Transgenic mice were used to study the expression of pairs of genes with distinctly different tissue specificities, covalently linked and integrated into the same chromosomal site. A transgenic strain carrying, in close proximity and in the same orientation, the rat fast skeletal muscle myosin light-chain 2 (MLC2) gene and the mouse rearranged immunoglobulin K light-chain gene expressed the immunoglobulin gene specifically in the lymphoid tissues, whereas rat MLC2 transcripts were found in skeletal muscle but not in the spleen or the other tissues that were tested. In another transgenic strain, carrying the rat MLC2 gene and a modified rat skeletal muscle actin gene (actin–globin chimeric gene), transcripts of the rat MLC2 gene were detected in skeletal muscle only, whereas the actin–globin transcripts were detected in skeletal muscle as well as in the heart. Moreover, the expression of the chimeric gene was also developmentally regulated. Expression was higher in cardiac muscle than in the skeletal muscle of neonatal mice, whereas expression was higher in skeletal muscle in adult mice. This pattern is consistent with the regulation of the expression of the endogenous skeletal muscle actin gene. Thus, in those transgenic strains that expressed both genes, each gene retained its tissue specificity, in spite of their close proximity. These results indicate a high degree of autonomy of the control elements included in the cloned genomic DNA fragment and demonstrate that a single chromosomal site can be permissive for the proper expression of two genes with different tissue specificities.

Received August 10, 1987; revised version accepted October 12, 1987.

DNA-mediated gene transfer experiments reveal a wide variation in the expression of exogenous genes among various clones of transfected cells (Renkawitz et al. 1982; Chao et al. 1983; Kondoh et al. 1983; Charnay et al. 1984; Melloul et al. 1984). Similar quantitative variations in the levels of gene expression are commonly observed in transgenic mice. More interestingly, qualitatively stably inherited differences in gene expression have been observed among transgenic mouse strains produced by microinjection of identical gene constructs (Babinet et al. 1985; Chada et al. 1985; Shani 1985, 1986; Townes et al. 1985a; Hammer et al. 1986; Shani and Yaffe 1986). These variations were attributed to the effects of the host DNA sequences at the site of integration on the expression of the exogenous genes. This notion is further supported by a number of cytogenetic and genetic studies showing chromosomal position effects on gene expression. A classic example of a position effect occurs in Drosophila, where the white mutant is produced by a chromosome rearrangement in which a gene for eye color is translocated from its normal euchromatic environment to the vicinity of a heterochromatic region (Spofford 1976). A similar phenomenon is also observed in mice when autosomal loci are inactivated due to translocation into the heterochromatonic X chromosome (Cattanach 1974). Another example of a chromosomal position effect is the formation of tissue-specific tumors associated with translocations of proto-oncogenes (reviewed in Klein and Klein 1985).

Gene transfer into the mouse germ line provides a useful tool for analyzing the interrelation between a gene and its immediate DNA environment on its expression in various tissues. As an approach to studying the possible cis-acting effects of the DNA environment on the expression of the inserted gene, we have microinjected pairs of well-characterized cloned genes of differing tissue specificities, which were previously covalently linked, thus bringing them into close proximity. Introduction of such constructs into the germ line enables the comparison of their expression in many tissues following a single integration event. In the present communication, we describe experiments in which the rat fast skeletal muscle myosin light-chain 2 (MLC2) gene was introduced into the mouse germ line on a plasmid DNA also containing either the rearranged mouse im-

1Present address: Institute of Animal Sciences, ARO, The Volcani Center Bet-Dagan 50-250, Israel.
munoglobulin κ light-chain gene or a chimeric actin–globin gene. We have shown previously that the exogenous rat MLC2 gene is specifically expressed in skeletal muscle, whereas the chimeric actin–globin gene is expressed in skeletal, as well as in cardiac, muscles of transgenic mice (Shani 1985, 1986; Shani and Yaffe 1986). Brinster et al. (1983) have shown that the κ immunoglobulin gene is specifically expressed in the spleen. Our results with the two pairs of genes showed that in those transgenic strains in which both genes were expressed, each gene retained its tissue specificity, indicating a high degree of autonomous behavior of the control sequences included in the cloned gene DNA fragment.

