In this paper, we demonstrate a digital micromirror device (DMD) based optical microscopic apparatus for quantitative differential phase contrast (qDIC) imaging, coherent structured illumination microscopy (SIM), and dual-modality (scattering/fluorescent) imaging. For both the qDIC imaging and the coherent SIM, two sets of fringe patterns with orthogonal orientations and five phase-shifts for each orientation, are generated by a DMD and projected on a sample. A CCD camera records the generated images in a defocusing manner for qDIC and an in-focus manner for coherent SIM. Both quantitative phase images and super-resolved scattering/fluorescence images can be reconstructed from the recorded intensity images. Moreover, fluorescent imaging modality is integrated, providing specific biochemical structures of the sample once using fluorescent labeling.

Keywords: quantitative phase microscopy, structured illumination, phase gradient, resolution enhancement, multimodality imaging

INTRODUCTION

Quantitative phase microscopy (QPM) utilizing the phase information of the object wave can provide not only phase-contrast images but also quantitative information about the three-dimensional morphology and refractive index distribution of the samples [1–8]. Recently, a more compact module, nominated as quadriwave lateral shearing interferometry (QWLSI), was proved for quantitative phase imaging with one-shot. The QWLSI splits an object wave into four copies, two of which are sheared along the -x and -y directions respectively [9–11].

Most of the phase imaging techniques, or the coherent imaging techniques in more general cases, utilize monochromatic plane-wave illumination and consequently, the resolution of imaging systems is limited by wavelength (λ) and numerical aperture (NA) of the system [12]. A higher spatial resolution is favorable to resolve the finer details of the sample for everyone. However, when designing a microscopic objective, a higher spatial resolution often needs to be traded with a smaller field of view (FOV). People appeal an approach that can enhance spatial resolution and at the same time, maintain a large field of view. To meet this demand, synthetic aperture approaches in QPM have been reported, for instance, oblique illumination [13–15], structured illumination [16–19], and speckle illumination [20–22] (just to cite a few) have been proposed to improve the spatial resolution (or the space-bandwidth product) in QPM. Of note, structured illumination microscopy (SIM) [23–25], is a wide-field, minimally-invasive, super-resolution imaging technique, which utilizes moiré patterns created by illuminating the sample with periodic stripes. The structured illumination can downshift unresolvable high-frequency information into low-frequency falling in the supporting area of the system, as illustrated in Figure 1C, [26]. Furthermore, SIM was demonstrated having an
optical sectioning capability comparable with confocal microscopy [27]. Hence, SIM has found widespread applications in biomedical imaging [28, 29], and notably long-term observing dynamics in living cells [25, 30]. Recently, SIM was applied to phase imaging of transparent samples when being combined with digital holographic microscopy [31] or reference-less phase retrieval approaches [18, 32]. Till yet, QPM with structured illumination has been implemented using gratings or spatial light modulator (SLM), and the phase imaging modality is often isolated from other imaging modalities such as fluorescence imaging. Therefore, the value of QPM is limited due to the lack of multi-dimensional information for the same sample.

In this paper, we propose a DMD based optical microscope that integrate multiple imaging modalities. At first, structured illumination based QPM enables to providing quantitative phase image of a sample without fluorescent labeling. Second, coherent SIM provides absorption/scattering images of unlabeled samples with resolution-enhancement. Third, this system is integrated with a fluorescence imaging modality, providing additional (functional/biochemical) information on the same sample.

**METHODS**

The schematic diagram of the system is shown in Figure 1A, of which a diode laser with a wavelength of 561 nm (MLL-U-561, Changchun New Industries Optoelectronics Technology Co., Ltd., China) is used as the illumination source. After being reflected by the mirrors M1 and M2 sequentially, the laser beam is coupled into a fiber and sent to the setup. In the output end, the light from the fiber is collimated by the lens L1 and guided by the mirror M3 to a DMD (1920 × 1080 pixels, pixel size 7.56 μm, DLP F6500, UPO Labs, China) at an incidence angle of 24°. On DMD, two groups of fringe patterns with orthogonal orientations and five-phase shifts (∆m = 2 (m-1)π/5, m = 1, . . . , 5) for each orientation are loaded to the DMD in sequence (as shown in the inset of Figure 1A). The fringe patterns displayed on the DMD are further relayed by the telescope systems L2-L3 and L4-MO1, and eventually projected onto the sample placed on the common focal plane of MO1 and MO2. Preferably, the illumination beam is filtered before entering the sample plane: the illumination light is Fourier transformed by the objective MO1 and its spectrum appears in the focal plane of L2. A mask is placed in the Fourier plane and blocks the unwanted diffraction orders except the ±1st orders. As a consequence, the fringe patterns on the sample plane are of ideal cosine distribution.

