We analyze a quantum Otto refrigerator based on a superconducting qubit coupled to two LC resonators, each including a resistor acting as a reservoir. We find various operation regimes: nearly adiabatic (low driving frequency), ideal Otto cycle (intermediate frequency), and nonadiabatic coherent regime (high frequency). In the nearly adiabatic regime, the cooling power is quadratic in frequency, and we find a substantially enhanced coefficient of performance $\epsilon$, as compared to that of an ideal Otto cycle. Quantum coherent effects lead invariably to a decrease in both cooling power and $\epsilon$ as compared to purely classical dynamics. In the nonadiabatic regime we observe strong coherent oscillations of the cooling power as a function of frequency. We investigate various driving wave forms: Compared to the standard sinusoidal drive, a truncated trapezoidal drive with optimized rise and dwell times yields higher cooling power and efficiency.

I. INTRODUCTION

Dynamical control of open systems within the framework of quantum thermodynamics is gaining increased attention. Several theoretical proposals and a few experimental ones have recently been put forward for quantum heat engines [1–9] and refrigerators [10–13]. Most of the proposed engines are candidates to work in both classical and quantum regimes, but understanding the influence of quantum dynamics on their performance calls for more research [9,11]. Different quantum systems, such as single atoms and superconducting circuits, are to be employed as a working substance in quantum engines, often in the form of two-level systems or harmonic oscillators.

The basic Otto cycle consists of adiabatic expansion, rejection of heat at constant volume, adiabatic compression, and heat extraction at constant volume. This paper, discussing quantitatively the performance of a quantum Otto refrigerator based on a superconducting qubit, is organized as follows. In Sec. II we present the design of the refrigerator coupled to two reservoirs [12]. Using a standard quantum master equation, we analyze in Sec. III its power in various driving frequency regimes. We present an expansion of the density matrix at low frequencies and find expressions for heat flux between the reservoirs with explicit classical and quantum contributions. Section IV is devoted to a discussion of different driving wave forms that yield improved performance beyond that based on the obvious sinusoidal protocol. In Sec. V, we study the coefficient of performance of the Otto refrigerator and the effect of quantum dynamics on it. Owing to the rapid progress in superconducting qubit technology, this setup is fully feasible for experimental implementation, which will be briefly discussed in Sec. VI.

II. DESCRIPTION OF THE SYSTEM AND THERMODYNAMIC CYCLE

The studied quantum Otto refrigerator is schematically illustrated in Fig. 1(a). The superconducting qubit in the middle consists of a loop interrupted by Josephson junctions. It is coupled to two resonators via mutual inductances $M_1$ and $M_2$ on the left and right, and a bias circuit on the top controls the flux $\Phi$ through the loop with $q \equiv \delta \Phi/\Phi_0$. Here, $\delta \Phi \equiv \Phi - \Phi_0/2$ and $\Phi_0 = h/2e$ is the superconducting flux quantum. Each resonator is a series $RLC$ circuit. Resistors $R_C$ and $R_H$, in general, with different inverse temperatures, $\beta_1 = (k_BT_C)^{-1}$ and $\beta_2 = (k_BT_H)^{-1}$, are the cold and hot baths, respectively. Strictly speaking, “hot” and “cold” refer here to the resonance frequencies of the two LC circuits, “cold” (“hot”) being that with lower (higher) frequency $\omega_2 (\omega_1)$. In general, the two temperatures can take arbitrary values. In this paper we present inductive coupling of the qubit to the resonators, but this can be replaced by capacitive coupling when more appropriate.

The thermodynamic cycle of this refrigerator is sketched in Fig. 1(b) and it consists of four legs labeled A–D with the following ideal properties. (A) Isentropic expansion ($q = 0 \Rightarrow q = \frac{1}{2}$): The qubit is isolated from the two baths as it is not in resonance with either of the two LC circuits, and its population is determined by the temperature of the cold resistor $R_C$. (B) Thermalization with the hot bath: The qubit is coupled to the hot resistor $R_H$ at $q = \frac{1}{2}$ and the energy flows from the qubit to the resistor. (C) Isentropic compression ($q = \frac{1}{2} \Rightarrow q = 0$): The qubit is in thermal equilibrium with the hot bath but decoupied from both the baths during the ramp.