Results

Production of transgenic mice carrying the rat MLC2 gene linked to the mouse rearranged immunoglobulin κ light-chain gene

The structure of plasmid pMLC-K, carrying the two genes, is shown in Figure 1. A 7.0-kb EcoRI–BamHI DNA fragment containing the rearranged mouse κ light-chain gene from the myeloma cell line MOPC41 (Bergman et al. 1984) was inserted into the SalI site of plasmid pMLCH, containing the entire rat MLC2 gene in a 4.8-kb DNA fragment (Nudel et al. 1984), so that both genes were present in the same transcriptional orientation. The resultant 16-kb plasmid was linearized by a single NdeI cut within the pBR322 vector before injection. Approximately 100 molecules of DNA were microinjected into the pronucleus of fertilized eggs, as described (Shani 1985). A total of 80 microinjected eggs were transferred into the oviducts of four pseudopregnant CD-1 females. Of the 15 mice born, three contained the injected DNA.

Expression of the rat MLC2 and the immunoglobulin genes

RNA was prepared from skeletal muscle, spleen, and other organs of the progeny of the three transgenic mice and assayed for the amount of κ or MLC2 mRNA. The presence of immunoglobulin gene transcripts in these RNA preparations was determined by the S1 endonuclease assay using the 180-bp PvuI–BstNI DNA fragment labeled in the leader exon as a probe (Fig. 2). Spleen RNA from the three transgenic mice and thymus RNA from mice LCk3 and LCk4 protected the diagnostic 80-nucleotide DNA fragment. The level of expression of the microinjected κ gene in the spleen was about fourfold higher than that in the thymus. No κ transcripts could be found in thymus RNA of transgenic strain LCk5. Because thymus preparations are known to be easily contaminated with parathymic lymph nodes (Storb et al. 1984), it is possible that the low level of transcripts found in the thymus of two of these mice reflects a contamination with these lymph node cells. No κ transcripts were detected in skeletal muscle RNA from any of the mice. κ mRNA was not detected in spleens of normal mice and transgenic mice containing other exogenous genes, except for a scarcely detectable level of hybridization with RNA from the spleen of mouse CV2 (a transgenic strain carrying the chimeric actin–globin gene). A similar finding was reported by Storb et al. (1984), using another κ gene probe and normal mouse spleen RNA.

The presence of rat MLC2 transcripts in the RNA preparations was determined by the RNase protection assay, using a uniformly 32P-labeled complementary SP6 RNA probe derived from the 5′ region of the rat MLC2 gene (see Fig. 3). Hybridization of the probe with RNA prepared from rat skeletal muscle protected a 50-nucleotide fragment (Fig. 3). No rat transcripts could be detected in skeletal muscle or any of the other tissues of transgenic mice LCk3 and LCk5. In mouse LCk4, however, transcripts were detected in skeletal muscle but not in spleen or the other tissues tested (Fig. 3). Thus, in this transgenic mouse strain, the rat MLC2 gene was specifically expressed in skeletal muscle, despite the close physical association with the strong control elements of the immunoglobulin gene.

