Abstract
In order to kill competing strains of the same or closely related bacterial species, many bacteria produce potent narrow-spectrum protein antibiotics known as bacteriocins. Two sequenced strains of the phytopathogenic bacterium *Pectobacterium carotovorum* carry genes encoding putative bacteriocins which have seemingly evolved through a recombination event to encode proteins containing an N-terminal domain with extensive similarity to a [2Fe-2S] plant ferredoxin and a C-terminal colicin M-like catalytic domain. In this work, we show that these genes encode active bacteriocins, pectocin M1 and M2, which target strains of *Pectobacterium carotovorum* and *Pectobacterium atrosepticum* with increased potency under iron limiting conditions. The activity of pectocin M1 and M2 can be inhibited by the addition of spinach ferredoxin, indicating that the ferredoxin domain of these proteins acts as a receptor binding domain. This effect is not observed with the mammalian ferredoxin protein adrenodoxin, indicating that *Pectobacterium spp.* carries a specific receptor for plant ferredoxins and that these plant pathogens may acquire iron from the host through the uptake of ferredoxin. In further support of this hypothesis we show that the growth of strains of *Pectobacterium carotovorum* and *atrosepticum* that are not sensitive to the cytotoxic effects of pectocin M1 is enhanced in the presence of pectocin M1 and M2 under iron limiting conditions. A similar growth enhancement under iron limiting conditions is observed with spinach ferredoxin, but not with adrenodoxin. Our data indicate that pectocin M1 and M2 have evolved to parasitise an existing iron uptake pathway by using a ferredoxin-containing receptor binding domain as a Trojan horse to gain entry into susceptible cells.

Introduction
Bacteriocins are highly potent narrow-spectrum antibacterial protein toxins produced by a variety of Gram-negative bacteria that are active against bacteria closely related to the producing strain [1]. The best characterised of the bacteriocins are the colicins from *E. coli* and genes encoding putative bacteriocins with cytotoxic domains highly homologous to cytotoxic domains of the colicins can be identified in the genomes of a wide variety of Gram-negative bacteria. The cytotoxic activity of colicin-like bacteriocins is housed in a C-terminal domain, with central and N-terminal domains encoding receptor-binding and translocation functions [2]. Colicin cytotoxic domains take the form of a specific nuclease domain that hydrolyses DNA, tRNA or 16S rRNA, a pore-forming domain that depolarises the cytoplasmic membrane, or as in the case of colicin M, inhibits cell wall production through degradation of undecaprenyl-phosphate-linked peptidoglycan precursors [3,4]. The C-terminal domain is also the site of binding for a specific immunity protein that protects the producing cell from the lethal effects of the toxin [5,6]. To gain entry into target cells, colicins initially bind to a specific outer membrane receptor and cross this membrane through recruitment of host proteins of the Tol/ABQR-Pal or TonB-ExbBD complexes in the periplasmic space [7,8]. A number of the receptors for colicins and for the closely related pyocins are TonB dependent with a normal physiological role in iron siderophore uptake [9,10]. Unlike the colicins, little is known about the receptors and mechanisms of entry used by bacteriocins from plant pathogenic bacteria.

The genus *Pectobacterium* contains necrotrophic plant pathogens, characterised by their ability to secrete cell wall degrading enzymes including pectinases, cellulases, proteases and xylanases. These enzymes are produced in greater abundance in *Pectobacterium* spp. than in other phytopathogenic bacteria and give the genus its distinctive soft rot phenotype. The genus *Pectobacterium* is divided into four species *atrosepticum*, *betavasculorum*, *carotovorum* and *wasabiae* [11,12]. Strains of *carotovorum* and *wasabiae* have a broad host range, while *atrosepticum* and *betavasculorum* are restricted to potato and sugar beet respectively [13]. *P. atrosepticum* is the causative agent of black leg in potato, one of the most economically important diseases of any temperate crop [14].

