Sustained oscillations in multi-topic belief dynamics over signed networks

Anastasia Bizyaeva, Alessio Franci, and Naomi Ehrich Leonard

Abstract—We study the dynamics of belief formation on multiple interconnected topics in networks of agents with a shared belief system. We establish sufficient conditions and necessary conditions under which sustained oscillations of beliefs arise on the network in a Hopf bifurcation and characterize the role of the communication graph and the belief system graph in shaping the relative phase and amplitude patterns of the oscillations. Additionally, we distinguish broad classes of graphs that exhibit such oscillations from those that do not.

I. INTRODUCTION

Having the means to evaluate what can happen when a group of social agents forms beliefs on a set of related topics is key to understanding belief propagation in human social networks and to enabling decentralized decision-making in teams of robots and other distributed technological systems. Dynamic models of social belief formation provide a tool for systematic investigation of belief processes and for principled design of distributed algorithms for decision-making.

In this paper we investigate conditions under which oscillations emerge in the beliefs of agents in social networks. Temporal oscillations in attitudes and beliefs may be an important feature of individual cognition [1]. Oscillations in beliefs are common in social systems; e.g., periodic swings in public opinion between more conservative and more liberal attitudes are characteristic of the American electorate [2]. In a multi-robot problem such as task allocation, it may be important to reliably promote or avoid oscillations. Designing oscillations will also be necessary for building electronic circuits with complicated, but well controlled, oscillation patterns as those needed for neuromorphic applications [3].

However, sustained oscillations are rarely observed in popular models of belief formation. Classically, formation of beliefs or opinions on a single topic is modeled as a discrete-time or continuous-time linear weighted averaging process on a network [4], [5]. For the multi-topic scenario, multi-dimensional averaging models have been investigated, e.g., see [6]–[12]. According to linear models, the beliefs of agents in a static social network typically converge to an equilibrium. The study of these models is thus concerned with characterizing the agents’ beliefs at steady state.

Recently, an alternative modeling paradigm for social opinion formation was proposed that assumes the belief or opinion update rules of agents to be nonlinear [13], [14]. The nonlinearity is deceptively simple: each agent saturates information it accumulates from its social network. The imposition of a saturating function is a well-motivated and mild extension of classic averaging models [13], [14]. Despite the simplicity, networked beliefs that follow this nonlinear update rule can have dramatically different properties from those predicted by classic averaging models, including sustained oscillations. These nonlinear dynamics are also general. Beyond opinion formation, they are closely related to recurrent neural network and neuromorphic electronic circuit models. To date, analysis of these nonlinear dynamics focused on characterizing multi-stable equilibria [13]–[15]. In this paper we add to this body of work and present novel analysis that characterizes the emergence of belief oscillations and their properties as a function of design parameters including mixed-sign network structure.

Our main contributions are as follows. 1) We establish sufficient conditions and necessary conditions for the onset of stable sustained oscillations in belief dynamics. 2) We characterize the relative phase and amplitude patterns of the oscillations in terms of the parameters of the model.

Section II reviews mathematical preliminaries. Section III introduces the belief dynamics model. Section IV presents the main results. Classes of graphs that can lead to oscillations are distinguished from those that cannot in Section V. Section VI presents numerical examples.

II. MATHEMATICAL PRELIMINARIES

A. Notation

For $x = a + ib = re^{i\phi} \in \mathbb{C}$, $\overline{x} = a - ib = re^{-i\phi}$ is its complex conjugate, $|x| = \sqrt{x\overline{x}} = r$ its modulus, and $\arg(x)$ its argument $\phi$. The inner product of vectors $v, w$ is $\langle v, w \rangle = \overline{w}^T v$. $\mathbf{0} \in \mathbb{R}^N$ is the zero vector and $\text{diag}(v)$ is the diagonal matrix with diagonal entries the elements of $v$.

The spectrum of $A \in \mathbb{R}^{n \times n}$ is $\sigma(A) = \{\lambda_1, \ldots, \lambda_n\}$ and its spectral radius $\rho(A) = \max\{|\lambda_i|, \lambda_i \in \sigma(A)\}$. The kernel of $A$ is $N(A) = \{v \in \mathbb{R}^n \ s.t. \ Av = \mathbf{0}\}$. An eigenvalue $\lambda \in \sigma(A)$ is a leading eigenvalue of $A$ if $\text{Re}(\lambda) \geq \text{Re}(\mu)$ for all $\mu \in \sigma(A)$. A leading eigenvalue $\lambda$ of $A$ is a dominant eigenvalue if $\lambda = \rho(A)$. Given vectors $v, w$ or matrices $M, N$, we say $v \succ w$ if $v_i > w_i$ for all $i$ and $M \succ N$ if $M_{ij} > N_{ij}$ for all $i, j$. For matrices $M, N \in \mathbb{R}^{m \times n}$, the element-wise Hadamard product $M \odot N \in \mathbb{R}^{m \times n}$ is defined as $(M \odot N)_{ij} = M_{ij}N_{ij}$. For matrices $A = (a_{ij}) \in \mathbb{R}^{m \times n}$, $B = (b_{ij}) \in \mathbb{R}^{k \times k}$, the Kronecker product $M \otimes N \in \mathbb{R}^{m \times n}$ is defined as $(M \otimes N)_{ij} = M_{ij}N_{ij}$.
A ⊗ B ∈ R^{ml×nk} is defined as