Linkage between the exogenous rat MLC2 and the immunoglobulin genes in the genome of the transgenic strain LCk4

As both the immunoglobulin and the MLC2 genes were expressed and retained their tissue specificity in the transgenic mouse strain LCk4, it was important to determine whether the exogenous genes were still linked and integrated in a single chromosomal site in this strain. Figure 4 shows a Southern blot analysis of the linkage between the two genes in genomic DNA of the three transgenic strains. High-molecular-weight tail DNA samples were digested with the restriction en-
Permissiveness of single chromosomal site for expression of two genes

Figure 2. S1 analysis of κ gene transcripts in various tissues of transgenic mice carrying plasmid, pMLC-k. Total RNAs (10 μg) from the indicated tissues of transgenic mice were hybridized with a 5′-end-labeled 180-bp PvuII-BstNI fragment derived from the 5′ region of the κ gene. Spleen RNAs from transgenic mice carrying the chimeric actin-globin gene [CV1, CV2, CV3] were used as controls. The labeled fragment protected by the exogenous gene transcripts is indicated by an arrow. The minor band found under the 80-nucleotide protected fragment probably resulted from overdigestion by the S1 nuclease. [Bottom] (Solid boxes) Immunoglobulin coding sequences; (open box) the 5′-untranslated region. The 5′ label is indicated by an asterisk. The numbers indicate the lengths of the probe and the protected fragments (nucleotides).

zymes BamHI, BgIII, or HindIII, fractionated by gel electrophoresis, and blot-hybridized with either the 1-kb DNA probe derived from the 5′ end of the rat MLC2 gene [probe I] or the 7.0-kb DNA fragment carrying the rearranged immunoglobulin gene [probe II].

HindIII cuts twice at the ends of the MLC2 gene and once within the κ gene. Hybridization with the MLC2 probe reveals the expected 4.8- and 8.0-kb bands of the exogenous and endogenous MLC2 genes, respectively, in the genome of strain LCK4. The faint band of 7.9 kb is a result of contamination of the probe with pBR sequences. The κ probe reveals the expected 7.9- and 3.5-kb bands of the exogenous κ-gene and the 2.7- and 4.5-kb bands of the endogenous genes. The number of copies of the integrated DNA was determined by comparing the intensities of the endogenous and exogenous κ-gene bands. Thus, strain LCK4 carries two to three copies per diploid genome.

BgIII cuts at two adjacent sites in the MLC2 gene and at two sites, 2.8 kb apart, in the κ gene. A 2.6-kb fragment, containing 5′ sequences of the MLC2 gene and 3′ sequences of the κ gene and pBR sequences, is expected and is indicative of the integrity of linkage between the two genes. The MLC2 probe reveals only this band in the genome of strain LCK4. The κ probe also reveals this band, just under the intense 2.8-kb band of the exogenous and the endogenous genes. In addition, it hybridizes with the 4.1- and the 7.2-kb bands of the endogenous κ-gene and the 10.7-kb fragment of the exogenous gene, which is expected from a head-to-tail orientation of the integrated copies. A 9.2-kb band, indicative of head-to-head integration, is found in strains LCK3 and LCK5, and a band of 11.8 kb, indicative of tail-to-tail integration, is found in strain LCK3.

BamHI cuts once within the vector DNA. A fragment of 16 kb (the original plasmid size) is expected if the mi-
Figure 3. RNase mapping of the rat MLC2 transcripts in various tissues of transgenic mice carrying pMLC-κ. Total RNAs from the indicated tissues of transgenic mice and from skeletal muscle of normal rat and mouse were hybridized with uniformly labeled complementary SP6 RNA probe derived from the 5' region of the rat MLC2 gene. The protected fragment of 50 nucleotides results from specific hybridization to the rat MLC2 mRNA, whereas the products of cross-hybridization with the endogenous gene yield discrete bands of smaller sizes (Shani 1985; Shani and Yaffe 1986). The apparent signal in transgenic strain LCk5 in the 50 bp is due to cross-hybridization with the endogenous gene transcripts and is also detectable in an appropriate exposure of the control. The labeled fragment protected by the exogenous gene transcripts is indicated by an arrow. (Bottom) The probe was synthesized from an EcoRI—Sau3A DNA fragment of the rat MLC2 gene cloned in the vector SP6. (Solid box) First coding exon of the rat MLC2 gene; (open box) 5' untranslated exon.

