We investigate how much amount of Greenberger-Horne-Zeilinger (GHZ) entanglement is required in order to prepare a given multipartite state by local operations and classical communication (LOCC). We present a LOCC procedure that asymptotically converts GHZ states into an arbitrary multipartite pure state, whose conversion rate is given by the multipartite discord of the state. This reveals a previously unknown fact that the GHZ entanglement cost of preparing a pure state is not higher than the multipartite discord of the state. It also provides an operational interpretation of multipartite discord for pure states, namely, the consumption rate of GHZ entanglement in the devised procedure.

Introduction.– Quantum entanglement lies at the heart of notable features of quantum physics and the power of quantum information processing [1–4]. Its quantification is an issue of great importance. A possible approach is based on the idea that entanglement is a resource shared between distant parties that cannot be generated by local operations and classical communication (LOCC). More specifically, a scale of entanglement can be created by considering asymptotic conversion (i.e., conversion of \( m \) copies of a state into \( n \) copies of another state for large \( n \) and \( m \)) under LOCC. Entanglement is then quantified as the optimal rate of the asymptotic conversion, \( m/n \), from a resource state to the given state (or vice versa).

Bennett et al. showed that, in the bipartite case, the asymptotic conversion between any pure states is reversible [5], so when quantifying entanglement of bipartite systems, any choice of a pure entangled state as a resource state results in an equivalent quantification. The singlet state is a natural choice for a resource state, and the corresponding conversion rate is called the entanglement cost (and it is called the distillable entanglement for the reverse direction) [2, 5, 6]. The entanglement cost of preparing a bipartite pure state has been shown to equal the entropy of entanglement or, equivalently, the von Neumann entropy of one of the subsystems [6].

Entanglement of multipartite states can be quantified in the same way, but different choices of the resource state may give rise to independent quantifications. For example, there exist asymptotically inequivalent multipartite states such as the Greenberger-Horne-Zeilinger (GHZ) state and the W state. Hence, one may choose a resource state and correspondingly define a multipartite entanglement cost as the optimal conversion rate from the resource state to a given state [8, 11]. However, even achievable rates (i.e., upper bounds for the optimal rate) are not known for any resource state, except in the case where the singlets shared among the multiple parties are used as resource [12]. This can be attributed to the difficulty of analyzing general LOCC [13]. The LOCC conversion between multipartite states has been little studied especially in the asymptotic limit, while there have been studies on the stochastic LOCC conversion [14, 15] and the conversion under asymptotically non-entangling operations [16, 17] in the asymptotic limit.

Here, we consider the GHZ entanglement cost of preparing a quantum state of an arbitrary number of parties, where the \( k \)-partite GHZ state is defined as

\[
|\text{GHZ}\rangle = \frac{1}{\sqrt{2}}(|0\rangle^\otimes k + |1\rangle^\otimes k),
\]

with \(|0\rangle\) and \(|1\rangle\) denoting orthogonal basis states for local subsystems. We present a LOCC procedure, \( \mathcal{L}_D \), for the asymptotic conversion from GHZ states to a multipartite pure state \( \psi \), namely,

\[
|\text{GHZ}^\otimes n\rangle \xrightarrow{\mathcal{L}_D} \psi^\otimes n
\]

for sufficiently large \( n \). We find that the conversion rate of this procedure, \( R_D \), is given by the multipartite discord of state \( \psi \), captured by the relative entropy of discord. This implies that the optimal rate is upper bounded by the relative entropy of discord. Our study further provides an operational interpretation of multipartite discord for pure states, namely, the consumption rate of GHZ entanglement in the devised procedure. In the multipartite setting, quantum discord is a measure that is independent from entanglement (although they are equal for bipartite pure states), but its roles and meanings are not well understood compared to those of bipartite discord in several information tasks [13, 18].