FIG. 1. (a) Scheme of the quantum refrigerator presented. (b) Thermodynamic Otto cycle of the refrigerator. (c) Configuration of the two-level energies of the qubit under sinusoidal driving depicted on top of the diagram.
(D) Thermalization with the cold bath: The system is brought back to the initial thermal state in equilibrium with the cold resistor at $q = 0$. Energy in this process flows from the cold resistor to the qubit. The cycle as a whole can also be viewed as periodic alternating control of the Purcell effect of the qubit [14] with the two resonators. The Hamiltonian of the whole setup is given by

$$H = H_{R_0} + H_{R_c} + H_{dH} + H_{Q} + H_Q,$$

(1)

where $H_{R_0}$ and $H_{R_c}$ are the Hamiltonians of the two reservoirs, $H_Q$ that of the qubit, and $H_{dH}$ and $H_{Q}$ represent the coupling between the qubit and the corresponding reservoir. Our analysis applies to a generic superconducting qubit [15]: For instance, in transmon [16] and flux qubits [17], the two-level system is formed of Josephson junctions for which $E_J/E_C \gg 1$. Here, $E_J$ is the Josephson coupling energy of the junctions and $E_C$ is the Cooper pair charging energy. The Hamiltonian of the qubit is given by

$$H_Q = -E_0(\Delta \sigma_x + q \sigma_z),$$

(2)

where $\sigma_x$ and $\sigma_z$ are the Pauli matrices, and $E_0$ is the overall energy scale of the qubit, such that the level spacing between the instantaneous eigenstates (ground state $|g\rangle$, excited state $|e\rangle$) is given by $E = 2E_0/\sqrt{4 + \Delta^2}$. The maximum and minimum level separations at $q = \frac{1}{2}$ and $q = 0$ are denoted by $E_1 = h\omega_1$ and $E_2 = h\omega_2$, respectively, and $\Delta = E_2/(2E_0)$. Referring to the common transmon and flux qubits, the parameters in Eq. (2) attain values $E_0 \sim E_J$ and $\Delta \sim E_C/E_J$. The transition rates between the two levels of the qubit due to the two baths are given by

$$\Gamma_{\downarrow \uparrow, j} = \frac{E_0^2 M_j^2}{h^2} \frac{\Delta^2}{\Delta^2 + \Delta^2} S_{\downarrow \uparrow, j}(\pm E/h),$$

(3)

where $S_{\downarrow \uparrow, j}(\omega) = |(R_j[1 + Q_j^2(\omega_{ee} - \omega_{EC}/\omega)]^{-2} S_{\downarrow \uparrow, j}(\omega)$ is the unsymmetrized noise spectrum. Here, $\omega_{EC,j} = 1/\sqrt{L_j/C_j}$ and $Q_j = \sqrt{L_j/C_j}/R_j$ for the bare resonance angular frequency and the quality factor of circuit $j$, and $S_{\downarrow \uparrow, j}(\omega) = 2R_j/h\omega(1 - e^{-\beta \omega})$ denotes the voltage noise of the resistor. The $+$ and $-$ signs refer to the relaxation ($\downarrow$) and excitation ($\uparrow$) of the qubit, respectively. For more details, see Appendix.

