Cavity QED characterization of many-body atomic states in double-well potentials –

The role of dissipation

When an incident light beam is scattered off a sample of ultracold atoms trapped in an optical lattice, the statistical properties of the retro-reflected field contain information about the quantum state of the atoms, and permit for example to distinguish between atoms in a superfluid and a Mott insulator state. This paper extends our previous analysis of this problem to include the effects of cavity damping. We use a Monte Carlo wave function method to determine the two-time correlation function and time-dependent physical spectrum of the retro-reflected field in the case of a simple two-well lattice. We also analyze quantitatively the entanglement between the atoms and the light field for atoms in a Mott insulator and a superfluid state.

I. INTRODUCTION

Ultracold atoms in optical lattices provide a remarkable test system to simulate a number of situations in condensed matter physics [1] under exquisitely controlled conditions. The first example along these lines was the superfluid to Mott insulator transition [2, 3] in bosonic systems, but the list of strongly correlated condensed matter systems that can be simulated by atoms or molecules [4, 5, 6, 7] in optical lattices has continued to grow since these pioneering experiments. Examples include, but are not limited to the Bose-Hubbard and Fermi-Hubbard models [8, 9], spin systems [10] and the Anderson lattice model [11]. In other examples, rotating lattices [12] are expected to lead to the realization of analogs of the quantum Hall effect, and random lattices have recently been used to study Anderson localization in atomic systems [13].

The ability to characterize the many-particle state of the atomic fields in optical lattices is of course central to the realization of these experiments. Some schemes are designed for probing those states nondemolitionly [14, 15]. In a recent paper [16], we proposed an optical technique that is analogous to the Bragg reflection of X-rays off a crystal, but operating in the quantum regime. The intensity reflected by the atoms via Bragg scattering is discussed in section III, and section IV presents the time-dependent physical spectrum of the reflected light. The quantum entanglement that may develop as a result of Bragg diffraction is quantified in section V in terms of the logarithmic negativity. Finally, section VI is a conclusion and outlook.

II. MODEL

We consider a sample of ultracold bosonic two-level atoms [3] with transition frequency \(\omega_0\) trapped in the lowest Bloch band of a one-dimensional double-well potential [20, 21, 22] placed inside an optical ring resonator. The atoms are driven by two counterpropagating cavity modes of wave vectors \(\pm k\) and frequency \(\omega_k = kc\), see Fig. I. This interaction is described by the dipole interaction Hamiltonian

\[
\hat{V}_d = \int dx \hat{\psi}_e^\dagger(x) \hat{d} \cdot \hat{\mathbf{E}}(x) \hat{\psi}_g(x) + h.c.
\]

where \(\hat{d}\) is the dipole moment of the transition, \(\hat{\mathbf{E}}(x)\) is the electric field operator, and \(\hat{\psi}_e\) and \(\hat{\psi}_g\) are field operators describing atoms in their excited and ground electronic states \(|e\rangle\) and \(|g\rangle\), respectively. We assume that the optical fields are sufficiently detuned from the atomic
transition frequency $\omega_{q}$ that the excited electronic state can be adiabatically eliminated.

We proceed by expanding $\psi_{e}$ and $\psi_{g}$ on the Wannier basis of the lowest Bloch band as

$$\psi_{e,g}(x) = \sum_{m} \psi_{m}^{(e,g)}(x) c_{m}^{(e,g)},$$

(2)

where $c_{m}^{(e)}$ and $c_{m}^{(g)}$ are the annihilation operators for excited and ground state atoms in the $m^{th}$ well, and $\psi_{m}^{(e)}$ and $\psi_{m}^{(g)}$ are the corresponding wave functions. Introducing also the operator

$$\hat{N}(d) = \hat{n}_{0} + \hat{n}_{1} e^{2 i kd},$$

(3)

where

$$\hat{n}_{m} = \hat{c}_{m}^{\dagger} \hat{c}_{m},$$

(4)

and $d$ is the well separation, the atom-field system is easily seen to be described by the Hamiltonian [16]

$$\hat{H} = \sum_{k} \hbar \omega_{k} \hat{a}_{k}^{\dagger} \hat{a}_{k} + \hbar g |\hat{N}(0)| (\hat{a}_{-k}^{\dagger} \hat{a}_{k} + \hat{a}_{k}^{\dagger} \hat{a}_{-k})$$

$$+ \hat{N}(d) \hat{a}_{-k}^{\dagger} \hat{a}_{k} + \hat{N}(-d) \hat{a}_{k}^{\dagger} \hat{a}_{-k}$$