Iron acquisition mechanisms of *Pectobacterium* have not yet been studied extensively, however the genus has been shown to acquire iron by diverse mechanisms including siderophore, haem iron and ferric-citrate production/absorption [13,16]. The closely related soft rot pathogen *Dickeya dadantii* (formerly *Erwinia chrysanthemi*) has been shown to possess two high affinity iron siderophores (achromobactin and chrysobactin) and mutants impaired in the production of these siderophores are less virulent, suggesting iron...
acquisition is an important virulence determinant in infection [17].
Additionally, transcription of pectolin genes responsible for
degradation of the host cell wall during infection, has been shown
to be triggered by iron limitation, suggesting a link between iron
limitation and pathogenesis [18].

Plant-type ferredoxins are a super family of proteins containing
a single [2Fe-2S] cluster. They are predominantly present in the
chloroplasts, where they primarily function as electron carriers
from photosystem one to enzymes responsible for carbon, nitrogen
and sulphur assimilation [19]. Plant-type ferredoxins are also
present in the non-photosynthetic tissues of plants suggesting a
wider physiological relevance. Genes very closely related to those
encoding plant-type ferredoxins are also present, seemingly
uniquely among heterotrophic bacteria, in the genomes of a
number of Pectobacterium species. These genes were likely acquired
by horizontal gene transfer [20]. [2Fe-2S] ferredoxins more
distantly related to plant-type ferredoxins are widely distributed
through prokaryotic and eukaryotic kingdoms [21].

In this work we have purified and characterised two novel
bacteriocins from Pectobacterium species. These bacteriocins, named
pectocin M1 and M2, contain a predicted N-terminal domain with
high levels of sequence similarity to plant ferredoxins and a C-
terminal domain highly homologous to the catalytic domain of the
E. coli bacteriocin, colicin M. The cytotoxic activity of these
bacteriocins is limited to Pectobacterium spp. and is dependent on
iron availability. Our data indicate that the ferredoxin domain acts
as a receptor binding domain and that these bacteriocins have
evolved to gain entry into susceptible cells through parasitisation of
a previously unreported iron uptake system in Pectobacterium spp.

Results

Identification of pectocin M genes in the genomes of
Pectobacterium spp.

As part of a wider study into the identification and potential use
of bacteriocins as biocontrol agents we searched the genome
sequences of plant pathogenic bacteria for genes encoding putative
colin-like bacteriocins. Two putative colicin M-like bacteriocin
genes were identified in the genomes of P. carotovorum subsp.
carotovorum PC1 (Pc PC1) and P. carotovorum subsp. brasiliensis
BPR1692 (Pb BPR1692). These genes encode proteins that we
have named pectocin M1 and pectocin M2, respectively. Pectocin
M1 and M2 have an N-terminal domain with approximately 60%
identity to spinach ferredoxin I and a C-terminal domain with
approximately 46% identity to the catalytic domain of colicin M
(Figure 1a and b). The colicin M-like domains of both proteins
contain all residues that have previously been shown to be
important for the catalytic activity and consequently cytotoxicity of
colicin M [22]. A linker region of approximately 20 amino acids,
which is not conserved between pectocin M1 and M2 connects the
two domains and overall these proteins share 58% sequence
identity.

Phylogenetic analysis of the ferredoxin domains of these
pectocins show they cluster with a number of other ferredoxin
and ferredoxin-domain containing proteins from Pectobacterium
species (Figure 1c). This cluster of sequences is most similar to
[2Fe-2S] ferredoxins from plants and cyanobacteria, with
ferredoxins from the genus Arabidopsis sharing the highest sequence
identity. This cluster is much more distantly related to typical
bacterial ferredoxins (Figure 1c). The cysteine residues of plant
ferredoxins that coordinate the [2Fe-2S] cluster in the active
centre of these proteins are conserved in the pectocins, indicating
that these proteins may also contain the [2Fe-2S] cluster
(Figure 1b).