\[ A ⊗ B = \begin{pmatrix} a_{11}B & \ldots & a_{1n}B \\ \vdots & \ddots & \vdots \\ a_{m1}B & \ldots & a_{mn}B \end{pmatrix}. \]

A real square matrix \( A \) has the strong Perron-Frobenius property if it has a unique dominant eigenvalue \( \lambda = \rho(A) \) satisfying \( \lambda \geq |\lambda_i| \) for all \( \lambda_i \neq \lambda \) in \( \sigma(A) \) and its corresponding eigenvector satisfies \( v > 0 \). A matrix is irreducible if it cannot be transformed into an upper triangular matrix through similarity transformations. \( A \) is eventually positive (eventually nonnegative) if there exists a positive integer \( k \) such that \( A^k \succeq 0_{N×N} \) for all integers \( k > k_0 \).

**Proposition II.1.** [16, Theorem 2.2] The following statements are equivalent for a real square matrix \( A \): (1) \( A \) and \( A^T \) have the strong Perron-Frobenius property; (2) \( A \) is eventually positive; (3) \( A^T \) is eventually positive.

**B. Signed graphs**

A graph \( \mathcal{G} = (\mathcal{V}, \mathcal{E}) \) is a set of nodes \( \mathcal{V} = \{1, \ldots, N\} \) and a set of edges \( \mathcal{E} \). We assume the graph is simple, i.e., there is at most one edge between any two nodes. The adjacency matrix \( A = (a_{ik}) \) of \( \mathcal{G} \) satisfies \( a_{ik} = 0 \) if \( e_{ik} \notin \mathcal{E} \) and \( a_{ik} \neq 0 \) otherwise. \( A \) is weighted if nonzero entries \( a_{ik} \in \mathbb{R} \). \( \mathcal{G} \) is unweighted if \( a_{ik} \in \{0,1\} \) or signed unweighted if \( a_{ik} \in \{0,1,-1\} \) for all \( i,k \in \mathcal{V} \). \( \mathcal{G} \) is undirected whenever \( a_{ik} = a_{ki} \) for all \( i,k \in \mathcal{V} \), and directed otherwise.

The in-degree of node \( i \) on \( \mathcal{G} \) is \( \sum_k a_{ik} \). A path on \( \mathcal{G} \) is a finite or infinite sequence of edges that joins a sequence of nodes. \( \mathcal{G} \) is strongly connected if there exists a path from any node to any other node. \( \mathcal{G} \) is strongly connected if and only if \( A \) is an irreducible matrix. A switching matrix \( M \) is a diagonal matrix with diagonal entries that are either 1 or -1. Two graphs \( \mathcal{G}_1, \mathcal{G}_2 \) with adjacency matrices \( A_1, A_2 \) are switching equivalent whenever \( A_1 = MA_2M \).

**C. Hopf bifurcation**

Assume without loss of generality that \( (x,p) = (0,0) \) is an equilibrium of a system \( \dot{x} = f(x,p) \), where \( x \) is the state and \( p \) a parameter. Then \( (0,0) \) is a Hopf bifurcation point if it satisfies the following: i) The Jacobian \( DF(0,0) \) has a complex conjugate pair of eigenvalues \( \pm i\omega(0) \); ii) No other eigenvalues of \( DF(0,0) \) lie on the imaginary axis; iii) Let \( \lambda(p) = r(p) + i\omega(p), \bar{\lambda}(p) = r(p) - i\omega(p) \) be the eigenvalues of \( DF(x,p) \) that are smoothly parametrized by \( p \) and for which \( r(0) = 0 \); then \( \frac{\partial r}{\partial p}(0,0) \neq 0 \). We use Lyapunov-Schmidt reduction methods [17, Chapter VIII] to study the limit cycles that emerge through a Hopf bifurcation.