Definitions.– We consider a multipartite system \( P = \{P_1, \ldots, P_k\} \), consisting of \( k \) subsystems of an arbitrary dimension. A \( k \)-partite quantum state is called fully separable if it can be written in a form of \( \sum_j \rho_j \otimes \cdots \otimes \rho_{kj} \). We denote the set of separable states by \( \mathcal{S} \). We also denote an arbitrary orthonormal basis for the \( j \)-th subsystem by \( \{|x_j\rangle\} \), where \( x_j \)'s are integers from 0 to
dim(P) - 1. We can then construct a separable basis for the whole system as \{x_1, \ldots, x_k\} = \{x_1, \ldots, x_k\}. The basis states for the whole system contain no nonclassical correlation, so we call their classical mixtures classically correlated states. To clarify, a k-partite quantum state \(\sigma\) is said to be classically correlated if it can be written as

\[
\sigma = \sum_{x_1, \ldots, x_k} p(x_1, \ldots, x_k) |x_1, \ldots, x_k\rangle \langle x_1, \ldots, x_k|.
\]

We denote the set of classically correlated states by \(\mathcal{C}\).

Apart from the quantification of entanglement based on the LOCC conversion, there is an axiomatic approach to measuring entanglement. In this approach, an entanglement measure is given as a function of the density matrix that satisfies some desirable properties. One such measure is the relative entropy of entanglement defined as \[24\]

\[
\mathcal{E}_R(\rho) = \min_{\sigma \in \mathcal{S}} S(\rho||\sigma)
\]

where \(S(\rho||\sigma) = -\text{tr}(\rho \log_2 \sigma) - S(\rho)\) is the relative entropy of \(\rho\) to \(\sigma\) and \(S(\rho) = \text{tr}(\rho \log_2 \rho)\) is the von Neumann entropy of \(\rho\). When dealing with many copies of a state, it is desirable to consider the regularized version of \(\mathcal{E}_R\) defined as \[22\]

\[
\mathcal{E}_R^\infty(\rho) = \lim_{t \to \infty} \frac{\mathcal{E}_R(\rho^{\otimes t})}{t}.
\]

Using the set of classically correlated states, \(\mathcal{C}\), the relative entropy of discord \[26\] and its regularized versions are defined as

\[
\mathcal{D}_R(\rho) = \min_{\sigma \in \mathcal{C}} S(\rho||\sigma), \quad \mathcal{D}_R^\infty(\rho) = \lim_{t \to \infty} \frac{\mathcal{D}_R(\rho^{\otimes t})}{t},
\]

respectively. From the definitions, it is evident that \(\mathcal{D}_R^\infty \leq \mathcal{D}_R\) and \(\mathcal{E}_R^\infty \leq \mathcal{E}_R\). As already mentioned, \(\mathcal{D}_R = \mathcal{E}_R\) for any bipartite pure state, but they are generally not equal for k-partite pure states with \(k > 2\). It has been shown that one can always find a separable basis \(\{x_1, \ldots, x_k\}\) such that the complete set of projectors \(\{\Pi_j\} = \{|x_1, \ldots, x_k\rangle \langle x_1, \ldots, x_k|\}\) satisfies \(\mathcal{D}_R(\rho) = S(\rho||\sum_j \Pi_j \rho \Pi_j)\). We then obtain

\[
\mathcal{D}_R(\psi) = \min_{\{\Pi_j\}} \left[-\sum \text{tr}(\Pi_j \psi) \log_2 \text{tr}(\Pi_j \psi)\right]
\]

for a pure state \(\psi\).

To address the GHZ entanglement cost, we define the asymptotic preparation as follows. We say that a LOCC procedure, denoted by \(L\), asymptotically prepares \(\psi\) from GHZ states at rate \(R\) if \(F(\psi^{\otimes n}, L(\text{GHZ}^{\otimes m})) \to 1\) and \(m/n \to R\) as \(n \to \infty\), where \(F(\rho, \sigma) = \text{tr}(\sqrt{\rho \sigma \rho} \sigma)\) is the fidelity between two quantum states \(\rho\) and \(\sigma\). We then provide our main result as follows. First, we introduce a pure state \(\Psi\) that approximates \(\psi^{\otimes n}\). It is based on the asymptotic equipartition property (AEP) \[30\] which will be briefly explained. Next, we present a LOCC procedure that prepares \(\Psi\) from a certain number of copies of a GHZ state, say \(m\) copies. Finally, we prove that \(F(\Psi, \psi^{\otimes n}) \to 1\) and \(m/n \to R\) as \(n \to \infty\), so they collectively verify that the LOCC procedure asymptotically prepare \(\psi\) at rate \(R\).