Evolution of the pectocin M1 gene through gene
duplication and recombination

Analysis of the genomic context of pectocin M1 gives clues to its
evolutionary origin. As shown in Figure 2a, approximately 3000bp
upstream of the gene coding for pectocin M1, is a predicted open
reading frame encoding a plant-like ferredoxin with 52% amino
acid identity to the ferredoxin domain of pectocin M1. Alignment
of the nucleotide sequences of these regions (Figure 2b) shows high
nucleotide conservation (>50%) that encompasses the area of
sequence similarity between pectocin M1 and the plant-like
ferredoxin, as well as part of a hypothetical open reading frame
present in both regions, but truncated in the pectocin M1 region.
High levels of similarity and truncation of the adjacent open
reading in the pectocin M1 region strongly suggests a gene
duplication event. Evolution of the gene encoding the active
bacteriocin is therefore likely to have occurred after this gene
duplication event, through recombination between the duplicated
ferredoxin gene and an ancestral bacteriocin carrying a colicin M-
like cytotoxic domain. An open reading frame directly upstream of
the pectocin M1 gene encodes a likely pectocin M1 immunity
protein, which shares 24% amino acid identity with the immunity
protein of colicin M. Pectocin M2 does not share this genomic
context, however the open reading frame directly upstream codes
for a bacteriocin closely related to carocin S2 [23], suggesting it
may have been recruited to a genomic island.

Purification and characterisation of pectocin M1 and M2

Pectocin M1 and M2 were expressed in E. coli BL21 (DE3) and
purified by anion exchange chromatography and gel filtration to
>90% homogeneity based on analysis by SDS PAGE (Figure 3a).
The purified recombinant proteins were red-brown in colour and
the absorption spectra of both proteins displayed maxima at
330 nm, 423 nm, and 466 nm (Figure 3b), which are character-
istic of plant ferredoxins [21]. These data show both pectocins M1
and M2 contain a [2Fe-2S] cluster.

Initially the killing spectrum of pectocin M1 and pectocin M2
was tested against five P. atrosepticum and five P. carotovorum isolates
using the agar overlay spot test method on LB agar. Under these
experimental conditions pectocin M1 was found to be active
against three atrosepticum strains and one carotovorum strain. The
zones of inhibition in this experiment while distinct, were hazy
(Figure 3c). Pectocin M2 did not show activity against any of the
strains tested under these conditions. Since a number of
bacteriocins utilise outer membrane receptors involved in iron
uptake [2] we tested the activity of the pectocins under iron
limiting conditions induced by addition of the iron chelator 2,2-
bipyridine to the LB agar. Under these conditions, the activity of
pectocin M1 was greatly enhanced (Figure 3c), with seven of ten
Pectobacterium spp. being inhibited. For pectocin M2, three of the ten
strains were weakly inhibited (Table 1, Table S1). The minimum
inhibitory concentration of pectocin M1 under iron-limiting
conditions was calculated using the above method with serial
dilutions of pectocin M1 and varied from 14.5–145 nM among
susceptible strains. The cytotoxic effect of pectocin M1 in liquid
conditions was calculated using the above method with serial
dilutions of pectocin M1 and varied from 14.5–145 nM among
susceptible strains. The cytotoxic effect of pectocin M1 in liquid
culture was tested by adding varying concentrations of pectocin
M1 to an iron limited log-phase culture of the susceptible strain
Erwinea rhapontici strain. The

Experiment 1

Analysis of the genome context of pectocin M1 gives clues to its
evolutionary origin. As shown in Figure 2a, approximately 3000bp
upstream of the gene coding for pectocin M1, is a predicted open
reading frame encoding a plant-like ferredoxin with 52% amino
acid identity to the ferredoxin domain of pectocin M1. Alignment
of the nucleotide sequences of these regions (Figure 2b) shows high
nucleotide conservation (>50%) that encompasses the area of
sequence similarity between pectocin M1 and the plant-like
ferredoxin, as well as part of a hypothetical open reading frame
present in both regions, but truncated in the pectocin M1 region.
High levels of similarity and truncation of the adjacent open
reading in the pectocin M1 region strongly suggests a gene
duplication event. Evolution of the gene encoding the active
bacteriocin is therefore likely to have occurred after this gene
duplication event, through recombination between the duplicated
ferredoxin gene and an ancestral bacteriocin carrying a colicin M-
like cytotoxic domain. An open reading frame directly upstream of
the pectocin M1 gene encodes a likely pectocin M1 immunity
protein, which shares 24% amino acid identity with the immunity
protein of colicin M. Pectocin M2 does not share this genomic
context, however the open reading frame directly upstream codes
for a bacteriocin closely related to carocin S2 [23], suggesting it
may have been recruited to a genomic island.