(5)

where

$$g = \frac{2 e^{2}}{\Delta \hbar^{2}} \left| \int dx \mathcal{E}_{\pm k}(x) \psi_{0}^{(e)}(x) \psi_{0}^{(g)}(x) \right|^{2},$$

and $\mathcal{E}$ is the dipole matrix element of the atomic transition. We drop the label $(g)$ in the following for notational clarity since no confusion is possible once the excited electronic state has been eliminated.

Cavity damping is treated in the usual way by coupling the cavity modes to a Markovian reservoir of harmonic oscillators of frequencies $\{\omega_{q}\}$, with the interaction Hamiltonian

$$\hat{V}_{r} = \hbar (\hat{a}_{k} + \hat{a}_{-k}) \sum_{q} g_{q} \hat{b}_{q}^{\dagger} + h.c.$$  

(6)

Finally, the $+k$ cavity mode is driven by an oscillating classical current of amplitude $\eta$ and frequency $\omega = \omega_{k}$,

$$\hat{V}_{p} = \hbar \eta e^{-i \omega_{k} t} \hat{a}_{k}^{\dagger} + h.c.$$  

(7)

The numerical studies that are the subject of this paper are conveniently carried out using a Monte Carlo wave function approach [17]. In this case, the coupling of the system to the reservoir is described in terms of the effective non-hermitian Hamiltonian

$$\hat{H}_{eff} = \hat{H}_{S} - \frac{i \hbar}{2} \sum_{j=1,2} \hat{C}_{j}^{\dagger} \hat{C}_{j},$$

(8)

where

$$\hat{C}_{1} = \sqrt{2 \gamma} \hat{a}_{k}, \quad \hat{C}_{2} = \sqrt{2 \gamma} \hat{a}_{-k}.$$

(9)

Figure 1: Atoms trapped in an optical lattice with lattice constant $d$ and interacting with two counter-propagating modes with wave vectors $\pm k$ in a ring resonator. F: filter. D: Detector.

and $\gamma$ is the familiar Wigner-Weisskopf decay rate resulting from the coupling of the cavity modes to the Markovian reservoir. For the specific situation at hand this gives, in an interaction picture with respect to the Hamiltonian $\hat{H}_{0} = \sum_{k} \hbar [\omega_{k} + g \hat{N}(0)] \hat{a}_{k}^{\dagger} \hat{a}_{k}$,

$$\hat{H}_{eff} = \hbar \left[ g \hat{N}(0) \hat{a}_{-k}^{\dagger} \hat{a}_{k} + \eta \hat{a}_{k}^{\dagger} e^{i \omega_{k} t} + h.c. \right]$$

$$- i \hbar \gamma \left[ \hat{a}_{k}^{\dagger} \hat{a}_{k} + \hat{a}_{-k}^{\dagger} \hat{a}_{-k} \right].$$

(10)

III. REFLECTED INTENSITY

The light intensity transmitted and reflected by the trapped atoms depends strongly on the state of the atoms as well as on the well separation $d$. Throughout this paper we assume that the incident $+k$ mode is initially in a coherent state (with amplitude $\alpha = \sqrt{2}$ in our simulations) and the reflected $-k$ mode is in the vacuum state, and we concentrate on the special cases of well separations $d = \lambda/4$ and $\lambda/2$, for which the Hamiltonian $\hat{H}_{eff}$ becomes

$$\hat{H}_{eff} = \hbar g (\hat{n}_{0} \pm \hat{n}_{1}) \left( \hat{a}_{-k}^{\dagger} \hat{a}_{k} + \hat{a}_{k}^{\dagger} \hat{a}_{-k} \right)$$

$$+ \hbar \eta \left( \hat{a}_{k}^{\dagger} e^{i \omega_{k} t} + h.c. \right)$$

$$- i \hbar \gamma \left( \hat{a}_{k}^{\dagger} \hat{a}_{k} + \hat{a}_{-k}^{\dagger} \hat{a}_{-k} \right).$$