**Introduction of an approximate state.**—Here we introduce a pure state \(\Psi\) that approximates \(\psi^{\otimes n}\) (i.e., \(F(\psi^{\otimes n}, \Psi) \to 1\) for \(n \to \infty\)). For simplicity, we only consider tripartite systems, but the generalization to any k-partite system is straightforward.

We begin with summarizing the AEP \[30\]. Consider independent and identically distributed random variables \(X^{(1)}, \ldots, X^{(l)}\). Each of the variables has the same probability distribution \(p(x)\) and the Shannon entropy \(H\). We define a typical set \(A_\epsilon\) to be a set of sequences \(\{x^t = (x^{(1)}_t, \ldots, x^{(l)}_t)\}\) which satisfy \(2^{-l(H+\epsilon)} \leq p(x^t) \leq 2^{-l(H-\epsilon)}\). Then, the AEP states that the typical sequences \(\{x^t\}\) contain most of the probability, and the size of the typical set, \(|A_\epsilon|\), is about \(2^{lH}\). The AEP is summarized as follows. For any \(\epsilon > 0\),

\[
\Pr[x^t \in A_\epsilon] > 1 - \epsilon, \quad |A_\epsilon| \geq (1 - \epsilon)2^{l(H-\epsilon)}, \quad |A_\epsilon| \leq 2^{lH+\epsilon}
\]

for sufficiently large \(l\).

Consider a tripartite system \(P = \{P_1, P_2, P_3\}\) and a pure state \(\psi\) that we want to asymptotically prepare. We denote its t-copy state by \(\psi^{\otimes t}\) and write it in a separable basis \(\{|x_1, \ldots, x_k\rangle\}\) as

\[
|\psi^{\otimes t}\rangle = \sum_{x_1, x_2, x_3} C(x_1, x_2, x_3) |x_1, x_2, x_3\rangle
\]

with some coefficients \(C(x_1, x_2, x_3)\). We note that \(\{|x_j\rangle\}\’s can be any orthonormal bases for each subsystem, and we do not choose any particular separable basis at this point. The coefficients \(|C(x_1, x_2, x_3)|^2\) can be considered a joint probability distribution of random variables \(X_1, X_2,\) and \(X_3\), so we set \(p(x_1, x_2, x_3) = |C(x_1, x_2, x_3)|^2\) and

\[
H = -\sum |C(x_1, x_2, x_3)|^2 \log_2 |C(x_1, x_2, x_3)|^2
\]

We may consider independent and identically distributed random variables \(X_1^{(j)}, \ldots, X_3^{(j)}\) for \(j = 1, 2,\) and \(3\). Then, a typical set is defined as

\[
A_\epsilon = \{(x_1^{(j)}, x_2^{(j)}, x_3^{(j)}) : \|\log_2 p(x_1^{(j)}, x_2^{(j)}, x_3^{(j)}) - H\| \leq \epsilon\}
\]

Using the typical set, \(n = t \cdot l\) copies of \(\psi\) is represented as

\[
|\psi^{\otimes n}\rangle = \sum_{(x_1, x_2, x_3) \in A_\epsilon} C(x_1, x_2, x_3) |x_1, x_2, x_3\rangle + \sum_{(x_1', x_2', x_3') \in A_\epsilon^c} C(x_1', x_2', x_3') |x_1', x_2', x_3'|,
\]

where \(\mathcal{C}\) is the set of classically correlated states by \(\mathcal{C}\).
where $\mathcal{A}^c_r$ is the complement of $\mathcal{A}_r$. The approximated state $\Psi$ is defined to consist of only the terms corresponding to the typical sequences, so

$$|\Psi\rangle = N_r^{-\frac{1}{2}} \sum_{\{x_1, x_2, x_3\}} C(x_1, x_2, x_3) |x_1, x_2, x_3\rangle$$

where $N_r = \sum_{\{x_1, x_2, x_3\}} |C(x_1, x_2, x_3)|^2$ is a normalization factor. As the typical set contains most of the probability, we see that the fidelity between $\Psi$ and $\psi^{\otimes n}$ approaches one as $n \to \infty$. In addition, it follows from the AEP that the number of terms in the expansion of $\Psi$, $|\mathcal{A}_r|$, is approximately $2^{H_2}$.