**III. BELIEF FORMATION MODEL**

We study a nonlinear model of \( N_o \) homogeneous agents forming beliefs about \( N_s \) topics, adapted from [13, 14]. \( z_{ij} \in \mathbb{R} \) is the belief of agent \( i \) about topic \( j \). Whenever \( z_{ij} > 0(<0) \), agent \( i \) is in favor of (in opposition to) topic \( j \), and when \( z_{ij} = 0 \) it has a neutral belief on the topic. The magnitude \( |z_{ij}| \) signifies the strength of commitment to the belief on topic \( j \). The total belief state of agent \( i \) is the vector \( Z_i = (z_{i1}, \ldots, z_{in_s}) \in \mathbb{R}^{N_s} \), and the total network belief state is \( Z = (Z_1, \ldots, Z_{N_o}) \in \mathbb{R}^{N_o \times N_s} \). We say agents \( i \) and \( k \) agree (disagree) on topic \( j \) if they both form a non-neutral belief on the topic and \( \text{sign}(z_{ij}) = \text{sign}(z_{kj})(\neq \text{sign}(z_{ik})) \).

Agent \( i \) updates its belief on topic \( j \) in continuous time as

\[
\dot{z}_{ij} = -d z_{ij} + u \left( S \alpha z_{ij} + \gamma \sum_{k \neq i}^{N_o} (A_{ik} z_{kj}) + \sum_{l \neq j} S \beta (A_{il} z_{jl}) + \delta (A_{il} z_{kl}) \right) \]

(1)

where \( S_1, S_2 : \mathbb{R} \rightarrow \mathbb{R} \) are bounded saturation functions satisfying \( S_r(0) = 0, S'_r(0) = 1, S''_r(0) = 0, S'''_r(0) \neq 0 \), with an odd symmetry \( S_r(-y) = -S_r(y) \) where \( r \in \{1,2\} \). \( S_1 \) saturates same-topic information and \( S_2 \) saturates inter-topic information. These saturations reflect that social network influence on each topic is bounded, and that an agent is maximally affected by small changes in its neighbors’ beliefs on a topic when their weighted average is close to zero. Parameter \( d > 0 \) represents the agents’ resistance to forming strong beliefs. Parameter \( u \geq 0 \) regulates the amount of attention agents allocate towards their social interactions, or their susceptibility to social influence.

There are two signed directed graphs underlying the belief formation process. One is the communication graph \( \mathcal{G}_\alpha = (\mathcal{V}_\alpha, \mathcal{E}_\alpha, s_\alpha) \), with signed adjacency matrix \( A_\alpha = A_{N_o \times N_s} \), \( (A_\alpha)_{ik} = 1 \) means agent \( i \) is cooperative towards agent \( k \), and \( (A_\alpha)_{ik} = -1 \) means it is antagonistic towards agent \( k \). The other is the belief system graph \( \mathcal{G}_\omega = (\mathcal{V}_\omega, \mathcal{E}_\omega, s_\omega) \), with signed adjacency matrix \( A_\omega = A_{N_o \times N_s} \). The graph \( \mathcal{G}_\alpha \) encodes the logical interdependence between different topics in the set \( \mathcal{V}_\omega \). Whenever \( (A_\omega)_{jl} = 1(=1) \), topic \( j \) is positively (negatively) aligned with topic \( l \) according to the belief system, and whenever \( (A_\omega)_{jl} = 0 \), topic \( j \) is independent of topic \( l \). In the model (1) we assume that all agents form beliefs following a single shared belief system.

The gains \( \alpha, \gamma, \beta, \delta \geq 0 \) regulate the relative strengths of influence on beliefs in (1). \( \alpha \) is the strength of agent self-reinforcement of already-held beliefs; \( \beta \) is the strength of agent internal adherence to the belief system \( \mathcal{G}_\omega \); \( \gamma \) is the strength of agent social imitation, i.e. to mimic the beliefs of neighbors towards whom the agent is cooperative and to oppose the beliefs of those towards whom it is antagonistic; \( \delta \) is agent ideological commitment; when \( \delta \) is large, agents evaluate their neighbors’ influence more holistically according to the belief system \( \mathcal{G}_\alpha \) rather than through pure imitation along each topic. An illustration of these four effects and their respective cumulative weights in the model (1) is shown in Fig. 1.