(11)

Here the ‘plus’ sign corresponds to the $d = \lambda/2$ case and the ‘minus’ sign to the $d = \lambda/4$ case.

A. Mott insulator

When in a Mott insulator state the atomic field has a well-defined number of atoms in each well, and thus can be described by a product of Fock states. Atomic Fock states are eigenstates of the effective Hamiltonian [11], that is, the operators $\hat{n}_{0}$ and $\hat{n}_{1}$ are constants of motion with eigenvalues $n_{0}$ and $n_{1}$, and it is possible to replace the operators by these eigenvalues in Eq. (11).

It is known [22] that if a system of coupled harmonic oscillators satisfies Heisenberg equations of motion that can be expressed as

$$\dot{a}_{j} = F_{j}(\{\hat{a}_{k}(t)\}, t), \quad j = 1 \ldots n,$$

(12)
where the functions $F_j$ may depend explicitly on time, then if the oscillators are initially in a coherent state they will remain in a coherent state for all times. This is the case for the situation at hand. Hence the two modes of the light field are in coherent states whose amplitudes exhibit damped oscillations due to the combined effects of photon exchange between the incident and reflecting modes and of cavity decay. As is to be expected, the oscillation frequency is proportional to the total number of atoms for the $d = \lambda/2$ case and to the difference in the populations of the two wells for $d = \lambda/4$. The difference between the oscillation frequencies in these two cases permits therefore a full determination of the well populations.

Figure 2 illustrates the time dependence of the reflected intensity for equal well populations and for the two special well separations. Different atomic populations in the two wells also result in an oscillating signal for the “destructive well separation” $d = \lambda/4$, but they are is much weaker and slower than that in the “constructive case” $d = \lambda/2$.

We mentioned that the light field remains in a coherent state at all times. These are eigenstates of the annihilation operator, hence quantum jumps do not affect them, and all Monte Carlo Wave function trajectories are identical in this case.

### B. Superfluid

There are two particularly simple ways to approximate the state of the atoms in a superfluid state. The first one is essentially a mean-field approach that assumes that the atoms in the two wells are in coherent states,

$$|\psi_{SF1}\rangle = |\alpha_0, \alpha_1\rangle = \sum_{n_0, n_1} c_{n_0, n_1} |n_0, n_1\rangle,$$

(13)

whereas the second description accounts for the fixed total number $N$ of atoms and describes their state as

$$|\psi_{SF2}\rangle = N^{-1}(c_1^+ c_2^+) N |0, 0\rangle = \sum_{n_0} \sqrt{\frac{N!}{n_0!(N - n_0)!}} b_{n_0} |n_0, N - n_0\rangle,$$

(14)

This section compares the reflected optical field corresponding to these two descriptions, assuming as before that the incident light field is initially in a coherent state and the reflected field is in a vacuum state.

Consider first the coherent state description of Eq. (13). From the discussion of the Mott insulator case, we know that for fixed atom numbers in the two wells the state of the field remains a coherent state,

$$|\alpha, 0; n_0, n_1\rangle \rightarrow |\alpha_k(n_0, n_1, d, t), \alpha_{-k}(n_0, n_1, d, t); n_0, n_1\rangle,$$

so that without quantum jumps between times 0 and $t$

$$|\psi(t)\rangle = \sum_{n_0, n_1} c_{n_0, n_1} |\alpha_k(n_0, n_1, d, t), \alpha_{-k}(n_0, n_1, d, t); n_0, n_1\rangle.$$

(15)

It is apparent from this expression that the atoms and the light field become entangled, a point to which we return in section V. Also, since the optical field does not generally remain in a coherent state in this case, the quantum jumps resulting from the loss of photons due to dissipation become apparent in the single trajectories, see Fig. 3.