**Preparation of the approximate state.** – We now present the LOCC procedure $\mathcal{L}_D$ that converts $\log_2 |\mathcal{A}_r|$ copies of a GHZ state into $\Psi$, so $\mathcal{L}_D(\text{GHZ}^{\otimes \log_2 |\mathcal{A}_r|}) = \Psi$. For convenience of mathematical descriptions, we change the notation as follows. For $x_1', x_2'$, and $x_3$ such that $(x_1', x_2', x_3) \in \mathcal{A}_r$, consider the following sets: $\{x_1', x_2', x_3\}$, $\{x_1', x_2\}$, and $\{x_1, x_2, x_3\}$, whose sizes are $|\mathcal{A}_r|, \alpha, \beta$, and $\gamma$, respectively. We replace $(x_1, x_2, x_3)$ with $y$ where $y \in \{0, 1, \ldots, |\mathcal{A}_r| - 1\}$. Similarly, we do the same for other sets as

$$\{x_1\} \to \{f : f \in 0, \ldots, \alpha - 1\},$$

$$\{x_2\} \to \{g : g \in 0, \ldots, \beta - 1\},$$

$$\{x_3\} \to \{h : h \in 0, \ldots, \gamma - 1\}.$$ 

Because $f$, $g$, and $h$ are completely determined by $y$, we denote them by $f(y)$, $g(y)$, and $h(y)$. We can then rewrite the state $\Psi$ of the system $\mathcal{P}$ as

$$|\Psi\rangle_{\mathcal{P}} = N_r^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} C(y)|f(y), g(y), h(y)\rangle_{\mathcal{P}}.$$ 

The state $\Psi$ can be obtained from $GHZ^{\otimes \log_2 |\mathcal{A}_r|}$ by following four steps of LOCC. Assume that $\log_2 |\mathcal{A}_r|$ copies of a GHZ state are prepared in an ancillary system $\mathcal{P}' = \{P_1', P_2', P_3'\}$. It is equivalent to the $|\mathcal{A}_r|$-dimensional GHZ state, so that we write

$$|\text{GHZ}\rangle_{\mathcal{P}'}^{\otimes \log_2 |\mathcal{A}_r|} = |\mathcal{A}_r\rangle^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} |y, y, y\rangle_{\mathcal{P}'}.$$ 

The first step is to change the coefficients from $|\mathcal{A}_r|^{-1/2}$ to $N_r^{-1/2} C(y)$ as

$$|\mathcal{A}_r\rangle^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} |y, y, y\rangle_{\mathcal{P}'} \xrightarrow{\text{Step 1}} N_r^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} C(y)|y, y, y\rangle_{\mathcal{P}'}.$$ 

This can be done by local operations of any party. Consider a local measurement described by the measurement operators

$$\{M_j = N_r^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} D(y \oplus j)|y\rangle\langle y|, 0 \leq j \leq |\mathcal{A}_r| - 1\}$$ 

where $\oplus$ denotes addition modulo $|\mathcal{A}_r|$. It is easy to check that they satisfy the completeness relation $\sum_j M_j \otimes M_j = I$. After the measurement, if the outcome of the measurement is $j$, each of parties applies a unitary operation $U: |y\rangle \to |y \oplus j\rangle$ to complete the first step. The second step is to create the state $|f(y), h(y), g(y)\rangle_{\mathcal{P}}$ in the system $\mathcal{P}$, which is initially prepared in $|000\rangle_{\mathcal{P}}$.

$$\xrightarrow{\text{Step 2}} N_r^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} C(y)|y, y, y\rangle_{\mathcal{P}'} \otimes |f(y), h(y), g(y)\rangle_{\mathcal{P}}.$$ 

This is achieved by a local unitary operation on $P_1P_1'$ that transforms $|y\rangle_{P_1'} \otimes |0\rangle_{P_1}$ into $|y\rangle_{P_1'} \otimes |f(y)\rangle_{P_1}$, and similar local unitary operations on $P_3P_3'$ and $P_2P_2'$.