Upon the fringe illumination, the sample is then imaged by the microscope with QPM-L5 to the image plane with a distance Δz apart from the CCD plane (CCD1, 4000 × 3000 pixels, pixel size 1.85 μm, DMK 33UX226, The Imaging Source Asia Co., Ltd., China). The camera CCD1 records diffraction images for different imaging modes, defocused images in qDIC and focused images in fluorescence) from different excitations. Therefore, the value of QPM is limited due to the lack of multi-dimensional information for the same sample.

**Quantitative Differential Phase-Contrast (qDIC) Microscopy With Structured Illumination**

The structured illumination for qDIC microscopy (Figure 1B) can be expressed as $A^q_{m, n} = 2\cos \left( \frac{2r}{\Lambda + \delta_m} \right)$ with $m = 1, 2, \ldots, 5$, and $\xi$ indicates the orientation indices of $x$ and $y$, respectively, $r$ is the spatial position vector, $\Lambda$ is the stripe’s period, and $\delta_m$ is the phase shift. Passing through the sample, the object wave under $A^q_{m, n}$ is diffracted and relayed by the microscope with QPM-L5 to the image plane. After diffraction of a distance of Δz, the...
diffraction patterns are recorded by the CCD camera. The waves along the ±1st orders of $A^\pm_m$ at the camera plane are $U^1_1$ and $U^1_{-1}$. These two waves interfere with each other at the camera plane and the intensity distribution of the interferogram captured by the camera can be written as:

$$I_m^i(r) = \left| U^1_1(r) \right|^2 + \left| U^1_{-1}(r) \right|^2 + U^1_1(r)U^*_{-1}(r) + U^1_{-1}(r)U^*_{1}(r) = a_0^i + a_1^i \exp(i2\delta_m) + a_2^i \exp(-i2\delta_m)$$

(1)

where, $a_0^i$ equals to $\left| U^1_1(r) \right|^2 + \left| U^1_{-1}(r) \right|^2$, $a_1^i$ equals to $[I^1_1(r)I^1_{-1}(r)]^{1/2} \exp[i(\phi^\delta\text{diff} + 2\pi n/L)]$, and $a_2^i$ equals to $[I^1_{-1}(r)I^1_1(r)]^{1/2} \exp[-i(\phi^\delta\text{diff} + 2\pi n/L)]$. Here, $\phi^\delta\text{diff}$ denotes the phase difference between $U^1_1$ and $U^1_{-1}$ which is generated by the lateral shearing. And $\delta_m = 2(m-1)/5$ ($m = 1, 2, \ldots, 5$) is the phase shift induced by laterally translating the fringe on DMD. Despite this three-step phase-shifting is enough to solve these three terms $a_0^i$, $a_1^i$, and $a_2^i$, we use the five-step phase shifting to achieve a better reconstruction immune to phase shift error and environmental instability [33]. Accordingly, Eq. 1 can be rewritten as:

$$\begin{pmatrix}
1 \exp(i2\delta_1) & \exp(-i2\delta_1) \\
1 \exp(i2\delta_2) & \exp(-i2\delta_2) \\
1 \exp(i2\delta_3) & \exp(-i2\delta_3) \\
1 \exp(i2\delta_4) & \exp(-i2\delta_4) \\
1 \exp(i2\delta_5) & \exp(-i2\delta_5)
\end{pmatrix}
\begin{pmatrix}
a_0^i \\
a_1^i \\
a_2^i
\end{pmatrix} =
\begin{pmatrix}
I^1_1(r) \\
I^1_{-1}(r) \\
I^1_1(r) \\
I^1_{-1}(r) \\
I^1_1(r)
\end{pmatrix}$$

(2)

Here $a_0^i$, $a_1^i$, and $a_2^i$ can be solved in a least-square manner via multiplying both sides of Eq. 2 with the transpose of the coefficient matrix. Therefore, $a_0^i$, $a_1^i$, and $a_2^i$ along the $\xi$-direction can be achieved, respectively. In order to compensate for the linear phase terms in $a_0^i$ and $a_2^i$ induced by the oblique illumination of the ±1st orders of the structured illuminations, an accurate calibration was performed. Actually, the calibration was performed with the same procedure but in the absence of any samples, and we can get new terms $a_0^0$, $a_1^0$, and $a_2^0$. Eventually, the pure phase difference of the sample can be obtained by $\phi^\delta\text{diff} = \text{Ang}[a_1^0/a_0^0]$, where $\text{Ang}[\cdot]$ denotes the argument algorithm operator. Similarly, the phase difference $\phi^\delta\text{diff}$ along the $x$- and $y$-axes can be obtained by rotating the fringe $90^\circ$ with the same calculation procedure. Ultimately, the phase distribution $\phi(r)$ can be obtained by integrating $\phi^\delta\text{diff}$ and $\phi^\delta\text{diff}$ [34]:

$$\phi(r) = \text{IFT}\left\{\frac{-[v^*F\{\phi^\delta\text{diff}\} + vF\{\phi^\delta\text{diff}\}]}{2\pi (v^2 + (v')^2)}\right\}$$

(3)

where $v^*$ and $v'$ are the coordinates in the Frequency domain, respectively. $F\{}\cdot\text{\} and IFT\{\cdot\}$ represent the Fourier transform and inverse Fourier transform, respectively.