**IV. INDECISION-BREAKING AND OSCILLATIONS**

We establish sufficient conditions for the onset of small-amplitude periodic oscillations in the dynamics of beliefs (1). The indecision state \( Z = 0 \) in which all agents have neutral beliefs on all topics is an equilibrium of (1) for all parameter values. To establish the onset of oscillations we first study
the stability of $Z = 0$. The Jacobian of (1) about $Z = 0$ is

$$J(0, u) = (-d + u \alpha)I_{N_u} \otimes I_{N_\alpha} + u \gamma A_\alpha \otimes I_{N_u} + u \beta I_{N_\alpha} \otimes A_\alpha + u \delta A_\alpha \otimes A_\alpha. \tag{2}$$

The following proposition connects the eigenvalues and eigenvectors of (2) to the eigenvalues and eigenvectors of the signed adjacency matrices $A_\alpha$ and $A_\omega$.

**Proposition IV.1 (Eigenvalues and eigenvectors).** The following statements hold for (2), with some selection of parameters $d, u, \alpha, \gamma, \beta, \delta$:

1. For each $\eta \in \sigma(J(0, u))$, there exists $\lambda \in \sigma(A_\alpha)$ and $\mu \in \sigma(A_\omega)$ so that

$$\eta = -d + u(\lambda + \gamma \lambda + \beta \mu + \delta \lambda \mu) := \eta(u, \lambda, \mu); \tag{3}$$

2. Suppose $\lambda_1$ is an eigenvalue of $A_\alpha$ with an eigenvector $v_{a,i}$ and $\mu_1$ is an eigenvalue of $A_\omega$ with an eigenvector $v_{o,j}$, then the vector $v_{a,i} \otimes v_{o,j}$ is an eigenvector of (2) with corresponding eigenvalue $\eta(u, \lambda_1, \mu_1)$.

**Proof.** 1) By Schur’s unitary triangulation theorem [18, Theorem 2.3.1] there exist unitary matrices $U \in \mathbb{C}_{N_u \times N_u}$, $V \in \mathbb{C}_{N_\alpha \times N_\alpha}$ such that $U^* A_\alpha U = \Delta_u$, $V^* A_\omega V = \Delta_\omega$, where $\Delta_u, \Delta_\omega$ are upper triangular complex matrices with eigenvalues of $A_\alpha, A_\omega$ on the diagonal. Then, using the mixed-product property of the Kronecker product, $\Delta_J = (U \otimes V)^* J(0, u)(U \otimes V) = (-d + u \alpha)(U^* I_{N_u} \otimes (V^* I_{N_\alpha} V) + u \gamma (U^* A_\alpha U) \otimes (V^* I_{N_\alpha} V) + u \beta (V^* I_{N_\alpha} V) \otimes (V^* A_\omega V) + u \delta (U^* A_\alpha U) \otimes (V^* A_\omega V) = (-d + u \alpha)I_{N_u \otimes N_\alpha} + u \gamma \Delta_u \otimes I_{N_\alpha} + u \beta I_{N_u} \otimes \Delta_\omega + u \delta \Delta_u \otimes \Delta_\omega$. The matrix $\Delta_J$ is upper triangular, with its diagonal corresponding to the eigenvalues of $J(0_u, u)$. By inspection we see that all diagonal entries of $\Delta_J$ have the form $\eta(u, \lambda, \mu)$ for some $\lambda \in \sigma(A_\alpha)$, $\mu \in \sigma(A_\omega)$.

2) $v_{a,i} \otimes v_{o,j}$ is an eigenvector of $A_\alpha \otimes A_\omega$ with eigenvalue $\lambda_1 \mu_1$ by [19, Theorem 4.2.12]; it is also an eigenvector of $I_{N_u} \otimes I_{N_\alpha}, A_\alpha \otimes I_{N_u},$ and $I_{N_\alpha} \otimes A_\alpha$ with corresponding eigenvalues $1, \lambda_1, \mu_1$, respectively, and the proposition statement follows from multiplying (2) by $v_{a,i} \otimes v_{o,j}$. \qed

Whenever eigenvalues $\lambda \in \sigma(A_\alpha)$ and $\mu \in \sigma(A_\omega)$ define an eigenvalue $\eta \in \sigma(J(0, u))$ through (3), we say $\lambda$ and $\mu$ generate $\eta$. We define the maximal real part of the social network contribution to the eigenvalue (3) of the Jacobian as

$$K = \max_{\lambda \in \sigma(A_\alpha), \mu \in \sigma(A_\omega)} \text{Re}(\alpha + \gamma \lambda + \beta \mu + \delta \lambda \mu). \tag{4}$$

For every leading eigenvalue $\eta_{max}$ of (2), $\text{Re}(\eta_{max}) = -d + uK$. In the following lemma we establish existence of a critical value of attention to social interactions at which the neutral equilibrium $Z = 0$ loses stability.

**Lemma IV.2 (Stability of origin).** Consider (1) and suppose $K > 0$. If $u < u^* := d/K$, the neutral equilibrium $Z = 0$ is locally exponentially stable. If $u > u^*$ it is unstable.