The third step is to disentangle $P_2'$ and $P_3'$ as

$$\xrightarrow{\text{Step 3}} N_r^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} C(y)|y\rangle_{P_2'} \otimes |f(y), g(y), h(y)\rangle_{\mathcal{P}}.$$ 

In order to perform this step, the second and third parties perform local measurements on their systems using the measurement operators

$$\{N_j = |\mathcal{A}_r\rangle^{-1} |J_j\rangle\langle J_j|\},$$

where $J$ is the complex Hadamard operation, defined as $|yJ_j\rangle = \exp[2\pi i \cdot yJ_j]/|\mathcal{A}_r|$. Depending on the measurement outcomes, the first party can perform a phase-shifting operation to complete the third step.

The final step is to disentangle the ancillary system $P_1'$ from $\mathcal{P}$ to obtain $\Psi_{\mathcal{P}}$ as

$$\xrightarrow{\text{Step 4}} N_r^{-\frac{1}{2}} \sum_{y=0}^{\log_2 |\mathcal{A}_r| - 1} C(y)|f(y), g(y), h(y)\rangle_{\mathcal{P}} = |\Psi\rangle_{\mathcal{P}}.$$ 

To complete this, the first party needs to apply a suitable isometry transformation, which requires additional ancillary qubits. Then, this step can be completed by a measurement on $P_1'$ followed by local phase-shifting operations on $P_1$, $P_2$, and $P_3$. We leave the details of this step to Supplemental Material [3].

**Asymptotic preparation from GHZ states.** – The LOCC procedure $\mathcal{L}_D$ described above prepares $\Psi$ from $GHZ^{\otimes \log_2 |\mathcal{A}_r|}$, i.e., $\mathcal{L}_D(\text{GHZ}^{\otimes \log_2 |\mathcal{A}_r|}) = \Psi$. In practice, it can asymptotically prepares $\psi$ from GHZ states at rate $D_{\text{E}}(\psi)$. This can be explained as follows. First, the AEP implies that the fidelity $F(\Psi, \psi^{\otimes n})$ approaches one as $n \to \infty$, so $\mathcal{L}_D$ asymptotically prepares $\psi^{\otimes n}$. Second, the conversion rate, which is given by $n^{-1}\log_2 |\mathcal{A}_r|$, can be reduced down to $D_{\text{E}}(\psi)$. Recall that the typical set in Eq. 3 depends on the separable basis $\{x_1, x_2, x_3\}$, which we have not specified yet. We now choose the separable basis so that it gives the minimum size of the typical set. Let us denote the minimum size by $\log_2 |\mathcal{A}_r^c|$ and denote the corresponding Shannon entropy by $H^*$. 
It then follows from the AEP that \( \log_2 |A^*| \approx H^* \). In addition, a comparison between Eqs. 4 and 5 leads to \( H^* = D_R(\psi^{\otimes t}) \). Putting these together, we have
\[
n^{-1} \log_2 |A^*| = (t \cdot t^{-1} \log_2 |A^*| \approx t^{-1} D_R(\psi^{\otimes t}).
\]
Finally, from the definition of \( D_R^\infty \), the conversion rate is approximately found to be \( D_R^\infty(\psi) \) for large \( t \). We thus reach the following theorem.

**Theorem.** The above LOCC procedure \( L_D \) asymptotically prepares a multipartite pure state \( \psi \) from GHZ states at rate \( D_R^\infty(\psi) \). Namely, for any \( \epsilon > 0, \delta > 0, \)
\[
F[L_D(GHZ^{\otimes n}, |A^*|), \psi^{\otimes n}] > 1 - \epsilon, \\
|n^{-1} \log_2 |A^*| - D_R^\infty(\psi)| < \delta. 
\] (13)
for sufficiently large \( n \). A more rigorous proof of this theorem is presented in Supplemental Material [31].