For quantitative analysis, we consider the standard master equation for the time $t$ evolution of the qubit density matrix $\rho(t)$ in the instantaneous eigenbasis [18,19]. Ignoring pure dephasing, due to the intentionally large thermalization rate, we find the components of $\rho(t)$ as

$$\dot{\rho}_{ee} = -\frac{\Delta}{q^2 + \Delta^2} \hat{q} \text{Re}[\rho_{ee} e^{i\phi(t)}] - \Gamma_{ee} \rho_{ee} + \Gamma_{\downarrow},$$

$$\dot{\rho}_{ge} = \frac{\Delta}{q^2 + \Delta^2} \hat{q} \left(\rho_{ge} - \frac{1}{2} e^{-i\phi(t)} - \frac{1}{2} \Gamma_{ee} \rho_{ge},\right.$$

(4)

where $\hat{q}$ is the ramp rate, $\phi(t) = \int_0^t E(t') dt'/h$, $\Gamma_{ee} = \Gamma_{\downarrow \downarrow} + \Gamma_{\downarrow \uparrow}$, and $\Gamma_{\downarrow \downarrow} = \Gamma_{\downarrow \downarrow} + \Gamma_{\downarrow \uparrow}$.

The expression of power to the resistor $j$ from the qubit is given by

$$P_j = E(t)\rho_{ee} \Gamma_{\downarrow \downarrow} + \rho_{ee} \Gamma_{\downarrow \uparrow},$$

$$= E(t)\rho_{ee} \Gamma_{\downarrow \downarrow} + \rho_{ee} \Gamma_{\downarrow \uparrow},$$

(5)

where $\rho_{ee}(t) = 1 - \rho_{ee}(t)$. The details of deriving Eq. (5) are presented in the Appendix. The difference between the heating power $P_1$ to reservoir $R_H$, and the cooling power $-P_2$ of reservoir $R_C$, i.e., $P_1 + P_2$ equals ideally (that is with no other losses) the power that is taken from the source of the magnetic flux acting on the qubit.

III. DIFFERENT OPERATION REGIMES

We identify the main operation regimes of the Otto refrigerator in three different frequency $f$ ranges: nearly adiabatic regime at low frequencies, ideal Otto cycle in the intermediate frequency regime, and nonadiabatic coherent regime at high frequencies. In Fig. 2 we illustrate these
regimes by presenting the powers to the two reservoirs in dimensionless form, \( \Pi_j \equiv P_j/(E_0^2/h) \), \( j = 1, 2 \), as a function of \( \Omega = 2\pi hf/E_0 \), the dimensionless frequency of the drive, for chosen parameters. We assume periodic driving \( q(u) \) in (dimensionless) time \( u = 2\pi ft \). The powers are averaged over a cycle in steady state under periodic driving. Below we detail the properties of the refrigerator in these three regimes.

### A. Nearly adiabatic regime

Figure 2(a) shows the cooling and heating powers of the refrigerator at low frequencies \( \Omega \). We present below results for both cooling power and efficiency in the nearly adiabatic frequency range. In order to obtain \( \rho(t) \), we can here write it as an expansion in \( \Omega \) as

\[
\rho = \rho^{(0)} + \sum_{k=1}^{\infty} \delta \rho^{(k)},
\]

where \( \rho^{(0)} \) is the density matrix at a given constant \( q \), and \( \delta \rho^{(k)} \) is the \( k \)-th order correction to it. The expression for power averaged over a cycle is given by

\[
P_j = f \int_0^{T/\Omega} dt E(t)(\Gamma_{ij} - \Gamma_{ji}\rho_{gg}),
\]

and for \( k \geq 1 \), the correction to powers can be written as

\[
P_j^{(k)} = -f \int_0^{T/\Omega} dt E(t) \delta \rho^{(k)} \Gamma_{ij}.
\]

To find \( \rho^{(0)} \) in Eq. (6), we set \( \rho_{gg}, \dot{\rho}_{ge} \), and \( \dot{q} \) in Eq. (4) equal to zero and obtain

\[
\rho_{gg}^{(0)} = \Gamma_{ij}/\Gamma_{ji} \quad \text{and} \quad \rho_{ge}^{(0)} = 0.
\]