Purification and characterisation of pectocin M1 and M2

Pectocin M1 and M2 were expressed in E. coli BL21 (DE3) and
purified by anion exchange chromatography and gel filtration to
>90% homogeneity based on analysis by SDS PAGE (Figure 3a).
The purified recombinant proteins were red-brown in colour and
the absorption spectra of both proteins displayed maxima at
330 nm, 423 nm, and 466 nm (Figure 3b), which are character-
istic of plant ferredoxins [21]. These data show both pectocins M1
and M2 contain a [2Fe-2S] cluster.

Initially the killing spectrum of pectocin M1 and pectocin M2
was tested against five P. atrosepticum and five P. carotovorum isolates
using the agar overlay spot test method on LB agar. Under these
experimental conditions pectocin M1 was found to be active
against three atrosepticum strains and one carotovorum strain. The
zones of inhibition in this experiment while distinct, were hazy
(Figure 3c). Pectocin M2 did not show activity against any of the
strains tested under these conditions. Since a number of
bacteriocins utilise outer membrane receptors involved in iron
uptake [2] we tested the activity of the pectocins under iron
limiting conditions induced by addition of the iron chelator 2,2-
bipyridine to the LB agar. Under these conditions, the activity of
pectocin M1 was greatly enhanced (Figure 3c), with seven of ten
Pectobacterium spp. being inhibited. For pectocin M2, three of the ten
strains were weakly inhibited (Table 1, Table S1). The minimum
inhibitory concentration of pectocin M1 under iron-limiting
conditions was calculated using the above method with serial
dilutions of pectocin M1 and varied from 14.5–145 nM among
susceptible strains. The cytotoxic effect of pectocin M1 in liquid
culture was tested by adding varying concentrations of pectocin
M1 to an iron limited log-phase culture of the susceptible strain P.
aterospticum LMG 2386. A concentration-dependent reduction in
growth was observed upon the addition of pectocin M1 (Figure 3d).
To determine if pectocin M1 and M2 might be active against more
distantly related bacterial species, pectocin M1 and pectocin M2
were tested for inhibitory activity against strains of E. coli,
Pseudomonas syringae, Pseudomonas aeruginosa and Erwinia chrysanthemi
(see Table S2). None of these more distantly related bacteria showed
any susceptibility to pectocin M1 or M2 (at 1.2 and
10 mg/ml respectively) suggesting that the activity of these pectocins is limited species of *Pectobacterium* closely related to the producing strain.

The ferredoxin domain of pectocins M1 and M2 mediate receptor binding

As ferredoxin is a potential iron source for phytopathogenic *Pectobacterium* species we hypothesised that pectocins M1 and M2 were parasitising an existing iron uptake system by using their ferredoxin domain to bind to a cell surface receptor, which has a normal physiological role in iron acquisition from ferredoxin. If this is the case, the addition of a plant ferredoxin at sufficient concentration should abolish pectocin M1 binding to its receptor and therefore abolish its cytotoxic activity. To test this hypothesis spinach ferredoxin was spotted adjacent to pectocin M1 in an agar overlay spot test. Clear inhibition of cell killing was observed in the region where the diffusion zone of spinach ferredoxin overlaps with the pectocin M1 diffusion zone (Figure 4a). Indeed, for all 7 susceptible strains cytotoxicity of pectocin M1 could be abolished to a similar extent by the addition of spinach ferredoxin. This effect was not observed with adrenodoxin, a more distantly related mammalian [2Fe-2S] cluster containing ferredoxin, indicating a level of specificity for plant ferredoxins (Figure 4a). Additionally, in five pectocin M1 susceptible strains that are not sensitive to pectocin M2 the cytotoxicity of pectocin M1 could be abolished by the addition of pectocin M2, indicating these two bacteriocins utilise the same receptor.