**Super-Resolution Scattering Imaging With Coherent Structured Illumination**

Using the same stripes projection method as in phase imaging, a resolution enhancement in non-fluorescent imaging can be realized by using coherent structured illumination. The key to enhancing the spatial resolution in non-fluorescent/scattering imaging is the synthetic-aperture effect, as shown in Figure 1C, which can bring unobservable high-frequency information into the low-frequency supporting area through oblique illumination. Different from the phase imaging, the scattering imaging here records the diffraction patterns in an in-focus manner. Mathematically, the intensity images in the CCl plane can be written as $I^i_m(r) = [h(r) \Theta(O(r) \cdot A^i_m)^2]$, where $h(r)$ is the coherent point spread function of the system, $\Theta$ is the convolution operator, $O(r)$ is the object transmittance function, and $A^i_m$ is the structured illumination filed in the sample plane. After a Fourier transform, we can obtain the spectrum distribution of $I^i_m(r)$:

$$\tilde{I}^i_m(v) = \left[ G^0_m(v) + \exp(i2\delta_m) \cdot G^1_m(v - v^0_1) + \exp(-i2\delta_m) \cdot G^1_m(v + v^0_1) \right]$$

(4)

where $\tilde{I}^i_m(v)$ is the Fourier transform of $I^i_m(r)$, $v$ is the spatial frequency vector, and $G^m_{m}(m = 0, \pm 1)$ represent the spectral components along $x$- and $y$-directions. Notably, $G^1_m(v - v^0_1)$ and $G^1_m(v + v^0_1)$ have the high-frequency spectrum surpassing the supporting pupil of the imaging system, which was downshifted by the oblique illumination and therefore passing through the imaging system. To acquire these three spectral components, five-step phase-shifting was performed with the phase shifts $\delta_m = 2(m-1)/5$. After similar mathematical operations as described in Quantitative Differential Phase-Contrast (qDIC) Microscopy With Structured Illumination different spectra along with the 0th, and ±1st orders of the structured illuminations can be solved, and an extended-spectrum can be synthesized with:

$$G^0_m(v) = \frac{1}{2} \cdot \left[ G^0_m(v) + G^0_m(v - v_1^0) + G^0_m(v + v_1^0) + G^1_m(v - v_1^0) + G^1_m(v + v_1^0) \right]$$

(5)

Afterward, the resolution-enhanced image can be achieved using an inverse Fourier transform on Eq. 5 and multiplying weighting factor. It is worth noting that in such a coherent imaging system the phase distribution of different $G^m_{m}(m = 0, \pm 1)$ should be compensated e.g., with the experiment without any samples, making sure that there are no additional phase shifts between different terms in Eq. 5.

**EXPERIMENTS AND RESULTS**

**qDIC Microscopy Imaging of Living Cells**

In the first experiment, a confirmatory experiment is carried out to demonstrate qDIC for live samples imaging without fluorescent labeling. For this purpose, live mouse adipose stem cells were used as phase samples. The magnification and numerical aperture of the imaging system MO 2-L5 are 10× and 0.32, respectively. Two groups of binary patterns with the orientation along the $x$- and $y$-oriented patterns were shifted by five times and each time had a phase shift $\delta_m = 2(m-1)/5$ ($m = 1, 2, \ldots, 5$). The generated diffraction patterns were
recorded by the CCD1 camera, and shown in Figures 2A,B respectively. Using the reconstruction method described with Eqs. 1, 2, both the amplitude and phase derivatives of the sample are obtained. Figures 2C,D show the phase gradients along the x- and y-orientations, respectively. Despite the contours of the cells become visible in Figures 2C,D, the result is a mixture of amplitude and phase-gradient in a nonlinear manner. The final phase distribution of the sample is then obtained by integrating the phase derivatives along the x- and y-orientations, as shown in Figure 2F. Compared to the amplitude image of the sample shown in Figure 2E, where the structures of the cells are nearly invisible, the phase image (Figure 2F) visualizes clearly the structures of the cells, and notably in a quantitative manner. The comparison reveals that qDIC can not only visualize the transparent samples with high contrast but also provide us the quantitative information on the optical path difference (OPD) of the sample.