**Upper and lower bounds for the GHZ entanglement cost.** We denote by \( E_c \) the GHZ entanglement cost, equivalently, the optimal rate. LOCC does not increase entanglement, so \( E_c(GHZ^{\otimes n}) \leq E_c(GHZ^{\otimes n}) \) for any entanglement measure \( E \). Using this, we find that the regularized version of any entanglement measure, \( E^\infty \), is a lower bound for \( E_c \), provided that \( E^\infty(GHZ) = 1 \) and it satisfies the continuity condition, i.e., if \( F(\rho^{\otimes n}, \sigma^{\otimes n}) \rightarrow 0 \) as \( n \rightarrow \infty \), then \( 1/2 [E(\rho^{\otimes n}) - E(\sigma^{\otimes n})] \rightarrow 0 \) as \( n \rightarrow \infty \). The relative entropy of entanglement defined in Eq. 11 satisfies the continuity condition and \( E^\infty(GHZ) = 1 \) that leads to
\[
E^\infty(\psi) \leq E_c(\psi) \leq D_R^\infty(\psi).
\]
For generalized GHZ states, \( \sqrt{p}(000) + \sqrt{1-p}(111) \), the two bounds coincide, so that our procedure is optimal and \( E_c = D_R^\infty = -p \log_2 p - (1-p) \log_2(1-p) \). In addition, it is known that GHZ states can be distilled from the generalized GHZ states at the same rate [33].

The GHZ entanglement cost can be either greater or less than 1 as \( E^\infty \) and \( D_R^\infty \) can be so. For instance, the GHZ entanglement cost of generalized GHZ states is less than or equal to one as we have shown. For the state \( (|000| + |111|)/\sqrt{2} \), \( E^\infty = 1 \) and \( D_R = 1.5 \) [35] so that \( 1 \leq E_c \leq 1.5 \). In the case of the \( W \) state, \( |W\rangle = (|001\rangle + |010\rangle + |100\rangle)/\sqrt{3} \), \( E^\infty = 2 \log_2 2 - 3 \approx 1.169 \) [36] and \( D_R = \log_2 3 \approx 1.585 \), so that 1.169 < \( E_c < 1.585 \).

**Comparison with preparation of states from singlets.** For comparison, we consider a LOCC procedure that prepares a multipartite pure state \( \psi^{\otimes n} \) from the singlets shared among \( P \) [12]. In this procedure, a single party, say the first party, locally prepares the pure state \( \psi^{\otimes n}_P \) and uses quantum teleportation and data compression to distribute the state [12]. For the tripartite case, it requires \( n(S_2 + S_3) \) singlets between \( P_1-P_2 \) and \( nS_3 \) singlets between \( P_1-P_3 \), where \( S_i \) denotes the von Neumann entropy of the \( i \)-th subsystem. Therefore, it requires \( n(S_2 + S_3) \) singlets in total. Considering all the permutations of \( P_1, P_2 \) and \( P_3 \), the consumption rate of singlets is
\[
R_T = S_1 + S_2 + S_3 - \max\{S_1, S_2, S_3\}.
\]
Since a singlet is obtainable from a single copy of a GHZ state, this procedure can also be achieved by consuming GHZ entanglement at rate \( R_T \). We have no proof for \( D_R^\infty \leq R_T \) for general states. However, it has been shown in Ref. [37] that \( D_R \leq R_T \) (so \( D_R^\infty \leq R_T \)) for a few kinds of three-qubit states including the generalized \( W \) states \( \alpha(001) + \beta(010) + \gamma(100) \), and generalized GHZ states \( \alpha(000) + \beta(111) \). For instance, for the \( W \) state, \( D_R \approx 1.585 \) and \( R_T \approx 1.837 \). We also realize that \( D_R^\infty = 1/kR_T \) for the \( k \)-qubit generalized GHZ states, \( \alpha(0^{\otimes k}) + \beta(1^{\otimes k}) \). In the case of the \( k \)-qubit \( W \) state \( (|00 \cdots 1\rangle + |00 \cdots 0\rangle + \cdots + |10 \cdots 0\rangle)/\sqrt{k} \), one can check that \( D_R \leq R_T \) for any \( k \).