The results using three different restriction enzymes show that in strain LCk4, two to three copies of the plasmid had integrated in one chromosomal site, all of them in the same orientation. No visible rearrangements could be detected.

**Production of mice carrying the rat MLC2 and the chimeric actin-globin genes**

The structure of plasmid CV-LC, containing the rat MLC2 gene juxtaposed to a chimeric actin-globin gene (pCV-LC), is shown in Figure 5. The 4.8-kb HindIII DNA fragment, including the entire rat MLC2 gene (Nudel et al. 1984), was inserted into the HindIII site of plasmid pCV, containing the chimeric actin-globin gene. The chimeric actin-globin gene contains about two-thirds of the 5' region of the rat skeletal muscle actin gene plus 730 bp of its 5'-flanking sequences spliced to about one-third of the 3' end of the human embryonic e-globin gene (Melloul et al. 1984). Both genes are in the same tran-
Permissiveness of single chromosomal site for expression of two genes

Figure 4. The organization of the exogenous MLC2 and the κ genes in the genome of the Lck transgenic strains. Tail DNA (10 μg) from transgenic strains LCK3, LCK4, and LCK5 was digested with BamHI, HindIII, or BglII, and the fragments were blot-hybridized to 32P-labeled probe, as described (Shani et al. 1984). (probe I) A 1-kb DNA fragment derived from the 5' end of the rat MLC2 gene; (probe II) a 7-kb fragment carrying the rearranged immunoglobulin gene. The arrows mark junction fragments containing inserted and host DNA, indicating a single site of integration in each transgenic strain. (Bottom) Location of restriction sites within plasmid pMLC-k that were used in the analysis and the probes used. [bam] BamHI; [H] HindIII; [B] BglII.

Expression of the rat MLC2 and the chimeric actin–globin genes

RNA was prepared from skeletal and cardiac muscles and from several other tissues of offspring of the four transgenic strains. The presence of the rat MLC2 gene transcripts in the RNA preparations was determined by the RNase protection assay, as described above. In mice of the transgenic strains CVLC3 and CVLC4, no rat MLC2 transcripts could be detected in RNA prepared from striated muscles or from any of the other tissues tested. However, in offspring of mouse CVLC1, rat MLC2 transcripts were specifically found in skeletal muscle but not in cardiac muscle (even after long exposures of the autoradiograms) nor in the other tissues tested. The tissue-specific expression was stable for at least three generations (Fig. 6).
The presence of the chimeric actin–globin gene transcripts was determined by an S1 endonuclease assay, using the 187-bp DdeI DNA fragment derived from the human ε-globin region of the construct as a probe (Mel-loul et al. 1984; Shani 1986). As observed for the rat MLC2 gene, no transcripts could be detected in mice of the transgenic strains CVLC3 and CVLC4. However, specific transcripts were detected in skeletal, as well as in cardiac, muscles of mouse strain CVLC1 (Fig. 7). The level of the chimeric gene transcripts in skeletal muscle was about three times higher than that in cardiac muscle. This tissue specificity is consistent with the expression of the endogenous skeletal muscle actin gene (Minty et al. 1982; Mayer et al. 1984; Shani 1986).

In RNA prepared from the cardiac and skeletal muscles of the founder of a fourth transgenic strain, CVLC2, the actin–globin chimeric gene was expressed in the skeletal and cardiac muscles, whereas the MLC2 gene was expressed in the skeletal muscle only (data not shown). This mouse transmitted the exogenous genes to its offspring with normal Mendelian segregation. Southern blot analysis showed no difference in the pattern of the hybridizing fragments between the founder and its progeny over three generations (data not shown). However, no transcripts of the exogenous genes were detected in the heart and skeletal muscle, nor in other tissues, of the four transgenic offspring tested. The results for one of these mice are shown in Figures 6 and 7. A similar phenomenon was observed by Palmiter et al. (1982) in transgenic mice carrying a metallothionein–thymidine kinase chimeric gene.