For equal temperature \( \beta_j = \beta \), we use the two reservoirs \( j = 1, 2 \), \( \Gamma_{ij}/\Gamma_{ji} = \Gamma_{ij}/\Gamma_{ji} = (1 + e^{-\beta \Delta})^{-1} \), and the power vanishes in the zeroth order, \( P_j^{(0)} = f \int_0^{T/\Omega} dt E(t) (\Gamma_{ij} - \Gamma_{ji}\rho_{gg}^{(0)}) = 0 \), as one would expect for fully adiabatic driving. In general, for arbitrary temperatures, we find the zeroth-order heat flux between the two resistors, \( P^{(0)} = P_j^{(0)} = -P_i^{(0)} \), as an average over a "static" cycle as

\[
\delta \Lambda_{j,Q}, \text{where}
\]

\[
\Lambda_{j,CL} = \frac{1}{\pi} \int_0^{2\pi} du \frac{\Delta^2}{u^2 + \Delta^2} \times \left[ \left( \frac{d\rho_{gg}}{du} - \frac{d\rho_{ge}}{du} \right) \frac{d\rho_{ge}}{du} \right] \xi_{1,j} \xi_{2,j} \varepsilon_{1,j} \varepsilon_{2,j} \left( \frac{\xi_1}{\xi_2} \right)^2 \left( \frac{\xi_2}{\xi_1} \right)^2 \left( \frac{\xi_1}{\xi_2} \right)^2 \left( \frac{\xi_2}{\xi_1} \right)^2
\]

and

\[
\delta \Lambda_{j,Q} = \frac{1}{\pi} \int_0^{2\pi} du \frac{\Delta^2}{u^2 + \Delta^2} \left( \frac{dq}{du} \right)^2 \times \left( \frac{\xi_1}{\xi_2} \right)^2 \left( \frac{\xi_2}{\xi_1} \right)^2
\]

We observe that based on Eq. (14), the energy transferred in a cycle reads \( P_j/f = 2\pi \Lambda_j/h \). Yet the dimensionless prefactor \( 2\pi \Lambda_j \) is system dependent, in particular, it depends inversely on the coupling \( g \). This dependence is vivid in Fig. 2(b) if one zooms the very low \( \Omega \) regime for different values of \( g \).

In the quadratic regime, the total powers on the two resistors \( j \) can be written for arbitrary temperatures as

\[
\Pi_j = (-1)^j \Pi^{(0)} + \Lambda_j \Omega^2.
\]

The results of the fully numerical calculation are shown together with the semianalytic quadratic result \( \Lambda_j \Omega^2 \) in Fig. 2(a) for the equal temperature case. The two results are nearly indistinguishable.

It is interesting to note that the coherent effects via \( \delta \Lambda_{j,Q} \) increase the dissipation unconditionally. This is because the integrand of the quantum correction in Eq. (16) is strictly non-negative; in particular, all the rates \( \xi_i \) are positive and, moreover, \( \xi_1 > \xi_1 \)
B. Intermediate frequencies (Otto cycle)

In the intermediate regime, as shown in Fig. 2(b), the cooling power $-P_2$ is approximately linear in frequency with a slope given below in Eq. (18). This behavior corresponds to the ideal Otto cycle. To find the powers $P_1, P_2$, we assume that the qubit thermalizes at both $q = 0$ and $q = \frac{1}{2}$, and that the population of the qubit does not change between the two extremes of the cycle. At $q = \frac{1}{2}$, the qubit population is $\rho_{gg} = 1/(1 + e^{-\beta_1 h_0 \omega})$. When brought to $q = 0$, $\rho_{gg}$ ideally attains the value $\rho_{gg} = 1/(1 + e^{-\beta_2 h_0 \omega})$ when interacting with $R_C$. In this process energy is transferred from resistor $R_C$ to the qubit, ideally with power $-P_2$, and from the qubit to resistor $R_H$ with power $P_1$ given by [12]

\[
P_1 = + \frac{\hbar \omega_1}{2} \left[ \tanh \left( \frac{\beta_1 h_0 \omega}{2} \right) - \tanh \left( \frac{\beta_2 h_0 \omega}{2} \right) \right] f,
\]

\[
P_2 = - \frac{\hbar \omega_2}{2} \left[ \tanh \left( \frac{\beta_1 h_0 \omega}{2} \right) - \tanh \left( \frac{\beta_2 h_0 \omega}{2} \right) \right] f. \tag{18}
\]