Comparing the present case to the situation for a Mott insulator state, we observe that there are no contributions to the backscattered intensity from situations with

Figure 2: Single trajectory (or average reflected intensities $\langle \hat{n}_{-k}(t) \rangle$) for atoms in an Mott insulator state with 3 atoms per well for (a) $d = \lambda/4$ and (b) $d = \lambda/2$, $\eta = 1.5g$ and $\gamma = 0.9g$.

Figure 3: Reflected intensity $\langle \hat{n}_{-k}(t) \rangle$ for atoms initially in the superfluid state $|\psi_{SF1}\rangle$ with 4 atoms on average per well and $d = \lambda/4$. (a) typical single trajectory. (b) average over 100 trajectories, for $\eta = 1.5g$ and $\gamma = 0.9g$. 
equal populations in the two wells, since the coupling between the incident and reflected fields is zero in these cases. Also, the oscillatory character of the back-reflected light is now largely washed out by the uncertainty of the atom numbers in the two wells.

The number-conserving description of the superfluid state leads to similar results, although the details of the dynamics are slightly different because of the fixed total number of atoms which results in less atom number uncertainty, see Fig. 4. In practice, it is therefore not expected that the backscattered intensity will allow to unambiguously distinguish between the two descriptions.

IV. PHYSICAL SPECTRUM

We now turn to the analysis of the physical spectrum of the reflected optical field, which also provides a signature of the state of the atomic field.

Because the process under study is not stationary, the usual spectrum obtained from the Wiener-Khinchine theorem is not appropriate, and we use instead the time-dependent physical spectrum of Ref. [18]. We recall that this spectrum is defined as

\[
S(t, \omega; \Gamma) = \int_{0}^{t} \int_{0}^{t} H^*(t-t_1, \omega, \Gamma) H(t-t_2, \omega, \Gamma) \times \langle \hat{a}_{k}\rangle dt_1 dt_2,
\]

where the response function of the filter, \( H(t, \omega, \Gamma) \) its response function of the filter, \( \omega \) its setting frequency, and \( \Gamma \) its bandwidth, see Fig. 4. Following Ref. [18], we assume that it is constant for the frequency range of interest, and choose the filter response function as

\[
H(t, \omega; \Gamma) = \Theta(t) e^{-\Gamma t}.
\]

where \( \Theta(t) \) is the unit step function.

Figure 5 shows the real part of the two-time correlation function

\[
G(t, t + \tau) = \langle \hat{a}_{-k}^\dagger(t) \hat{a}_{-k}(t + \tau) \rangle.
\]

for \( d = \lambda/4 \) and in the range \( 0 \leq t + \tau \leq 2\pi/g \), where the atoms are in a Mott insulator state, while Fig. 6 shows that same function for the initial superfluid state \( \langle \psi_{\text{SF1}} \rangle \), and Fig. 7 for the initial superfluid state \( \langle \psi_{\text{SF2}} \rangle \). As was the case for the reflected intensity, the periodic oscillations of the reflected intensity characteristic of the Mott insulator case are washed out in the superfluid regime. Since the number-conserving description \( \langle \psi_{\text{SF2}} \rangle \) of the superfluid state corresponds to a smaller atom number uncertainty, the corresponding correlation function is characterized by stronger oscillations, intermediate between its description in terms of coherent states and the Mott insulator case, see Fig. 7.

In terms of \( \tau = t_1 - t_2 \), the physical spectrum \( S(t, \omega; \Gamma) \)
may be reexpressed as

\[ S(t, \omega, \Gamma) = 2\Gamma^2 e^{-2\Gamma t} \int_0^t dt e^{(\Gamma - i\omega) t} \]
\[ \times \int_0^t dt' e^{2\Gamma t'} \text{Re}\left[ (\hat{a}_{-k}(t_2 + \tau)\hat{a}_{-k}(t_2)) \right] \]
\[ \equiv 2\Gamma^2 e^{-2\Gamma t} S_0(\omega, \Gamma). \quad (18) \]

with \( \tau \geq 0 \).