**Proof.** Let $\eta_{max}$ be a leading eigenvalue of (2). Whenever $u < u^*(> u^*)$, $\text{Re}(\eta_{max}) < (> 0)$. Furthermore since $\eta_{max}$ is a leading eigenvalue, whenever $u < u^*$, $\text{Re}(\eta) < 0$ for all $\eta \in \sigma(J(0, u))$. The stability conclusions follow by Lyapunov’s indirect method [20, Theorem 4.7]. \qed

**Lemma IV.2** establishes the existence of a bifurcation point $u = u^*$ at which the origin loses stability. As a consequence of the center manifold theorem [21, Theorem 3.2.1] for values of attention parameter $u$ in a neighborhood of $u^*$, trajectories of (1) that start in a neighborhood of $Z = 0$ will settle on an attracting manifold with dimension determined by the number of eigenvalues of $J(0, u^*)$ with zero real part. We examine the onset of network oscillations along this manifold which result from a Hopf bifurcation.

The following standing assumption ensures that Conditions 1), ii) for a Hopf bifurcation (Section II-C) are satisfied.

**Assumption 1.** The leading eigenvalues of (2) are a complex-conjugate pair, $\eta_+ \text{ and } \eta_- = \eta_+^*, \text{ with } \text{Im}(\eta_+) \neq 0$.

In Section V we establish several broad classes of graphs for which this assumption is either always, or never, satisfied. Let the pair $\lambda_1 \equiv \lambda_0 + i \epsilon \in \sigma(A_\alpha)$ and $\mu_1 \equiv \mu_0 + i \epsilon \in \sigma(A_\omega)$ generate one of the leading eigenvalues of Assumption 1 according to (3), i.e. suppose that either $\eta_+ = \eta(u, \lambda_1, \mu_1)$ or $\eta_- = \eta(u, \lambda_1, \mu_1)$. Then it holds that

$$\text{Re}(\eta_+) = -d + u(\alpha + \gamma \lambda_0 + \beta \mu_0 + \delta(\lambda_{0} \mu_0 - \lambda_0 \epsilon)), \tag{5a}$$

$$\text{Im}(\eta_+) = \pm u[\alpha + \gamma \lambda_0 + \beta \mu_0 + \delta(\lambda_0 \mu_0 - \lambda_0 \epsilon)]. \tag{5b}$$

Note that in this case,

$$K = \alpha + \gamma \lambda_0 + \beta \mu_0 + \delta(\lambda_0 \mu_0 - \lambda_0 \epsilon). \tag{6}$$

We are now ready to establish our first main result.

**Theorem IV.3 (Hopf bifurcation).** Consider (1) with communication graph $G_a$ and belief system graph $G_o$. Let Assumption 1 hold, and suppose $K > 0$.

Suppose $\lambda_1 \in \sigma(A_\alpha), \mu_1 \in \sigma(A_\omega)$ generate $\eta_+(u)$. Let $w_a, v_a \in \mathbb{C}_{N_a}^N$ be the left and right eigenvectors of $A_\alpha$ corresponding to $\lambda_1$ and $\lambda_1^\dagger$, respectively; let $w_o, v_o \in \mathbb{C}_{N_\omega}^N$ be the left and right eigenvectors of $A_\omega$ corresponding to $\mu_1$ and $\mu_1^\dagger$, respectively. Choose the eigenvectors to satisfy the biorthogonal normalization condition

$$\langle w_a \otimes w_o, v_a \otimes v_o \rangle = 2, \quad \langle w_a \otimes w_o, v_a \otimes v_o \rangle = 0.$$

1) There is a unique 3-dimensional center manifold $W^* \subset \mathbb{R}^{N_a \times N_\omega} \times \mathbb{R}$ passing through $(Z, u) = (0, u^*)$, tangent to $\text{span}\{Re(v_a \otimes v_o), \text{Im}(v_a \otimes v_o)\}$ at $u = u^* = d/K$. There
is a family of periodic orbits of (1) that bifurcates from the neutral equilibrium $Z = 0$ along $W_c$ at $u = u^*$;  

2) Let $b = \text{Re} \left( \left( S''_1(0) \right) (\alpha + \gamma \lambda^1) |\alpha + \gamma \lambda^1|^2 + \right.$

$\left. + S''_2(0) \right) (\beta + \delta \lambda^1) \mu^1 |\beta + \delta \lambda^1|^2 |\mu^1|^2 \right) \times (v_a \otimes w_o, |v_a \otimes v_o|^2 \otimes (v_a \otimes w_o))$ (7)

where $|x|^2 = x \circ x$. Whenever $b < 0$ the bifurcating periodic solutions appear supercritically (for $u > u^*$) and are locally asymptotically stable; whenever $b > 0$, the solutions appear subcritically (for $u < u^*$) and are unstable; 