We showed previously that similar to the endogenous skeletal muscle actin gene (Minty et al. 1982; Mayer et al. 1984), the chimeric actin–globin gene underwent a transition in the relative tissue specificity during the development of four transgenic strains (Shani 1986). In neonatal mice the expression of the chimeric gene was higher in cardiac muscle than in skeletal muscle, whereas in adult mice it was higher in skeletal muscle. Figure 8 (left) shows a similar developmental transition in the expression of the chimeric actin–globin gene in mouse strain CVLC1. However, it is of interest that in neonatal mice of this transgenic strain, no rat MLC2 transcripts could be detected in the skeletal muscle, whereas the endogenous gene is expressed in this tissue (Fig. 8, right).

**Figure 6.** RNase mapping of the rat MLC2 transcripts in tissues of offspring of transgenic strains carrying plasmid pCVLC. Total RNAs (10 μg) from the indicated tissues of offspring of transgenic mice strains CVLC1 and CVLC2, and from skeletal muscle of a control normal mouse and differentiated cultures of the rat myogenic cell line L8 (L8 post) were hybridized with the SP6 RNA probe, as described in the legend to Fig. 3. The first three lanes demonstrate the stable inheritance of expression of the exogenous gene in the skeletal muscle of the founder (SK.G0) in first-generation (SK.G1) and second-generation (SK.G2) mice of the transgenic strain CVLC1. [Bottom] See details in the legend to Fig. 3.

**Linkage between the exogenous rat MLC2 and the chimeric actin–globin genes in the transgenic strain CVLC1**

Figure 9 shows the Southern blot analysis of genomic DNA of mice of the CVLC1 and CVLC2 strains. The EcoRI- and BamHI-digested DNAs were hybridized to the plasmid DNA carrying the rat MLC2 gene, whereas the SspI-digested DNAs were hybridized to the CV-LC plasmid. BamHI cuts the construct twice, generating the expected 8.3- and 5.3-kb major bands. EcoRI cuts twice in the rat MLC2 and twice at the edges of the actin–globin gene, generating major bands of 5.3, 2.2, and 1.6 kb. The 4.4-kb band of the actin–globin gene was not labeled because the probe did not contain the relevant homologous sequences. SspI cuts the construct once, generating the 13.5-kb major fragment. In each of the three digests of CVLC1 DNA, there are only two minor bands [indicated by asterisks] that do not have counterparts in the DNA of the control mouse. These results indicate that in the strain CVLC1, the exogenous DNA integrated at a single chromosomal site, all copies are found in a head-to-tail tandem array, and no detectable rearrangements occurred. In contrast, CVLC2 DNA has a few more minor bands, some of them more intense than the minor bands seen in CVLC1 DNA. As all tested transgenic progeny of this strain had the same pattern of hybridizing bands as the founder (data not shown), it appears that all of the copies of the injected plasmid inte-
Figure 7. S1 analysis of actin–globin gene transcripts in tissues of transgenic strains CVLC1, CVLC2, CVLC3, and CVLC4 carrying plasmid pCV-LC. Total RNAs (10 μg) from the indicated tissues were hybridized with a 187-bp DdeI DNA fragment derived from the human e-globin region of the construct. (Bottom) (Solid box) Human e-globin-coding sequences; (open box) actin-coding sequences. The 3' label is indicated by an asterisk. The numbers indicate the length of the probe and the protected fragment (nucleotides).

Integrated into one chromosome. The more intense minor bands most probably indicate that rearrangements occurred in a number of copies. We estimate the number of integrated plasmid copies to be about 5 and 10 for strains CVLC1 and CVLC2, respectively. Strains CVLC3 and CVLC4 each contain about 20 copies, with no detectable rearrangements (data not shown).