Figure 8 shows the real part of \( S_0(\omega) \) for atoms initially in a Mott insulator state, while Figs. 9 and 10 are for atoms initially in superfluid states. In Fig. 8 the temporal oscillations of the correlation function \( G(t + \tau, t) \) translates into a modulation of the lorentzian spectrum due to the filter function at the oscillation frequency \( \omega \equiv g|n_0 - n_1| \) between the incident and reflected light fields. The physical spectrum provides therefore a direct measure of the population difference between the two wells for \( d = \lambda/4 \), of their sum for \( d = \lambda/2 \) and hence of \( n_0 \) and \( n_1 \) separately, i.e.,

\[ \omega_{\pm} = g(n_0 \pm n_1) \]
\[ n_{0,1} = (\omega_{+} \pm \omega_{-})/2g \quad (19) \]

where we assumed \( n_0 > n_1 \) for concreteness. The second small dip at frequency \( g(n_0 + n_1) \) originates from the pump term, \( \hbar\eta(a_{\downarrow}^\dagger e^{i(\hat{n}_0 + \hat{n}_1)t} + h.c.) \), in the Hamiltonian \( H \).

Figures 9 and 10 show the physical spectrum for the coherent and number-conserving superfluid states \( |\psi_{SF1}\rangle \) and \( |\psi_{SF2}\rangle \), respectively. In the number-conserving description \( (14) \) the total atom number \( N \) is fixed, hence for \( d = \lambda/4 \) the population difference between the two wells \( |2n_0 - N| \) can only take all even or all odd numbers, depending on \( N \). This restriction disappears in the coherent state description of \( |\psi_{SF1}\rangle \), so that additional peaks appear although the mean number of atoms in each well are the same in Figs. 9 and 10.

We conclude this discussion by mentioning that for a well separation \( d = \lambda/2 \) case the superfluid spectrums \( |\psi_{SF1}\rangle \) and \( |\psi_{SF2}\rangle \) result in completely different spectra. For \( |\psi_{SF1}\rangle \) the spectrum is similar to that of the \( d = \lambda/4 \) case since \( n_0 \) and \( n_1 \) are independent and hence give all combinations of different total numbers \( (n_0 + n_1) \) to form the spectrum. By contrast, the number-conserving description \( |\psi_{SF2}\rangle \) results in a single sharp peak, just as in the Mott insulator case, see Fig. 8.

Next we use the number-conserving approximation \( |\psi_{SF2}\rangle \) to investigate the relation between the full width at half maximum (FWHM) of the physical spectrum and the atomic number uncertainties in the two wells. We evaluate that width with the help of an envelope function fitted as illustrated in Fig. 11. The atomic number...
The logarithmic negativity \[ \rho \] is the partial transpose of \( \rho \) and \( \| \cdot \|_1 \) denotes the trace norm.

where \( \tilde{\sigma} = \sqrt{\sum_{m=0}^{N} (m - \bar{m})^2 b_m^2} \), \( N \) is the total number of atoms, and \( b_m^2 \), the probability of having \( m \) atoms in one of the wells, is a binomial distribution. Figure 12 which plots the FWHM \( w \) of the physical spectrum as a function of \( \sigma \), shows as expected a linear dependence, further illustrating the use of that spectrum in helping characterize the many-body state of the atomic system.

\[ \text{V. ENTANGLEMENT} \]

In this section we make some brief remarks on the entanglement generated between the light fields and the atoms, and its dependence on the state on the atomic system. We characterize the entanglement in terms of the logarithmic negativity \[ E_N(\rho) = \log_2 \| \rho^{T_A} \|_1, \] where \( \rho^{T_A} \) is the partial transpose of \( \rho \) and \( \| \cdot \|_1 \) denotes the trace norm.