These powers depend critically on the energy separation at $q = 0$. We maximize the cooling power $-P_2$ of Eq. (18) with respect to $\omega_2$ keeping other parameters constant, obtaining

\[
\tanh(\beta_2 E_0 \Delta) + \frac{\beta_2 E_0 \Delta}{\cosh^2(\beta_2 E_0 \Delta)} - \tanh \left( \beta_1 E_0 \sqrt{\frac{1}{4} + \Delta^2} \right) = 0. \tag{19}
\]

We assume that the gap at $q = \frac{1}{2}$ is large enough such that we can set $\tanh(\beta_2 E_0 \sqrt{\frac{1}{4} + \Delta^2}) \simeq 1$. This yields the equation $2x - e^{-2x} - 1 = 0$ for $x = \beta_2 E_0 \Delta$, with $x \approx 0.6392$ as the solution. Numerically obtained powers to the two resistors as a function of $\Delta$ and $g \equiv g_1 = g_2$ (inset) are shown in Fig. 3 for typical parameters. These figures are plotted for different quality factors of the RLC circuits. The vertical arrow indicates the optimal point $x = 0.6392$...obtained above. It is vivid that the maximum value of cooling power shifts towards higher values of $\Delta$ and $g$ when increasing $Q$, and for $Q = 100$, the powers are very close to those of the ideal Otto cycle [Eq. (18)] at this value of frequency ($\Omega = 0.01$).

C. Nonadiabatic coherent regime

At high frequencies coherent oscillations of the qubit are reflected in the powers as seen in the inset of Fig. 2(b). The oscillatory regime essentially spans frequencies from $E_2/(2\pi h)$ to $E_1/(2\pi h)$. In this frequency range, the population of the qubit in the adiabatic legs of the cycle does not remain constant due to driving-induced coherent oscillations. At still higher frequencies, both powers are positive (dissipative) and almost constant. Lower $Q$ means more dissipation in general, explaining the relative results of $\Pi_j$ in the figure for different quality factors. One needs to bear in mind, however, that our analysis based on instantaneous eigenstates is not rigorous at these high frequencies [20,21] that may also exceed the bath correlation time in practice.

IV. DIFFERENT DRIVING WAVE FORMS

In assessing the influence of the driving wave form on the cooling power and efficiency of the refrigerator, we apply sinusoidal $q(u) = \frac{1}{2}(1 + \cos u)$, trapezoidal (specifically with a symmetric form consisting of rising sections of 20% of the cycle time each, and plateaus of 30% duration each), and truncated trapezoidal $q(u) = \frac{1}{2}(1 + \tan(\alpha \cos u)/\tan \alpha)$, specifically with $\alpha = 2$. These rising times and the particular value of $\alpha$ yield nearly optimal performance under the conditions of our numerical simulations for the two latter wave forms. See the inset of Fig. 4(a) for the illustration of the three protocols.

The obtained dimensionless powers $\Pi_1$ and $\Pi_2$ as a function of frequency are displayed in Fig. 4. The data in Figs. 4(a) and 4(b) are for equal and unequal temperatures of the two reservoirs, $\beta_1 = \beta_2$ and $2\beta_1 = \beta_2$, respectively. At equal temperatures we can obtain higher cooling power with trapezoidal and truncated trapezoidal drives than with sinusoidal drive, while in the case of unequal temperatures, the highest values of cooling power are obtained with truncated trapezoidal drive. The inferior performance of the sinusoidal drive stems from the short available thermalization times at $q = 0, \frac{1}{2}$, whereas the large dissipation $\Pi_1$ with the trapezoidal drive is likely to originate from the abrupt changes of the slope of this wave form [19].