**Coherent SIM Imaging of SiO2 Particles**

In the second experiment, resolution-enhanced nonfluorescent/scattering imaging using coherent structured illumination was proved by imaging SiO2 beads (diameter: 500-nm). Binary fringe patterns were loaded on DMD to generate sinusoidal fringe stripes at the sample plane after being filtered in the Fourier plane. The period of the binary patterns was set as five pixels, and after the de-magnification, the period of the sinusoidal fringe stripes was 0.95 μm at the sample plane. As explained in Super-Resolution Scattering Imaging With Coherent Structured Illumination, the binary fringe patterns were shifted by five times (yielding the phase shifts $\delta_m = 2 (m-1)\pi/5$, $m = 1, 2, \ldots, 5$) along the x- and y-direction, and the generated diffraction patterns are recorded in sequence by CCD1 located at the image plane. The super-resolution reconstruction is then realized with the method elaborated in Super-Resolution Scattering Imaging With Coherent Structured Illumination. The reconstructed image of SiO2 beads is shown in Figures 3A,B shows the conventional wide-field image obtained using a perpendicular plane-wave illumination. It is clear that the coherent structured illumination provides a high-resolution image on the SiO2 beads.

The numerical aperture ($N_A_{detect} = 0.32$) of the detection objective MO2 limits the lateral resolution to $\delta_{plan} = 1.44$ μm for
the conventional imaging using a perpendicular plane wave illumination. When the structured illumination is used, the illumination angle of the ±1st diffraction orders of the fringe stripes is $\theta_{\text{illum}} = 0.30$ rad, and thus the theoretical lateral resolution can be estimated with $\delta_{\text{str}} = \frac{0.82\lambda}{(\sin(\theta_{\text{illum}}) + \text{NA}_{\text{detect}})} = 0.75 \mu m$ [35]. For a quantitative evaluation of the lateral resolution, ten random SiO$_2$ beads were randomly chosen, and the intensity distributions along the line crossing the center of each bead are analyzed, as shown in Figure 3C. The statistics on the ten beads tells that the averaged full widths at half maximum (FWHM) under these two illuminations are $1.86 \pm 0.20 \mu m$ for perpendicular uniform illumination while $1.10 \pm 0.10 \mu m$ for coherent structured illumination. When considering the non-negligible size (the diameter $d = 500 \, \text{nm}$) of the SiO$_2$ beads, the final resolution can be calculated by $\delta_{\text{res}} = [(\delta_{\text{plan/str}})^2 + d^2]^{1/2}$, yielding the lateral resolution $\delta_{\text{res}} = 1.80 \pm 0.20 \mu m$ and $0.98 \pm 0.10 \mu m$ for the conventional wide-field imaging mode and coherent structured illumination mode, respectively. It should be noted that there is a mismatch between the measured and theoretical resolutions due to the system’s aberration and other uncertain factors.

**Dual-Modality (Scattering/Fluorescence) Imaging of Lily Anther**

In the third experiment, the dual-modality (non-fluorescent scattering/fluorescent) imaging capability of the proposed SIM apparatus was demonstrated with lily anther as the sample. The coherent SIM image was shown in Figure 4B, and the fluorescence image was captured by the camera CCD after being filtered by a color filter (600/50 nm, central wavelength/full-width at half maximum) and is shown in Figure 4C. Compared with the wide-field image in Figure 4A obtained by using a uniform illumination, the SIM image in Figure 4B shows more detailed structures and clearer background. Moreover, the fluorescent image in Figure 4C shows clear pollen structures (having autofluorescence) in the context of a clean background. It is also distinct that the SIM image (transmission) and the
flourescent image (reflection) have the opposite contrast for the same sample.

**DISCUSSION**

In this paper, we have proposed a DMD based transmission SIM apparatus, which can be exploited for multi-modality imaging, including quantitative differential phase-contrast (qDIC) imaging, coherent SIM with resolution enhancement, fluorescence imaging. Structured illumination based qDIC is immune to environmental disturbances, compared with interferometric approaches. Coherent SIM provides super-resolved, scattering images of non-fluorescent samples. Fluorescent imaging furnishes specific, biochemical structures of samples once using fluorescent labeling. For both qDIC and coherent SIM, a DMD is used to generate structured illumination, and therefore, it has the features of high speed and high flexibility. It is worth noting that the qDIC is only applicable to continuous samples since the integration of phase derivatives are used. Moreover, both qDIC and coherent SIM cannot be realized in a real-time manner since both need to record multiple raw images once a sample is illuminated with structured patterns of different orientations and phase shifts. We believe such a simple and versatile apparatus will be widely applied for biomedical fields and life science.

In the proposed approach periodic patterns were projected to obtain the resolution enhancement and/or the phase information. As future prospective non periodic patterns (e.g., Walsh functions) can be projected and by that practically obtain the decomposing of the spatial information of the inspected sample. Projecting such functions can also be connected to compressed sensing and it may allow high resolution extraction of the spatial information in the inspected sample with smaller number of projected patterns (i.e., having faster process of information extraction).