To determine if the activity of the colicin M-like domain of pectocin M1 is essential for its cytotoxicity, we made a mutant protein in which Asp222 is replaced by Ala. The equivalent Asp of colicin M has been shown to be essential for the catalytic activity and consequent cytotoxicity of colicin M [22]. Purified pectocin M1 Asp222Ala had no detectable cytotoxicity, but was able to abolish cytotoxicity of wild-type pectocin M1 indicating that it is fully functional in binding to its receptor (Figure 4a). Taken together, these data indicate that receptor recognition occurs through the ferredoxin domain of pectocin M1 and M2 and that the normal physiological role of pectocin M1/M2 receptor is to bind plant ferredoxins.

Growth enhancement under iron limiting conditions by pectocins and spinach ferredoxin

During spot tests on iron limiting media to determine the killing spectrum of pectocin M1 and M2 we observed that the growth of a number of insensitive *Pectobacterium* strains was observably enhanced where the pectocins were spotted onto the plate. Additionally, some strains that were inhibited by pectocin M1 displayed a zone of enhanced growth peripheral to the zone of inhibition. Four and five of the ten *Pectobacterium* isolates exhibited enhanced growth in the presence of pectocin M1 and M2 respectively. The enhancement of growth due to pectocin M1 was significantly more pronounced than that due to pectocin M2, with strongest enhancement present at 200 \mu M \text{2,2'-bipyridine} for both pectocin M1 and pectocin M2 (Table S1). This observation led us to hypothesise that *Pectobacterium* strains are able to utilise these ferredoxin domains as an iron source under iron limiting conditions.

To test this idea further, and to test the specificity of this growth enhancement, related plant and mammalian ferredoxin-type proteins (spinach ferredoxin I and human adrenodoxin) as well as syringacin M, a colicin M homologue from *Pseudomonas syringae* which contains an active colicin M catalytic domain but an unrelated N-terminal region [24] (unpublished data) were tested for their ability to enhance the growth of *Pectobacterium* spp.

under iron-limiting conditions. Five strains exhibited strongly enhanced growth due to the spinach ferredoxin at either 20 or 2 mg ml\(^{-1}\) (Figure 4b), this enhanced growth was dependent on the concentration of the iron chelator 2,2'-bipyridine, with the strongest enhancement at 400 \(\text{mM}\) (Table S1). No enhanced growth was observed with the [2Fe-2S] cluster containing protein adrenodoxin at 30 mg ml\(^{-1}\) or syringacin M at 5 mg ml\(^{-1}\).

**Discussion**

In this work we have identified, purified and characterised two novel bacteriocins, pectocin M1 and M2, which are active against selected strains of *Pectobacterium* spp. These bacteriocins share a common domain structure, with an N-terminal ferredoxin domain containing a [2Fe-2S] cluster and a C-terminal cytotoxic domain homologous to colicin M. Activity of pectocin M1 was inhibited by...
the addition of spinach ferredoxin, which strongly suggests that the ferredoxin domain mediates binding to a receptor on the surface of sensitive *Pectobacterium* strains. The mammalian ferredoxin adrenodoxin was unable to elicit this effect, even at a concentration 15 times higher than the lowest tested spinach ferredoxin concentration. This suggests that the pectocin M receptor is specific for plant-type ferredoxin and is not merely binding due to the presence of an iron sulphur cluster. The inhibition of bacteriocin cytotoxicity as an indicator of competition is well established by previous studies of bacteriocin-receptor interactions in *E. coli*. For example, colicin M, which gains entry to the cell via the ferrichrome receptor FhuA, can be blocked by the addition of ferrichrome, the normal physiological ligand of FhuA. In addition, colicin M is able to block albomycin activity, an antibiotic which also uses FhuA as a receptor [22,25,26]. Similarly vitamin B12, the substrate of the BtuB receptor, is able to inhibit cytotoxicity of the E group colicins which also bind this receptor [27].