There is always some ambiguity in the way a quantum system is described in terms of subsystems. One simple way to describe the system at hand is as a four-partite system comprised of two optical modes and the atoms in the two wells. It is then possible to trace over any two parts of the full system, and to consider the remaining subsystems only. We find that independently of our choice of the subsystems being considered the resulting reduced density operator does not retain any trace of whatever entanglement may have characterized the full system. This leads us to describe instead the full system as a bipartite system, the two subsystems being the optical field and the atoms.

The situation is particularly simple if the atomic system is initially in a Mott insulator state. As discussed in Section III in the absence of quantum jumps between the times 0 and \( t \) we have that

\[ |\psi(t)\rangle = |\alpha_k(n_0, n_1, d, t), \alpha_{-k}(n_0, n_1, d, t); n_0, n_1 \rangle \] (22)

where the amplitudes of the coherent states \( \alpha_k \) and \( \alpha_{-k} \) depend on the atomic populations of the wells and on their separation. It is immediately apparent from Eq. (22) that the total optical field is not entangled with the atoms. As previously remarked, in the case of coherent states, which are eigenstates of the annihilation operator, quantum jumps do not affect the light field, hence \( |\psi(t)\rangle \) is always a product state for this four-partite system, that is, no entanglement builds up between the atoms and the field.

The situation is markedly different for atoms in a superfluid state. For example, in the atom number-conserving approximation \( |\psi_{SF2}\rangle \), and in the absence of quantum jumps between times 0 and \( t \), the state of the system at time \( t \) is

\[ |\psi(t)\rangle = \sum_{n_0} b_{n_0} |\alpha_k(n_0, d, t), \alpha_{-k}(n_0, d, t); n_0, N - n_0 \rangle, \] (23)

a state for which the light field and atoms are clearly entangled. Dissipation and the associated quantum jumps will also clearly impact the amount of entanglement in that case. To illustrate that point, we first evaluate the logarithmic negativity of the bipartite atoms-optical field system for a well separation of \( d = \lambda/4 \), while neglecting pump and decay mechanisms. In that case, from Eqs. 43 and 45 the system is described by the Hamiltonian

\[ \hat{H} = \hbar g [(\hat{n}_0 + \hat{n}_1)(\hat{a}_k^\dagger \hat{a}_k + \hat{a}_{-k}^\dagger \hat{a}_{-k}) + (\hat{n}_0 - \hat{n}_1)(\hat{a}_{-k}^\dagger \hat{a}_k + \hat{a}_k^\dagger \hat{a}_{-k})], \] (24)

and we find easily that

\[ |\psi(t)\rangle = \sum_{n_0}^8 \beta_{n_0} |\alpha_k(n_0, t), \alpha_{-k}(n_0, t); n_0, N - n_0 \rangle \]

where

\[ \alpha_k(n_0, n_1, t) = \frac{\alpha}{2} (e^{-2i\gamma n_0 t} + e^{-2i\gamma n_1 t}), \]

\[ \alpha_{-k}(n_0, n_1, t) = \frac{\alpha}{2} (e^{-2i\gamma n_0 t} - e^{-2i\gamma n_1 t}). \] (25)
As a final point, we remark that similar results hold in case the superfluid atomic system is described by the state $|\psi_{SF1}\rangle$, although the maximum value of the logarithmic negativity is now larger, due to the larger number of terms in the expansion of that state in terms of number states.

VI. CONCLUSIONS

We have studied the interaction of a light field and ultracold atoms either in the Mott insulator state or in the superfluid state in a two-well optical lattice in a lossy cavity. We have calculated the reflected intensity, the physical spectrum and the logarithmic negativity, and shown that all three observables present completely different features for the two different many-body atomic states, allowing one can distinguish these states.

Future work will generalize this analysis to more complex many-body atomic states, using in particular Laguerre-Gaussian modes of the light field to characterize the state of vortex lattices. We are also extending this work to optomechanical situations, using radiation pressure force on Fabry-Pérot resonators with moving mirrors to induce quantum phase transitions and monitor them optically in real time.