We finally note that the relation \( E_C \leq D_R^\infty \) does not hold for general mixed states as shown in Supplemental Material [31]. For a mixed state, our LOCC procedure can be used to prepare each pure state that constitutes the mixed state so that the mixed state is prepared by classically mixing the pure states. The corresponding consumption rate of the GHZ entanglement is provided in Supplemental Material [31].

**Conclusion.** We have suggested a LOCC procedure that asymptotically prepares an arbitrary pure state from GHZ states where the conversion rate is found to be the multipartite quantum discord. It leads to a previously unknown fact that the GHZ entanglement cost of preparing a multipartite pure state is not higher than multipartite quantum discord of the state. Our work provides an operational interpretation of multipartite quantum discord in relation to a multipartite entanglement cost.

SUPPLEMENTAL MATERIAL

In the main text, a series of local operations and classical communication (LOCC), denoted by $L_D$, is given to asymptotically prepare a multipartite pure state. In this Supplemental Material, we provide the fourth step of $L_D$, the rigorous proof of the theorem in the main text, and the application of $L_D$ to general mixed states.

The fourth step of $L_D$

The fourth step of the procedure $L_D$ is

$$N_c^{-\frac{1}{2}} \sum_{y=0}^{\lvert A_c \rvert - 1} C(y)|y\rangle_p^f \otimes |f(y), g(y), h(y)\rangle_p \quad (14)$$

where $f$, $g$, and $h$ are variables that can have values from 0 to $\alpha - 1$, $\beta - 1$, and $\gamma - 1$ respectively, as defined in Eq. (8) of the main text. We note that they satisfy $(f(y'), g(y'), h(y'))|f(y), g(y), h(y)\rangle = \delta_{y,y'}$. The fourth step can be achieved by the following local operations and classical communication (LOCC). First, we introduce a new variable $K(y)$, which is defined as

$$K(y) = \beta \gamma f(y) + \gamma g(y) + h(y), \quad (15)$$

where we note that $K(|A_c|) \geq |A_c|$. We attach additional ancillary qubits to $P'_1$ so that the dimension of $P'_1$ equals $K(|A_c|) + 1$. Then, we can consider a linear isometry transformation $V$ on $P'_1$ which transforms $|y\rangle$ into $|K(y)\rangle$. Applying $V$ to the state in Eq. (14) gives

$$\sum_{y=0}^{\lvert A_c \rvert - 1} C(y)|y\rangle_K \otimes |f(y), g(y), h(y)\rangle_p.$$

Next, the first party performs a measurement on the ancillary system $P'_1$ using the operators

$$\left\{ N_j : N_j = |K(|A_c|) + 1|^{-\frac{1}{2}} |j\rangle \langle j|, \quad 0 \leq j \leq K(|A_c|) \right\},$$

where $J$ is the complex Hadamard operation defined as

$$\langle y|J|y'\rangle = \exp \left[ 2\pi i \cdot yy' \cdot [K(|A_c|) + 1]^{-1} \right]$$

for $0 \leq y, y' \leq K(|A_c|)$. The completeness relation, $\sum_j N_j^\dagger N_j = I$, can be checked from the orthogonality of the Hadamard operation, $JJ^\dagger = |A_c| \cdot I$. If the measurement outcome is $j$, the resulting state is

$$|0\rangle_{P'_1} \sum_{y=0}^{\lvert A_c \rvert - 1} C(y)|j\rangle_K |f(y), g(y), h(y)\rangle_p$$

$$= |0\rangle_{P'_1} \sum_{y=0}^{\lvert A_c \rvert - 1} C(y)e^{-2\pi i \cdot jK(y)} \otimes |f(y), g(y), h(y)\rangle_p.$$

