Spontaneous motion of an oil droplet driven by chemical nonequilibrium is reported. It is shown that the droplet undergoes regular rhythmic motion under appropriately designed boundary conditions, whereas it exhibits random motion in an isotropic environment. This study is a novel manifestation on the direct energy transformation of chemical energy into regular spatial-motion under isothermal conditions. A simple mathematical equation including noise reproduces the essential feature of the transition from irregularity into periodic regular motion. Our results will inspire the theoretical study on the mechanism of molecular motors in living matter, working under significant influence of thermal fluctuation.

PACS numbers: 83.80.Jx, 47.70.Fw

The second law of thermodynamics prohibits specific spontaneous motion in macroscopic systems under equilibrium; nature obeys the law of equipartition. In contrast, living organisms exhibit a specific spatio-temporal structure in a self-organized manner under thermodynamically open conditions, where chemical processes play the major role. Over the past several decades, reaction-diffusion systems have attracted considerable attention as a simple model for the formation of spatio-temporal structures in living organisms. It has been shown both experimentally and theoretically that various dissipative structures can be generated, such as travelling waves and a Turing pattern. However, in a reaction-diffusion system there is essentially no mass-flow, or geometric motion, in contrast to actual observations in living things. In the present study, we found regular spatial movement could be induced in a reactive droplet by adopting an appropriate boundary condition under chemically nonequilibrium conditions. We will discuss a novel scenario for the generation of macroscopic directed and/or periodic motion under a large fluctuation.

Since the 19th century, it has been known that an oil/water system exhibits spontaneous mechanical agitation, i.e. the Marangoni effect. Two different kinds of self-agitation, thermal and chemical Marangoni convection, have been reported. Chemical Marangoni convection is described as the time-dependent fluctuation of interfacial tension under isothermal conditions, where the driving force is the transfer of solute through the interface. One type of chemical Marangoni convection is the spontaneous mechanical motion of a reactive liquid droplet on a solid substrate. The motion of a reactive droplet has been predicted theoretically and verified experimentally. However, in such a system the trajectory of motion cannot overlap itself because the substrate surface is changed in an irreversible manner, which would preclude periodic or circular motion. In the present study we found that irregular agitation induced by a chemical Marangoni effect can be transduced into characteristic repetitive, rhythmic motion, simply by choosing appropriate boundary conditions.

The aqueous phase contained 1 mM stearyl trimethyl ammonium chloride, and the organic phase was 5 mM iodine solution of nitrobenzene saturated with potassium iodide are used. Stearyl trimethyl ammonium chloride was prepared through recrystallization from acetone. For glass substrates, we used micro slide glass (Matsunami, Osaka; S9111) without any pre-treatment. As for a measuremen 20 – 60 µl of the oil is placed in an aqueous phase on a glass substrate. Movement of the oil droplet is recorded by high speed video camera (RedLake MASD Inc.) Motion Scope PCI in 60 frames per second. All the measurements are carried out at the room temperature.