V. EFFICIENCY OF THE OTTO REFRIGERATOR

The efficiency of a refrigerator is defined by the coefficient of performance $\epsilon$ as

\[
\epsilon = -\frac{Q_2}{W}, \tag{20}
\]

where $Q_2 = \int dt \dot{Q}_2(t)$ is the heat deposited to the cold bath in a steady state cycle (the integral is extended over such a cycle), and $W$ is the work done to achieve this. If we ignore the parasitic losses in producing the flux drive of the qubit (which can be made arbitrarily small in principle), we have $W = \int dt [\dot{Q}_1(t) + \dot{Q}_2(t)]$. We have then
There are two reference values to be considered. One is the Carnot efficiency of a refrigerator, given by $\epsilon_c = 1/(\Gamma H/TC – 1)$, which cannot be exceeded. Another one is the ideal $\epsilon$ of the Otto refrigerator, which turns out to be

$$\epsilon_{\text{ideal}} = \frac{1}{\omega_1/\omega_2 - 1},$$

(21)

according to Eqs. (18). Based on our result of Eq. (14), we introduce $\epsilon_p$ for a quadratic low frequency regime given by

$$\epsilon_p = \frac{1}{\Lambda_1/|\Lambda_2| - 1}$$

(22)

for the equal temperature case. Numerical results on $\epsilon$ as a function of $\Omega$ for different wave forms are presented by solid lines in Fig. 5. It is evident in Fig. 5(a) that at equal temperatures $\beta \equiv \beta_1 = \beta_2$, the truncated trapezoidal drive has the highest efficiency among the three driving protocols at low frequencies, but all of them are, somewhat surprisingly, higher than $\epsilon_{\text{ideal}}$ shown by the dashed-dotted horizontal line. Naturally, the Carnot efficiency exceeds all other efficiencies in the figure: in Fig. 5(a) $\epsilon_c = \infty$, and in Fig. 5(b) $\epsilon_c = 1$. Thus we see that our system reaches high efficiency at low frequencies, which is consistent with the general expectations of thermodynamics towards the adiabatic limit. The dashed lines illustrate the semianalytical result of $\epsilon_p$ for different drives. These results are fully consistent with numerical ones at low frequency. For unequal bath temperatures, $\beta_2 = 2\beta_1$, in Fig. 5(b), we have a similar hierarchy among the three wave forms, but with these parameters the (abrupt) trapezoidal drive does not even reach the efficiency of the ideal Otto cycle at any frequency. The rising part at low frequencies is due to the finite $P^{(0)}$ at unequal temperatures. For reference, the results ignoring quantum effects, solving the corresponding rate equation $\dot{\rho}_{gg} = \Gamma_1 - \Gamma_S\rho_{gg}$ with truncated trapezoidal drive, are shown in Figs. 5(a) and 5(b) by the red line. These results lie above any other curve, which is consistent with what we obtained for the quantum correction of $\Lambda_1$, in the quadratic low frequency regime. That is, the numerical result supports the observation that quantum corrections decrease the efficiency of the quantum Otto refrigerator, in agreement with the general linear response results in Ref. [11].

**VI. EXPERIMENTAL FEASIBILITY**

Finally, we make a few remarks about the experimental parameters. The energy scale of a typical superconducting qubit is of order $E_0/k_B \sim 1 \text{ K}$ [15]. With realistic mutual inductances $M_i$, values for coupling up to $g_i \sim 1$ can be achieved with proper design [12]. The quality factors in the range presented in this paper can also be achieved, since a typical $\sqrt{1/C}$ impedance is of order $10^2 \Omega$, and a metallic resistor can have values in the range of $\sim 1 \Omega$. With these values, the presented numerical graphs are feasible, and the power $E_0^2/h \sim 1 \text{ pW}$ and frequency $E_0/2\pi h \sim 1 \text{ GHz}$ scales should lead to experimentally observable heat fluxes (several fW) [22] at feasible operation frequencies (100 MHz) [15].

