operator acting on \( k \)-forms. The one-loop contribution to the free energy of the non-zero modes is then given by

\[
-\frac{1}{2} \sum_{j=0}^{p} (-1)^j (j+1) \ln \det(\Delta_{p-j}^\prime).
\]

(3.2)
where the ′ indicates that we are removing the zero modes. In an odd-dimensional spacetime, \(a_{d/2}\) vanishes and using (2.7) and (3.2) we get the logarithmic contribution to the free energy from the non-zero modes to be

\[
- \sum_j (-1)^j (j + 1) n_{\Delta_{p-j}}^0 \log L
\]

where \(n_{\Delta_{p-j}}^0\) is the number of zero modes of the Hodge–Laplace operator \(\Delta_{p-j}\). Taking into account the contribution of zero modes given in (2.9), we obtain the general expression

\[
\Delta F = \sum_j (-1)^j (\beta_{p-j} - j - 1) n_{\Delta_{p-j}}^0 \log L
\]

for the logarithmic contribution to the free energy of all the physical fields and ghost fields appearing in the quantization of a \(p\) form. In our case, \(n_{\Delta_{p-j}}^0\) is only different from zero when \(p = 3\) and \(j = 1\). This gives

\[
\Delta F = -(\beta_2 - 2) n_{\Delta_3}^0 \log L.
\]

Thus we have to compute \(n_{\Delta_3}^0\) and \(\beta_2\).

Physically the \(-\beta_2\) factor in (3.5) is the result of integration over the zero modes of the two-form field. Since the two-form field is a ghost field, one might wonder what it means to integrate over its zero modes. For this we can offer the following interpretation. In theories with gauge invariance, the definition of the path integral involves dividing by the volume of the group of gauge transformations \(\text{vol}(G)\). In the usual Faddeev–Popov gauge fixing, this factor is cancelled by the ghost path integral. However, when there are zero modes in the Faddeev–Popov operator, there is only a partial cancellation, and after gauge-fixing the path integral still includes a factor of \(1/\text{vol}(H)\), where \(H\) is the subgroup of gauge transformations generated by zero modes (see [11], section 3.1, for a review of this fact in the context of gauge theories, and [33], section 3.4, for an example in gravity). In our case, since the gauge transformation parameters of the three-form field are given by a two-form, the path integral will contain in the denominator an integration over the zero modes of the two-form fields. The contribution in (3.5) proportional to \(\beta_2\) can then be interpreted as the result of dividing the path integral by the integral over the zero modes of the gauge transformation parameter. This also explains why this contribution comes with a minus sign.

Notice that there is another potential source of zero modes—these could arise if \(X_7\) has a harmonic one-form so that we can get a harmonic three-form on \(\text{AdS}_4 \times X_7\) by taking the wedge product of a harmonic two-form on \(\text{AdS}_4\) times a harmonic one-form on \(X_7\). However, the \(X_7\) are compact Einstein manifolds of positive curvature, and they have \(b_1 = 0\) (see for example [34], page 57). Thus we conclude that there are no zero modes from this decomposition.

### 3.2. Calculation of the number of zero modes

To compute \(n_{\Delta_3}^0\), we use (2.12). Thus we need to calculate two quantities: \(\sum_\ell |\phi_\ell^{(0)}(x)|^2\) and the regularized volume of \(\text{AdS}_4\). For the first quantity we can use the general result of [29], which says that on \(\text{AdS}_4\) and for \(M/2\)-forms,

\[
\sum_\ell |\phi_\ell^{(0)}(x)|^2 = \frac{1}{2^{M/2} M!} \frac{1}{M!} \frac{1}{L^4}.
\]

For \(M = 4\) this gives

\[
\sum_\ell |\phi_\ell^{(0)}(x)|^2 = \frac{3}{4\pi^2 L^4}.
\]
We can also arrive at this result by explicitly evaluating the left hand side at the origin of AdS₄. In this case only a few φₗ (x)’s are non-vanishing, and by explicitly summing over the contribution from these modes we again arrive at (3.7). The regularized volume of AdS₄ can be calculated by standard procedure (see for example [6, 35]) but since this forms an integral part of our analysis, we shall review it here. For this we write the AdS₄ metric as
\[ ds^2 = L^2 (d\eta^2 + \sinh^2 \eta \, d\Omega_3^2), \quad 0 \leq \eta < \infty, \] (3.8)
where dΩ₃ is the line element on the unit three-sphere. If we regularize the volume of AdS₄ by putting a cut-off η < η₀ then the volume is given by
\[ V_{\text{AdS}_4} = \frac{4\pi^2 L^4}{\Omega_3^2} \left( \frac{1}{2} e^{3\eta_0} - \frac{3}{8} e^{\eta_0} + \frac{2}{3} + O(e^{-\eta_0}) \right). \] (3.9)