Figure 1 shows the motion of an oil droplet on a glass substrate in an aqueous phase. We put a small amount (30 µl) of oil on the glass substrate through a pipette. The oil droplet spontaneously begins to move immediately after it is transferred to the glass substrate. As shown in Fig.1A, the oil droplet exhibits random agitation within the circular glass vessel. Note that the trajectory of the oil-droplet motion crosses itself. In contrast to the irregular motion shown in Fig.1A, a regular rhythmic motion can be generated in the same chemical system simply by changing the spatial geometry, as in Fig.1B. Corresponding movies are available online. Such periodic motion along the glass substrate continues over several tens of seconds and then stops. Figure 1 also shows time traces of the x-component of velocity, together with their Fourier transformation, indicating the appearance of periodicity f ≈ 0.5 Hz for motion on the glass strip (B) in contrast to the noisy behaviour in the circular vessel (A). Careful observation of Fig.1B reveals that the advancing contact angle of the oil droplet is smaller than its receding contact angle. Figure 1C shows the enlarged image of an oil droplet moving towards the right, where...
FIG. 1: According to the configuration of the glass substrate, an oil droplet showed a distinct mode of motion. (A): (upper left) Schematic diagram of the experimental setup. The volume of the oil droplet is 30µl. (upper right) Random motion appears under isotropic conditions. Also see movies in [22]. (lower figure) The trace of the x-component of oil-droplet velocity and its Fourier transformation, indicating a peak at 0.5 [Hz]. (lower right) Periodic forward-and-backward motion appears on a narrow and straight glass substrate. The time scale in the picture on the right is 1/6 second per frame. The rhythmic motion continues for 10 seconds. Also see movies in [22]. (B): (upper left) Schematic diagram of the experimental setup. The volume of the oil droplet is 30µl. (upper right) Periodic forward-and-backward motion appears on a narrow and straight glass substrate. The time scale in the picture on the right is 1/6 second per frame. The rhythmic motion continues for 10 seconds. Also see movies in [22]. (lower figure) Trace of the magnitude of oil-droplet velocity motion continues for 10 seconds. Also see movies in [22]. (C): Schematic representation of an oil droplet, moving toward the red arrow. $θ_{\text{adv}}$ was smaller than $θ_{\text{rec}}$. On average, $θ_{\text{adv}} \approx 105^\circ$, $θ_{\text{rec}} \approx 116^\circ$.

the advancing contact angle is greater than its receding angle. This large difference in contact angles suggests that the driving force can be attributed to the difference in surface tension between the front and rear of the oil droplet.

Next, we conducted an experiment to check for differences in the surface of the glass plate by mimicking the conditions before and after the oil droplet had passed. We examined the contact angle of a droplet with pure water on the glass plates A and B under air. The glass plate A was pre-treated with the procedure of immersion in an aqueous solution for 5 minutes, rinse with distilled water, and then drying in the air. The other substrate B was pre-treated in the same procedure as in plate A, then dipped into an organic phase for 5 minutes, carefully rinsed with distilled water, and dried in the air. A large difference in the contact angle was observed [$θ_A \approx 68^\circ$, $θ_B \approx 43^\circ$] (Fig 2A), indicating that plate B is less hydrophobic than plate A. Thus, it is apparent that a difference in surface tension $Δγ$ between the front and rear of an oil droplet is generated accompanied by its translational motion. Once $Δγ$ becomes non-zero due to some spontaneous small motion driven by the Marangoni effect, an oil droplet tends to continue the directed motion by avoiding the backward movement due to the memory effect of the chemical condition [14, 15].

The generation of a difference in surface tension between the front and rear can be explained as schematically shown in Fig 2B. Since the surface of the glass substrate has a negative charge, STA$^+$ (Stearyl Trimethyl Ammonium Ion) is arranged on the glass plate with the head group attached to the surface and the hydrophobic tail toward the water phase; as a result, the glass surface that faces the aqueous solution is hydrophobic. When an oil droplet exhibits a directed motion due to the
Marronogi effect, STA$^+$ attached to the surface tends to dissolve into the organic phase. Consequently, the glass surface becomes less hydrophobic, and the difference in surface tension is generated between the front and rear of the droplet. This imbalance in the surface tension promotes directed motion against viscous damping. The existence of I$^-$, made from I$^{-}$ and I$_2$ in an oil droplet accelerates the transfer of STA$^+$ from the surface into the organic phase $\xi$ by creating a hydrophobic ion pair with STA$^+$. Significantly, the surface of the glass substrate spontaneously returns to the hydrophobic state soon after an oil droplet passes by, since STA$^+$ in the aqueous phase tends to be absorbed onto the glass substrate. This mechanism allows the trajectory of an oil droplet to cross itself; thus, rhythmic and repetitive motion is generated in our system.

An oil droplet ceases its motion accompanied with the decrease of the chemical nonequilibricity. This is explained as follows. As I$^-$ concentration decreases in the oil droplet because of pairing with STA$^+$, the oil droplet cannot afford enough driving force, then the oil droplet stops. We have also found that with the decrease of the size of droplet, its translational speed tends to be larger and the lifetime of self-motion to be shorter. This may be due to the enhanced surface effect on smaller system.