The cytotoxicity and spectrum of killing of pectocin M1 and M2 is greatly enhanced under iron limiting conditions suggesting that production of their receptor is unregulated and that this receptor likely plays a role in iron acquisition. This idea is supported by the observation that some strains of *Pectobacterium* spp. are able to exhibit enhanced growth under iron limiting conditions in the presence of a plant-like ferredoxin, either in the form of spinach ferredoxin or the pectocins themselves. The growth enhancement is specific to the extent that adenodoxin does not elicit this effect. The enhanced growth observed under iron limiting conditions in the presence of the pectocins and spinach ferredoxin, suggests that the iron contained in plant-like ferredoxins can be specifically utilised by *Pectobacterium* species. Taken together, these data strongly suggest that the pectocin M receptor has a normal physiological role in iron acquisition from plant ferredoxin.

The importance of iron acquisition in bacterial pathogenesis of animals is well established and the ability to acquire sufficient iron often determines the success or failure of an infection [28]. The dynamics of iron availability during bacterial pathogenesis of plants is less well understood, although a number of studies have strongly correlated iron acquisition and virulence in *plant* [17,18,29]. During infection, *Pectobacterium* species release large quantities of pectinases and cellulosomes which macerate host tissues creating the distinctive soft rot associated with the genus. This disease phenotype results in cell lysis and the release of intracellular nutrients for absorption by the bacteria [11]. Since ferredoxin is the major iron containing protein in plants it undoubtedly represents an attractive potential source of iron in an environment of low iron availability [30]. As such, the ability of *Pectobacterium* spp. to acquire iron from ferredoxin may represent an important virulence mechanism, although this remains to be tested.

A number of iron acquisition systems involving absorption from iron containing proteins have been identified in pathogenic bacteria [28]. The best studied system involves the transferrin-binding proteins TbpA and TbpB of *Neisseria* spp. These outer membrane proteins bind transferrin with a preference for the holoprotein, strip the protein of its two iron atoms before releasing the apoprotein into the extracellular environment. These proteins have been shown to be specific for the transferrin of the host and are essential for virulence [31]. Whether the entire ferredoxin protein or simply the iron which it contains is taken into the cell by *Pectobacterium* is currently unknown.

The ferredoxin domain of pectocin M1 is closely related to plant ferredoxins and the pectocin M1 gene has seemingly evolved through duplication of a horizontally acquired plant ferredoxin gene and subsequent recombination with an ancestral colicin M-like bacteriocin. The presence of ferredoxin genes in *Pectobacterium* spp. that appear to have been acquired through horizontal gene transfer from plants has been previously noted [20]. In addition to pectocin M1 and M2, we have identified a further putative bacteriocin that contains an N-terminal ferredoxin domain. Analysis of the genome sequence of *Pectobacterium carotovorum* subsp. *carotovorum* WPP14 revealed a gene encoding a putative bacteriocin (designated pectocin P, Figure 1b) with an N-terminal ferredoxin domain and a C-terminal domain with 41% identity to the C-terminal 187 amino acids of pesticin, a peptidoglycan degrading bacteriocin with muramidase activity from *Yersinia pestis*.

[32,33,34]. Like colicin M the cellular target of pesticin is located in the periplasm and as such a receptor binding and translocation domain sufficient to deliver a colicin M catalytic domain to its site of action would also be sufficient to deliver the cytotoxic domain of a pesticin-like bacteriocin. Recombination and gene duplication have been well established as evolutionary mechanisms for generating bacteriocins with new specificities [1]. Many of the colicins and related bacteriocins identified to date are mosaics of related receptor binding, translocation and catalytic domains [2,33]. However, the evolution of ferredoxin containing bacteriocins seems to be unprecedented in that Pectobacterium spp. has successfully utilised a horizontally acquired host gene for competition against closely related bacterial strains.