3) When $|u - u^*|$ is small, the period of the solutions is near $2\pi / (u^*|\lambda_c + \beta \mu_c + \delta(\lambda_a \mu_c + \lambda_c \mu_o)|)$, the difference in phase between $z_{ij}(t)$ and $z_{kl}(t)$ is near $\varphi = \arg((v_a)_i(v_o)_j) - \arg((v_a)_k(v_o)_l)$, and the amplitude of $z_{ij}(t)$ is greater than the amplitude of $z_{kl}(t)$ if and only if $|v_a_k(v_o)_j| > |v_a_k(v_o)_l|$. 

Theorem IV.3 provide sufficient conditions for the emergence of stable sustained oscillations at an indecision-breaking bifurcation. Statement 3) of Theorem IV.3 relates the relative phase and amplitude pattern along the emerging oscillation to the spectral properties of $G_a$ and $G_o$. 

V. NECESSARY AND SUFFICIENT GRAPH PROPERTIES

Assumption 1 is a necessary condition for the emergence of oscillations at an indecision breaking bifurcation. The following proposition singles out classes of communication and belief system graphs for which the leading eigenvalues of (2) are necessarily real and therefore no oscillation in beliefs can emerge at the breaking of indecision.

Proposition V.1 (Graphs that never support oscillations). Consider (1) with communication graph $G_a$ and belief system graph $G_o$ with signed adjacency matrices $A_a$, $A_o$. Suppose at least one of the following statements is true: 1) $G_a$ and $G_o$ are undirected; 2) for both $G_a$ and $G_o$ there exist switching matrices $M_a,M_o$ such that $M_a A_a M_a$ and $M_o A_o M_o$ are eventually positive. Then the indecision-breaking bifurcation of the origin at $u = u^*$ cannot be a Hopf bifurcation. 

Proof. 1) All eigenvalues $\lambda \in \sigma(A_a)$ and $\mu \in \sigma(A_o)$ are real because $A_a, A_o$ are symmetric; all eigenvalues $\eta(u, \lambda, \mu)$ are also real which violates Assumption 1. 2) Eventually positive matrices have the strong Perron-Frobenius property by Proposition II.1. Conjugation by a switching matrix preserves eigenvalues as it is a similarity transformation. Thus, $A_a$ and $A_o$ possess unique dominant real eigenvalues $\lambda = \rho(A_a)$ and $\mu = \rho(A_o)$. The eigenvalue $\eta(u, \lambda, \mu)$ is therefore a unique dominant eigenvalue of the Jacobian (2), which violates Assumption 1. 

Proposition V.1 singles out two classes of communications and belief system graphs for which no oscillations in beliefs are possible at an indecision-breaking bifurcation. In the first class, both graphs are undirected. In the second class both graphs are eventually structurally balanced, that is, their adjacency matrices are switching equivalent to eventually positive matrices. The two classes have in common that all the loops between any pairs of agents are positive, which makes oscillations impossible. Conversely, when some negative feedback loops are present in either the communication or the belief system graph, then leading complex eigenvalues can appear in either graph and oscillations are possible.

Proposition V.2 (Graphs that support oscillations). Consider (1) with communication graph $G_a$ and belief system graph $G_o$ with signed adjacency matrices $A_a$, $A_o$. Suppose there exists a switching matrix $M$ such that $M A_a M$ ($M A_o M$) is eventually positive, and suppose the leading eigenvalues of $A_o(A_a)$ are a complex-conjugate pair with positive real part. Then there exists a critical value $\gamma^* (\beta^*)$ such that whenever $\gamma > \gamma^* (\beta > \beta^*)$, the indecision-breaking bifurcation of the origin at $u = u^*$ is a Hopf bifurcation. 

Proof. Consider without loss of generality an eventually structurally balanced $A_a$ with dominant eigenvalue $\lambda > 0$, and $A_o$ with leading eigenvalues $\mu, \overline{\mu}$. The eigenvalues $\eta(u, \lambda, \mu, \eta(u, \lambda, \overline{\mu})$ are the leading eigenvalues of the Jacobian (2) whenever $\gamma \text{Re}(\lambda - \lambda_o) + \beta \text{Re}(\mu - \mu_o) + \delta \text{Re}(\mu - \mu_o \lambda_o) > 0$ for all $\lambda_o \in \sigma(A_a)$, $\mu_o \in \sigma(A_o)$ with $\lambda_o \neq \lambda, \overline{\lambda}; \mu_o \neq \mu, \overline{\mu}$. This is satisfied whenever $\gamma > \text{max}_{\lambda_o \in \sigma(A_a), \mu_o \in \sigma(A_o)} (\beta \text{Re}(\mu - \mu_o) + \delta \text{Re}(\mu - \mu_o \lambda_o))/(\lambda - \lambda_o) =: \gamma^*$. Furthermore $K = \alpha + \gamma \lambda + \beta \text{Re}(\mu) + \delta \lambda \text{Re}(\mu) > 0$ and the necessary and sufficient conditions of Theorem IV.3 are satisfied. Analogous arguments establish existence of $\beta^*$. 