Let us now discuss the mechanism of the appearance of regular, rhythmic motion in the self-agitating system. The characteristic feature of the motion of an oil droplet can be described as

$$m \frac{dv}{dt} = -\eta v + \frac{v}{|v|} + \xi(t).$$

The first term represents the resistance force and the second term represents the driving force caused by the difference in surface tension, where we incorporate the characteristics of self-motion to prohibit backward motion as in Fig.2B. The third term $\xi$ represents the Gaussian random force whose standard deviation is $\sigma$ resulting from the inhomogeneity of the glass surface and the oil/water interface. Figure 2 shows schematic examples of simulated oil-droplet motion based on Eq.1. We consider that the driving force is comparable to the Gaussian random force ($\epsilon \sim \sigma$). As for the boundary condition corresponding to the edge of a glass substrate, an oil droplet is assumed to exhibit inelastic rebound at the boundary since there exists dissipation caused by reversing convective flow inside the oil droplet. In the absence of edge effect on a vessel, random motion is generated (Fig.3A). In contrast, when the width of the glass substrate $d$ becomes narrower, i.e., when a quasi one-dimensional boundary condition is imposed, periodic regular motion is generated (Fig.3B). This result indicates that the reduction of the effective freedom of motion with an appropriate boundary condition can cause a transition from irregular behaviour to regular behaviour for such a droplet under chemical nonequilibricty.

![Fig. 3: Numerical simulation on the spontaneous motion of an oil droplet at different boundary condition](image)

An oil droplet shows various types of regular motion depending on the shape of the glass substrate. Figure 3A shows an oil droplet moving around a vertical circle, like a roller coaster. The droplet can move up the circle against gravity, where the density of the oil droplet $\rho_{\text{oil}} \approx 1.2$ and the density of the aqueous phase $\rho_{\text{water}} \approx 1.0$. Figure 3B shows the stepping-up motion of an oil droplet. Based on observations in multiple experiments, we have found that the oil droplet tends to climb up the stairs rather than to fall down. Corresponding movies are available online.

In the present study, we have realized regular motion under nonequilibrium noise by setting suitable boundary conditions, where the broken spatial symmetry in the container of the oil/water system reduces the freedom of motion, inducing regular motion of the droplet. Recent studies on single motor proteins have indicated that the mode of such mechanical motion can be switched by changing the internal and boundary conditions. Although the spatial scale of molecular motors in living organisms is much smaller than that of the present experimental system, the generation of regular motion under nonequilibrium in a real experiment may inspire the theoretical consideration of the working mechanism of biological molecular motors.

[23] Simulation was performed through fourth-order Runge-Kutta method with the time step of 0.0001. Each parameter was taken to be as following: $\eta/m = 24$, $\epsilon/m = 0.9$, $\sigma/m = 10$, $d = 0.001$, $a = 0.013$ and (coefficient of rebound) = 0.5.

[24] Additional explanation on the simulation, in Figure 3: The mechanism to generate quasi one-dimensional motion on a narrow stripe. From Eq. (1), the characteristic velocity $v_c$ and the relaxation time $\tau_r$ are given as follows: $v_c = \epsilon/\eta$, $\tau_r = m/\eta$. The characteristic time span $\tau_r$ between each rebound is $\tau_r = d/v_c = \eta d/\epsilon$ where $d$ is the free width of glass substrate. We have concluded that, when $\tau_r \ll \tau_r$, i.e. when $d$ is small enough, the velocity that is perpendicular to long axis of substrate is suppressed as long as there is loss of velocity at each rebound.

[25] The magnitude of the driving force and the difference in surface tension. In Fig.4, an oil droplet moves up vertically on a glass substrate. In this case, the driving force generated by the difference in surface tension, $\Delta \gamma$, between the rear and front should be greater than the gravitational force, $f_{grav}$, acting on the oil droplet. For the experiment in Fig.4, $w \Delta \gamma = f_{grav} \geq 0.04$ [mN], where $w$ is the width of the oil droplet. Since $w \approx 3.4$ [mm], $\Delta \gamma$ should be larger than 11 [mN/mm], which is the same order as acquired value in Fig.2A.