Discussion

The present investigation shows that two genes of different tissue specificity are able to maintain their appropriate patterns of expression when linked in close proximity and integrated into the same chromosomal site. Thus, in a transgenic mouse strain carrying the rearranged immunoglobulin κ light chain and the rat MLC2 genes, the immunoglobulin gene was expressed specifically in the spleen, whereas the rat MLC2 gene was expressed in skeletal muscle only. Similarly, in the offspring of one transgenic strain and in the founder of another strain, both carrying the chimeric actin–globin and the rat MLC2 genes, the chimeric gene was expressed in skeletal as well as in cardiac muscles, whereas the rat MLC2 gene was expressed in skeletal muscle only. In addition, this pair of genes was also differentially controlled during development with a pattern similar to that of the endogenous skeletal muscle actin gene. Expression of the actin–globin gene was higher in cardiac muscle than in the skeletal muscle of neonatal mice, whereas in adult mice it was higher in the skeletal muscle. These results therefore demonstrate a very high degree of autonomy of the genes in their control of tissue and developmental specific expression. However, this does not exclude the possibility that the integration site may play a decisive role in other combinations of exogenous and endogenous DNA sequences.

The rat MLC2 and skeletal muscle actin genes contain enhancer elements in their 5’-flanking region (D. Meloul et al., unpubl.), whereas the immunoglobulin κ gene contains an enhancer in an intron between the variable-joining (V) and constant (C) regions (Queen and Baltimore 1983; Picard and Schaffner 1984). Both types of enhancers contribute to the tissue specificity of these genes, yet none of these enhancers exerted any detectable influence on the mode of expression of the neighboring genes. Recently, it was reported that the immunoglobulin κ enhancer can exert its influence evenly over a broad domain and that tandem κ promoters falling within this domain are activated independently, irrespective of whether they are located 1.7 or 7.7 kb away.

[Atchison and Perry 1986]. It is therefore of interest that although the distance of the immunoglobulin gene enhancer from its own promoter or from the rat MLC2 promoter was about the same [3.6 and 3.8 kb, respectively] in our construct, the enhancer had no detectable effect on the expression of the muscle-specific gene in three independent transgenic strains. It is possible that the κ gene enhancer is more efficient at stimulating transcription from its own promoter than from a heterologous promoter. Recent studies using the immunoglobulin heavy-chain enhancer showed that this enhancer is not efficient when located some distance from a heterologous promoter [Wasylyk and Wasylyk 1986]. In the case of transgenic strain LCK4, Southern blot analysis has shown clearly that the foreign genes are present in two or three copies per genome in a head-to-tail order, with no visible rearrangements of the inserted constructs. Thus, even if only the two distal genes are active in their respective tissues [with a distance of 20–36 kb between the two promoters], the fact remains that the promoters of both genes are adjacent to the enhancer sequences of an entirely different tissue specificity.

Activation of eukaryotic genes is associated with a reorganization of chromatin into a transcriptionally active conformation. The size of the chromosomal domain that is involved in the expression of genes has not yet been defined. DNase I-sensitivity mapping of several genes suggests that the active region extends from 12 to 100 kb [Lawson et al. 1982; Alevy et al. 1984; Forrester et al. 1986; Jantzen et al. 1986; Smith et al. 1986]. The domain of increased sensitivity includes the structural genes and large portions of their 5′- and 3′-flanking regions [Stadler et al. 1980; Weintraub et al. 1981]. Whether the differential expression of two genes with different specificities that are found at the same chromosomal site reflects the formation of an active chromatin conformation restricted to the expressed gene only, or whether activation of each gene leads to the formation of an extended DNase I-sensitive domain that includes both genes remains to be determined. Experiments addressing this question in the β-globin locus indicated that all globin genes are contained within a DNase I-sensitive domain in erythroid tissue, and each of these genes is probably differentially activated during development by stage-specific factors as yet unknown [Weintraub and Groudine 1976; Miller et al. 1978; Lachman and Mears 1983].