In conclusion, we have investigated theoretically quantum Otto refrigerator using a generic superconducting qubit. Explicit expressions for quadratic dependence of power on low frequencies were obtained. We show that the quantum dynamics inevitably decreases, as compared to the corresponding fully classical case, both the cooling power and the efficiency of the refrigerator, but it leads to interesting oscillatory behavior of power versus frequency. Different driving wave forms were studied, and we found that the coefficient of performance $\epsilon$ can exceed that of the ideal Otto refrigerator at low frequencies.

APPENDIX

We present here the derivation of the expressions for the transition rates and power to each resistor due to its coupling to the qubit [Eq. (5)] and calculation of the (vanishing) first-order contributions $\Pi_j^{(1)}$ [Eq. (8) for $k = 1$].

1. Transition rates and powers

The gold rule transition rates between the instantaneous eigenstates due to the baths [resistors $j$ in Fig. 1(a)] are given by

$$\Gamma_{j,1,j} = \frac{1}{\hbar^2} \left| \langle g | \frac{\partial H}{\partial \Phi} | e \rangle \right|^2 M_j^2 S_{V,j}(\pm E/\hbar),$$

(A1)

where the $\pm$ signs correspond to relaxation and excitation, respectively, and $S_{V,j}(\pm \omega)$ is the unsymmetrized noise spectrum of the qubit which is

$$S_{V,j}(\omega) = \int e^{i \omega t (\delta I_j(t) - \delta I_j(0))} dt$$

$$= |R_j + i[\omega L_j - 1/(\omega C_j)]|^2 S_{V,j}(\omega)$$

$$= |\text{Re}[Y_j(\omega)]|^2 S_{V,j}(\omega).$$

(A2)

Here, $S_{V,j}(\omega) = 2R_j/\hbar\omega(1 - e^{-\hbar/\omega})$ is the voltage noise of the resistor alone, and $\text{Re}[Y_j(\omega)] = \{R_j[1 + Q_j^2(\omega/\omega_{LC,j} - \omega_{LC,j})]\}^{-1}$ is the real part of admittance of circuit $j$, $\omega_{LC,j} = 1/\sqrt{L_j/C_j}$, and $Q_j = \sqrt{L_j/C_j}/R_j$. By using Eq. (2) for the Hamiltonian of the qubit, we have

$$\frac{\partial H}{\partial \Phi} = -\frac{\partial \rho_{ee}}{\partial \Phi},$$

and in order to calculate $\langle g | \frac{\partial H}{\partial \Phi} | e \rangle$, we consider the eigenvectors of the Hamiltonian, $|g\rangle = |\cos(\theta/2)\rangle$ and $|e\rangle = |\sin(\theta/2)\rangle$. Here, the angle $\theta$ is given by $\tan \theta = \Delta / q$. Then for Eq. (A1) we have

$$\Gamma_{j,1,j} = \frac{E_0^2 \Delta^2}{h^2 \Phi_0^2} \frac{\Delta^2}{q^2 + \Delta^2} S_{V,j}(\pm E/\hbar).$$

(A3)

Equation (A3) yields the transition rates for a generic superconducting qubit with the Hamiltonian (2). For instance, in the flux qubit, the factor $E_0/\Phi_0$ equals $I_F$, the persistent circulating current in the qubit loop [12]. In order to evaluate powers $P_j$, we first calculate the operator for the heat current from the resistors to the qubit as

$$\hat{H}_Q = -\frac{i}{\hbar} [H_Q, H_{C_j} + H_{\text{El}}].$$

(A4)

By inserting $H_{C_j} = \frac{\Phi_0}{\Phi_0} M_2 \delta I_2(t)\sigma_z$, and $H_{\text{El}} = \frac{E_0}{\Phi_0} M_2 \delta I_2(t)\sigma_z$ in Eq. (A4) and with $\sigma_i, \sigma_j = \{\sigma_i, \sigma_j\} = 2i \epsilon_{ij} \sigma_k$, we have

$$\hat{H}_Q = \frac{2 E_0^2}{h \Phi_0} [M_1 \delta I_1(t) + M_2 \delta I_2(t)]\sigma_y.$$  