On the other hand the radius of curvature of the boundary three-sphere at η = η₀ is given by
\[ R = L \sinh \eta_0 = \frac{L(e^{\eta_0} - e^{-\eta_0})}{2}. \] (3.10)

Thus the terms in (3.9) proportional to e^{3η₀} and e^{η₀} can be expressed as polynomials in R up to order 1/R corrections and hence can be cancelled by boundary counterterms. As a result we are left with the regularized volume
\[ \text{vol(AdS}_4) = \frac{4\pi^2 L^4}{3}. \] (3.11)

3.3. Calculation of β₂

We now compute β₂. To do this, we proceed as in [16–20]. The path integral measure over the two-form Bₘᵥ in D dimensions is normalized as
\[ \int [DB_{\mu\nu}] \exp \left[ -\int d^D x \sqrt{g} g^{\mu\nu} g^{\rho\beta} B_{\mu\rho} B_{\nu\beta} \right] = 1. \] (3.12)

The metric on AdS₄ × X₇ can be written as g_{μν} = L^2 g_{μν}^(0), where g_{μν}^(0) is an L-independent metric. The normalization becomes
\[ \int [DB_{\mu\nu}] \exp \left[ -L^{D-4} \int d^D x \sqrt{g} g^{\mu\nu} g^{\rho\beta} B_{\mu\rho} B_{\nu\beta} \right] = 1. \] (3.13)

Hence the correctly normalized integration measure corresponds to an integration
\[ \prod_{x, (\mu\nu)} d(L^{D/2-2} B_{\mu\nu}(x)). \] (3.14)

On the other hand, the zero modes of the Bₘᵥ field are associated with the usual gauge transformation of two-forms,
\[ \delta B_{\mu\nu} \propto \partial_\mu \theta_\nu - \partial_\nu \theta_\mu, \] (3.15)

but with non-normalizable θ_μ so that these are not pure gauge deformations. Now, since we are using a coordinate system in which the metric takes the form L^2 g_{μν}^(0), the range of coordinates is independent of L. Since in any coordinate system we expect \[ \int \theta_\mu \, dx^\mu \] to have L independent periods, in the coordinate system used here, in which x^μ’s have L independent range, the θ_μ’s should have L independent integration range. Equation (3.15) now shows that the integration
over each $B_{\mu\nu}$ zero mode has an $L$-independent integration range, but due to the $L^{D/2-2}$ factor in the measure in (3.14) it gives a factor of $L^{D/2-2}$. Thus we have

$$\beta_2 = \frac{D}{2} - 2 = \frac{7}{2}$$

(3.16)

for $D = 11$.

Since the above result depends crucially on the result for the range of integration of the zero mode of $B_{\mu\nu}$, we shall now elaborate on this further in the context of a compact manifold, regarding the $B_{\mu\nu}$ as the gauge transformation parameters of the three-form field. For this, let us consider, instead of AdS$_4 \times X_7$, a compact space with metric $L^2 g_{\mu\nu}(0)$, where $g_{\mu\nu}(0)$ is $L$-independent. In this case, the zero modes of $B_{\mu\nu}$ are harmonic two-forms, which can be represented locally as $d/\Lambda_1$ for some one-form $\Lambda_1$, but this one-form is not globally defined. This is analogous to the two-form zero modes on AdS$_4 \times X_7$ which are locally of the form $d/\Lambda_1$ but the one-form $\Lambda_1$ is not normalizable. Now returning to the compact case, we see that if we regard the two-forms as the gauge transformation parameters of the three-form fields, then the integral of the two form over a two-cycle of the manifold is a global symmetry transformation parameter, and the corresponding conserved charge is the winding number of the M2-brane on this two-cycle. Since the latter is quantized in integer units, the integral of the two-form over the two-cycles will have period $2\pi$. Since $g_{\mu\nu}(0)$ and hence the coordinate system we have used has no explicit dependence on $L$, this shows that the zero modes of the $B_{\mu\nu}$ fields have $L$-independent integration range.