In two out of the three transgenic strains containing the immunoglobulin-MLC2 construct, the rat MLC2-gene transcripts could not be detected in any tissue while the immunoglobulin gene was expressed specifically in lymphoid tissues. Offspring of three out of the four mice injected with the MLC2–actin–globin genes did not express either gene. However, since a similar variability of expression was also obtained when plasmids containing a single gene were microinjected [Chada et al. 1985; Shani 1985; Townes et al. 1985a; Hammer et al. 1986; Krumlauf et al. 1986; Shani and Yaffe 1986], these results do not necessarily indicate an effect of the neighboring gene. Rather, they suggest that even in this regard [i.e., stably inherited differences in expression between the transgenic strains], each gene behaves independently of its neighboring gene. Considerable variation in the frequency and the level of expression among different transgenic Drosophila strains carrying identical P-element constructs has also been observed [Goldberg et al. 1983; Richards et al. 1983; Spradling and Rubin 1983; Hazelrigg et al. 1984].

After the present experiments were initiated, it became evident that the vector DNA sequences have an inhibitory effect on the expression of genes introduced into the germ line [Chada et al. 1985; Townes et al. 1985a; Krumlauf et al. 1986; Shani 1986]. It is possible that the inhibitory effect of the pBR322 sequences contributed to the variability in the expression of the MLC2 and the actin–globin genes in our experiments.

Townes et al. [1985b] produced transgenic mice carrying the human β-globin gene and the mouse metal-
Materials and methods

DNA constructions

**Plasmid pMLC-k** A 7-kb EcoRI–BamHI fragment, containing the rearranged mouse immunoglobulin κ light-chain gene from myeloma MOPC41 (a gift from P. Leder), was filled in with Klenow fragment of DNA polymerase following ligation into the filled-in and dephosphorylated SalI site of plasmid pMLCH, containing the rat MLC2 gene in a 4.8-kb insert (Nudel et al. 1984). The orientation of the immunoglobulin gene was determined by HindIII digestion.

**Plasmid pCV-LC**. The 4.8-kb HindIII–HindIII fragment containing the rat MLC2 gene was ligated into the HindIII site of plasmid pCV, containing the rat α-actin–human ε-globin chimeric gene (Melloul et al. 1984). The orientation of the rat MLC2 gene was determined by EcoRI digestion.

Production of transgenic mice

Plasmids pMLC-k and pCV-LC were linearized with NdeI and SalI, respectively. They were then diluted to concentration of 10 μg/ml in 10 mM PIPES (pH 7.0), 150 mM KCl, and 5 mM NaCl.

Fertilized eggs were obtained from superovulated females of BALB/c × C57BL/6J[F1] 1 day after mating with males of C57BL/6J × DBA/2[F1]. After microinjection, the surviving eggs were implanted into the oviducts of pseudopregnant CD1 females.

DNA isolation and analysis

Genomic DNA was isolated from mouse tail by incubating 2-cm tail samples overnight at 55°C in 50 mM Tris (pH 8.0), 100 mM EDTA, 0.1% SDS, and 200 μg/ml proteinase K, followed by phenol/chloroform extractions.

Genomic DNA samples were digested with the appropriate restriction enzymes, separated on 1% agarose gels, transferred to nitrocellulose filters, and hybridized to nick-translated DNA fragment, which includes the first exon and the 5’-flanking region of the rat MLC2 gene (Nudel et al. 1984; Shani 1985; Shani and Yaffe 1986). Samples were hybridized at 55°C, followed by digestion with RNase at 37°C for 1 hr. SI protection analysis with end-labeled DNA probes was performed as described [Berk and Sharp 1977]. Hybridization was at 48°C both for the immunoglobulin κ probe (Bergman et al. 1984) and the ε-globin probe (Shani 1986). Protected fragments were analyzed on polyacrylamide/urea sequencing gels.