Methods

Bacterial strains and media

Strains of Pectobacterium spp. used in this study are listed in Table 2. Other bacterial strains are listed in Table S2. All bacterial strains were grown in LB broth with the exception of E. coli and P. aeruginosa which were grown in Kings B Broth. All strains were grown at 28°C, with the exception of E. coli and P. aeruginosa which were grown at 37°C. Media was supplemented with ampicillin 100 μg ml⁻¹, kanamycin 50 μg ml⁻¹, isopropyl-ß-D-thiogalactopyranoside (IPTG) 0.1–1 mM or 2,2'-ampicillin 100 μM when required.

Plasmid construction and DNA manipulation

Plasmids used in this study are outlined in Table 2. pJMPCI and pJMBPR which contain the open reading frames of pectocin M1 and M2 and unique NdeI and XhoI sites at the start codons and directly after the stop codons of the pectocin genes were synthesized by DNA 2.0. Plasmids pETMPCI and pMBPR, used for expression of the pectocin M1 and M2, respectively were created by subcloning the NdeI/XhoI fragments of pJMPCI and pJMBPR into the corresponding sites of pET-21a. The D222A mutant of pectocin M1 was created using the QuickChange Site Directed Mutagenesis Kit (Stratagene) utilising pETMPCI as a template and the following primers, 5'-GCA TCC GCG CAT ATA ACG CTC TGT ATG ATG CTA ATC CG-3', 5'-CGG ATT AGC ATC TGT ATG ATG CTA ATC CG-3' to give the D222A pectocin M1 encoding plasmid pETMPCID222A.

Protein expression and purification

Pectocin M1 and M2 were expressed in E. coli BL21 (DE3) carrying the plasmid pETPCI or pETBPR, respectively. Cells were grown at 37°C and protein expression was induced by the addition of IPTG at an OD₆₀₀ of approximately 0.6. Cultures were grown for a further six hours at 28°C. Cells were harvested and resuspended in 50 mM Tris-HCl, pH 7.5, 20 mM NaCl and Complete EDTA free protease inhibitor cocktail tablets (Roche) were added. After disruption by sonication the supernatant was clarified by centrifugation and applied to a DE-52 anion exchange column (Whatman) equilibrated in 50 mM Tris-HCl, pH 7.5, 20 mM NaCl. Bound protein was eluted with a linear gradient of 20–600 mM NaCl in lysis buffer. Pectocin containing fractions were identified based on colour and analysis by SDS-PAGE. Pectocin containing fractions were pooled and dialysed into 50 mM Tris-HCl, pH 7.5, 20 mM NaCl and loaded onto a Superdex S75 26/60 column, (GE Healthcare). To obtain homogenous protein a final purification step using a Mono Q

doi:10.1371/journal.pone.0033033.t002
(GE Healthcare) anion exchange column was employed with bound protein eluted with a linear gradient of 20–700 mM NaCl in 50 mM Tris-HCl, pH 7.5. Fractions were pooled as above and dialysed into 50 mM Tris-HCl, pH 7.5, 100 mM NaCl. Dialysed fractions were aliquoted and frozen at −80°C. The absorption spectrum of purified pectocins was determined using a UV-1700 Pharma Spec, UV-VIS spectrophotometer (Shimadzu). Pectocin M was added to at mid-log phase and the OD600 was monitored throughout the experiment.

Inhibition of growth on solid media was determined using the soft agar overlay method [36]. 100 µl of mid-log phase culture of the test strain was added to 5 ml of 0.6% agar in dH2O melted and cooled to 42°C. The molten agar was then overlayed onto LB medium with or without 100–400 µM 2,2'-bipyridine. Purified protein was spotted directly onto the surface of the overlay once solidified. To observe inhibition interference proteins were spotted within the others zone of diffusion on the plate. Plates were incubated for a further 12 hours and zones of inhibition/enhancement observed. For inhibition of growth in liquid culture cells were grown in LB broth with 200 mM 2,2'-bipyridine purified pectocin M1 was added at to mid-log phase and the OD600 was monitored throughout the experiment.

Identification of pectocins and bioinformatic analysis

Putative pectocins were identified by interrogating the National Center for Biotechnology (NCBI) non-redundant protein database.