In the classes of communication and belief system graphs singled out by Proposition V.2, the graph whose leading eigenvalues are not complex must be eventually structurally balanced. This ensures that the complex leading eigenvalues of the communication or belief system graph (as appropriate) are mapped to complex leading eigenvalues of (2).

VI. NUMERICAL EXAMPLES

We explore how different communication and belief system graphs shape the emerging oscillations. In all the examples, $S_1(\cdot) = \tanh(\cdot)$, $S_2(\cdot) = \frac{1}{2} \tanh(2 \cdot)$. 

A. Single topic: communication-induced oscillations

We first consider (1) in the case that agents evaluate a single topic so $Z_i = z_{i1} \in \mathbb{R}$ and only the communication graph $G_a$ plays a role in the belief dynamics. We denote $z_{i1}$ by $z_i$ and the dynamics are 

$$\dot{z}_i = -d z_i + u S_1 \left( \alpha z_i + \gamma \sum_{k=1}^{N_o}(A_o)_{ik} z_k \right).$$ (8)

Since the belief system adjacency matrix $A_o = 1$ in the one-topic case, $v_o = w_o = \mu = 1$ in Theorem IV.3.

Consider (8) for seven agents and communication graph $G_a$ of Fig. 2a, with model parameters $d = 1$, $\alpha = 0.1$. The adjacency matrix $A_o$ has complex conjugate leading eigenvalues $\lambda_{\pm} = 0.90 \pm 0.43i$, which generate the leading eigenvalues of the Jacobian $\eta_{\pm} = -d + u(\alpha + \gamma \lambda_{\pm})$. The
conditions for oscillations in Theorem IV.3 are satisfied. The origin loses stability at $u^* = 5.26$ and $b \approx -0.0041$ from (7), which predicts a supercritical bifurcation of stable oscillations. Since $|(v_a)_k| = |(v_o)_k|$ for $i, k = 1, \ldots, 7$, all agent opinions oscillate with the same amplitude. By Theorem IV.3 the predicted period of oscillation is approximately 27.53, and the predicted oscillation phases of the seven agents relative to agent 1 are $(0, 3.59, 0.90, 4.49, 1.80, 5.39, 2.69)$. Fig. 2b illustrates these predictions.

B. Multiple topics: communication and belief system-induced oscillations

In the multiple-topic case, it is the interaction of communication and belief system graphs that shapes the oscillations. We stress that in all examples interchanging agents for topics and communication graph for belief system graph preserves the model dynamical behavior (modulo a reordering of state variables) but changes its interpretation: a given phase difference and amplitude oscillation pattern between the agents (topics) is mapped to the same phase difference and amplitude oscillation pattern between the topics (agents). We consider three examples with the same belief system (Fig. 3a). The adjacency matrix $A_o$ has a complex conjugate pair of leading eigenvalues, $\mu \approx 0.66 \pm 0.56i$. For all three examples, $d = 1$, $\alpha = \gamma = 0.1$, and $\beta = \delta = 0.25$.

1) Agreement oscillations: Consider the strongly connected communication graph $G_o$ (Fig. 3b) with purely cooperative agents. Its adjacency matrix $A_o$ has the strong Perron-Frobenius property, and the conditions of Proposition V.2 are satisfied. By (7), $b \approx -0.46 < 0$, and thus a supercritical bifurcation of stable periodic orbits is expected at $u^* = 0.93$ (Fig. 4). Phase differences between any two belief trajectories on the same topic must be zero (Fig. 4a) because $A_o$ has the strong Perron-Frobenius property and its dominant eigenvector $v_o > 0$. In contrast, each agent’s beliefs on different topics are not in phase (Fig. 4b) as predicted by the entries of $v_o$.