(A5)

Now, in the interaction picture, with operators $O_j(t) = e^{i H_{\text{El}} t /\hbar} O_j e^{-i H_{\text{El}} t /\hbar}$, we have the expectation value of the operator $-\hat{H}_Q$, i.e., the heat deposited to the two resistors by the qubit in linear response (Kubo formula) as

$$P = -\langle \hat{H}_Q(t) \rangle = \frac{i}{\hbar} \int_{-\infty}^{\infty} dt' \langle [H_Q(t'), H_Q(t)] \rangle,$$

(A6)

where $H_q = H_{\text{El},1} + H_{\text{El},2}$. Substituting the expressions $\langle g | \sigma_z | e \rangle = \Delta / \sqrt{q^2 + \Delta^2}$, $\langle g | \sigma_y | e \rangle = i$, $\langle g | \sigma_y | g \rangle = \langle e | \sigma_z | e \rangle = i$, $\langle e | e^{i H_{\text{El}} t /\hbar} \sigma_y e^{-i H_{\text{El}} t /\hbar} | g \rangle = \langle g | e^{i H_{\text{El}} t /\hbar} \sigma_y e^{-i H_{\text{El}} t /\hbar} | e \rangle = i e^{-i\omega t - \Delta \sqrt{q^2 + \Delta^2}}$, and $\langle g | e^{i H_{\text{El}} t /\hbar} \sigma_z e^{-i H_{\text{El}} t /\hbar} | h \rangle = \langle g | e^{i H_{\text{El}} t /\hbar} \sigma_z e^{-i H_{\text{El}} t /\hbar} | h \rangle = -i e^{i \omega t + \Delta \sqrt{q^2 + \Delta^2}}$ in Eq. (A6), we have $P = P_1 + P_2$, where

$$P_j = E(t) \rho_{ee} \Gamma_{j,1} - \rho_{gg} \Gamma_{j,1}.$$  

(A7)

2. First-order contribution to powers

The first order in $\Omega$ contribution to the powers can be written as

$$P_j^{(1)} = -\int_0^1 dt E(t) \delta \rho_{gg}^{(1)} \Gamma_{j,1} = \frac{E_0^2}{\pi} \int_0^{\pi \hbar \Omega / \hbar} du \sqrt{q^2 + \Delta^2} \rho_{gg}^{(1)} \Gamma_{\Sigma,j},$$

(A8)

with the help of Eq. (11). Here, $u = 2\pi f t$. By inserting $\rho_{gg}^{(0)} = \frac{d\rho_{gg}^{(0)}}{du} du = \Delta \rho_{gg}^{(1)} du$, Eq. (A8) becomes

$$P_j^{(1)} = \frac{P_j^{(1)}}{E_0^2 / \hbar} = \frac{1}{\pi} \int_0^{\hbar \Omega / \hbar} du \sqrt{q^2 + \Delta^2} \frac{d\rho_{gg}^{(0)}}{du} \Gamma_{\Sigma,j}.$$  

(A9)

With a change of integration variable from $u$ to $q$ and using $du = \frac{1}{d\rho_{gg}^{(0)}} dq$, Eq. (A9) becomes

$$P_j^{(1)} = \frac{P_j^{(1)}}{E_0^2 / \hbar} = \frac{1}{\pi} \int_{q_0}^{q_1} dq \sqrt{q^2 + \Delta^2} \frac{d\rho_{gg}^{(0)}}{du} \frac{\Gamma_{\Sigma,j}}{\Delta \rho_{gg}^{(1)}}.$$  

(A10)

In cyclic operation, the initial and final values of $q$ are equal, $q_i = q_f$, and irrespective of the wave form, we have $P_j^{(1)} = 0$.