It is also worth noting that if instead of the two-form field we had zero modes of the metric—as in the case of [16–20]—then the result would be different. In this case, the metric zero modes would be associated with diffeomorphisms with non-normalizable transformation parameters $\xi^\mu(x)$, and the analogue of (3.15) would be $\delta g_{\mu\nu} = \nabla_\mu \xi_\nu + \nabla_\nu \xi_\mu$. However, now the natural variables which have $L$ independent range are the transformation parameters $\xi^\mu$, and so when we lower the index with the metric $g_{\mu\nu}$, we get a factor of $L^2$ in the range of integration over the metric zero modes [16–20]. Again, the validity of this argument can be checked using the example of a compact manifold. We take the familiar example of a square torus $T^2$ with metric $ds^2 = L^2(dx^2 + dy^2)$ and take $x, y$ to have period 1. Now consider a diffeomorphism $y \to y + ax, x \to x$, under which the metric is deformed to $L^2(dx^2 + (dy + adx)^2)$. Since this diffeomorphism does not preserve the periodicity in $x$ and $y$, it is not an allowed diffeomorphism and hence generates a genuine deformation of the metric. Thus this is analogous to non-normalizable diffeomorphisms in the non-compact case. But for $a = 1$ the periodicity in $x$ and $y$ is preserved showing that $a = 1$ is the same as $a = 0$. Hence the parameter $a$ has period 1, independent of $L$, as we expect on general grounds. Note however that since under this deformation the metric changes by order $L^2 \delta a$, the range of integration over the metric zero mode is of order $L^2$, as predicted from our general arguments.

### 3.4. Logarithmic correction to the free energy

Using (3.5), (3.11) and (3.16) we see that the logarithmic correction to the free energy is given by

$$- (\beta_2 - 2) \log L = -\frac{3}{2} \log L$$

(3.17)

which precisely matches (1.7).

---

6 Since $B_{\mu\nu}$ are Grassmann variables the factor is actually $L^{-(D/2-2)}$ but the extra minus sign has already been taken into account in (3.5).
4. Conclusions and outlook

In this note we have shown that the logarithmic correction to the three-sphere partition function, in a large class of three-dimensional CFTs generalizing ABJM theory, can be computed by doing a one-loop calculation in the dual 11-dimensional supergravity on AdS$_4 \times X_7$. This can be regarded as a generalization of the program for calculating logarithmic corrections to the black hole entropy developed in [16–20], and provides a non-trivial test of the AdS/CFT correspondence at next-to-leading order in the $1/N$ expansion. We have found that this correction is due only to zero modes, more precisely, to the zero mode of a ghost two-form appearing in the quantization of the three-form field of supergravity. This explains its universality: on the field theory side, the correction is independent of the data of the CFT, and on the supergravity side, it is independent of the seven-dimensional manifold $X_7$.

The computation we have done here can be extended in various directions. For example, it would be interesting to reproduce the logarithmic shift in the type IIA string picture obtained by dimensional reduction of the 11-dimensional supergravity backgrounds considered in this paper, which leads to backgrounds of the form AdS$_4 \times X_6$. In this case there will be contributions from both non-zero and zero-modes, and the answer depends in principle on the details of the six-dimensional manifold $X_6$ appearing in the compactification. Another interesting extension concerns the study of logarithmic corrections for type IIA string theory on the backgrounds of the form AdS$_6 \times X_4$ found in [36]. In this case the partition function can be also computed in the CFT side, and it agrees with the gravity dual at large $N$ [37], so one might try to compare the logarithmic corrections.

Acknowledgments

We would like to thank M Gaberdiel, J Maldacena, R Minasian, G Moore, B Panda, M Rocek and A Tseytlin for useful conversations. MM would like to thank the 2011 Simons Workshop for hospitality in the preliminary stages of this work. The work of AG and MM is supported by the Fonds National Suisse under subsidies 200020–126817 and 200020–137523. The work of SB and AS is supported in part by the project 11-R and D-HRI-5.02-0304. The work of AS is also supported in part by the J C Bose fellowship of the Department of Science and Technology, India.