2) Clustered disagreement oscillations: Consider the mixed-sign communication graph, $G''_o$ in Fig. 3c. The adjacency matrix $A''_o$ of this graph is generated from $A_o$ of the previous example as $A''_o = M A'_o M$ where $M = \text{diag}(1, 1, -1, -1)$ is a switching matrix. As in the previous example, $b \approx -0.46$ and $u^* \approx 0.93$. In contrast to the previous example, $\text{sign}(v_o)_1 = \text{sign}(v_o)_2 = -\text{sign}(v_o)_3 = -\text{sign}(v_o)_4$. As a result, the beliefs of agents 1 and 2 oscillate in anti-phase with respect to the beliefs of agents 3 and 4 (Fig. 5).

3) Asynchronous disagreement oscillations: Consider the mixed-sign communication graph $G''_o$ in Fig. 3d, whose adjacency matrix $A''_o$ has a complex-conjugate set of leading eigenvalues, $\lambda \approx 0.88 \pm 0.74i$. The two pairs $(\mu_+, \mu_-)$ (i.e., $\lambda_+ \mu_+$) generate the two complex-conjugate leading eigenvalues of $J(0, u)$ which satisfy the conditions of Theorem IV.3. We compute $b \approx -0.13$ and a supercritical bifurcation of stable periodic orbits is expected at $u^* \approx 1.64$ (Fig. 6). In contrast to the previous examples, the leading eigenvectors of $J(0, u)$ are a product of two complex eigenvectors, and there is no phase synchronization in the resulting oscillations along any topic or within the agents’ internal dynamics.
Fig. 5: Trajectories $z_{ij}(t)$ of (1) with belief system $G_0$ and communication graph $G''$ of Fig. 3 from random initial conditions, grouped by topic. Parameters: $u = 1.25$, $d = 1$, $\alpha = \gamma = 0.1$, $\beta = \delta = 0.25$, $u = 1.25$

Fig. 6: Representative trajectories $z_{ij}(t)$ of (1) with belief system $G_0$ and communication graph $G'''$ of Fig. 3, from random initial conditions. a) Beliefs of all agents on topic 1; b) beliefs of agent 1 on all topics. Color legend for a) and b) the same as in Fig. 4 a) and b). Parameters: $d = 1$, $\alpha = \gamma = 0.1$, $\beta = \delta = 0.25$, $u = 1.7$

APPENDIX: PROOF OF THEOREM IV.3

1) To establish existence of periodic orbits we check that the system (1) under the stated assumptions satisfies the conditions of the Hopf bifurcation theorem [21, Theorem 3.4.2]. When $u = u^* = d/K$, the leading eigenvalues of (2) are a simple purely imaginary pair $\eta_{\pm}(u^*) = \pm iu^*\gamma \lambda_0 + \beta \mu_c + \delta(\lambda_a \mu_c + \lambda_c \mu_a) \neq 0$, which satisfies the eigenvalue condition (H1) of the Hopf theorem. Next, we check that the leading eigenvalues cross the imaginary axis with nonzero speed as $u$ is varied, i.e. $\frac{du}{du} \text{Re}(\eta_{\pm}(u)) = K > 0$, which satisfies the nonzero crossing speed condition (H2) of the Hopf theorem. Existence of periodic orbits directly follows by the Hopf theorem. By this theorem and by the definition of a center manifold [21, Theorem 3.2.1], the solutions appear along a unique $W^s$ which is tangent at $u = u^*$ to $\mathcal{N}(J(0, u^*)) = \text{span}\{\text{Re}(v_a \otimes v_o), \text{Im}(v_a \otimes v_o)\}$.

To show 2) and 3) we first compute the coefficients of a third-order approximation of (1) following the Lyapunov-Schmidt reduction for a Hopf bifurcation [17, Chapter VIII, Proposition 3.3]. This approximation reads $f(y, u) = Ky(u - u^*) + \frac{1}{6!} u^*b^3$, where $K$ is defined in (6) and $b$ is defined in (7). As long as $b \neq 0$, by [17, Chapter VIII, Theorems 2.1 and 3.2] the reduced bifurcation equation $f(y, u)$ possesses a pitchfork bifurcation which is supercritical for $b < 0$ and subcritical for $b > 0$. When $|u - u^*|$ is small, solutions to $f(y, u) = 0$ are in one-to-one correspondence with orbits of small amplitude periodic solutions to the system (1) with period near $2\pi/(u^*\gamma \lambda_0 + \beta \mu_c + \delta(\lambda_a \mu_c + \lambda_c \mu_a)) = 1/\omega$. For $u$ near $u^*$, the small amplitude oscillations can be approximated to first order as scalar multiples of $e^{iu}\nu_a \otimes \nu_o$ from which the conclusions on phase and amplitude difference between agents follow. When $b < 0$ (>$0$), the bifurcating periodic solutions are stable (unstable) by [17, Chapter VIII, Theorem 4.1].