Finally, local phase-shifting operations can remove the phase $\exp[-2\pi i \cdot jK(y)]$ by using Eq. (15). Consider a phase-shifting operation by the first party that transforms

$$|f(y)\rangle \rightarrow \exp[2\pi i \cdot j\gamma f(y)]|f(y)\rangle.$$

Similarly, consider phase-shifting operations by the second and the third parties that transform

$$|g(y)\rangle \rightarrow \exp[2\pi i \cdot j\gamma g(y)]|g(y)\rangle,$$

$$|h(y)\rangle \rightarrow \exp[2\pi i \cdot jh(y)]|h(y)\rangle.$$

Applying those operations completes the fourth step.

Proof of the theorem

The LOCC procedure, $L_D$, works for any separable basis $\{|x_1, x_2, x_3\}\}$ in Eq. (5) of the main text. In a given separable basis, the Shannon entropy of the random variables $X_1, X_2,$ and $X_3$ is given as

$$H = -\sum |C(x_1, x_2, x_3)|^2 \log_2 |C(x_1, x_2, x_3)|^2,$$

where $|C(x_1, x_2, x_3)|^2 = \text{tr}(|x_1, x_2, x_3\rangle\langle x_1, x_2, x_3|\psi^{\otimes 3})$. Note that the typical set $A_c$ depends on the separable basis and so does the Shannon entropy. We can make $H = D_R(\psi^{\otimes 3})$ by choosing a suitable separable basis. Using the expression of $D_R$ in Eq. (3) of the main text, we can write

$$D_R(\psi^{\otimes 3}) = \min_{\{\{x_1, x_2, x_3\}\}} \left[ -\sum \text{tr}(|x_1, x_2, x_3\rangle\langle x_1, x_2, x_3|\psi^{\otimes 3}) \log_2 \text{tr}(|x_1, x_2, x_3\rangle\langle x_1, x_2, x_3|\psi^{\otimes 3}) \right].$$

If we choose a separable basis that attains the minimum in the above equation, then we have $H = D_R(\psi^{\otimes 3})$. For clarity, we denote the corresponding typical set by $A_c^*$ and the corresponding Shannon entropy by $H^*$. Then, it
follows from the AEP that, for any $\epsilon' > 0$,

$$N_{\epsilon'} > (1 - \epsilon'),$$

$$2^{-l(H^* + \epsilon')} \leq |C(x_1^t, x_2^t, x_3^t)|^2 \leq 2^{-l(H^* - \epsilon')}$$

and

$$(1 - \epsilon')2^{l(H^* - \epsilon')} < |A^*_\epsilon| \leq 2^{l(H^* + \epsilon')}$$

for sufficiently large $l$. From the first inequality in Eq. (16), the fidelity is bounded as

$$F \left[ L_D(GHZ^{[\log_2 |A^*_\epsilon|]}, \psi^\otimes n) \right] = \sum_{x_1^l} \frac{|C(x_1^l, x_2^l, x_3^l)|^2}{N_{\epsilon}^2}$$

$$= N_{\epsilon'}^l > (1 - \epsilon')^\frac{l}{2}.$$ 

We can choose $\epsilon'$ such that $\epsilon' < 1 - (1 - \epsilon)^2$, and it gives $F[L_D(GHZ^{[\log_2 |A^*_\epsilon|]}, \psi^\otimes n)] > 1 - \epsilon$. 

Because the LOCC procedure asymptotically prepares $\psi^n$ from $GHZ^{[\log_2 |A^*_\epsilon|]}$, the conversion rate is given by $n^{-1} \log_2 |A^*_\epsilon|$ with $n = t \cdot l$. Using Eq. (16) and $H^* = D_R(\psi^\otimes t)$, it is straightforward to show that

$$\left| \frac{\log_2 |A^*_\epsilon|}{l} - D_R(\psi^\otimes t) \right| < \epsilon' = \frac{\log_2 (1 - \epsilon')}{l}.$$ 

By choosing $\epsilon'$ such that $\epsilon' - \frac{\log_2 (1 - \epsilon')}{l} < \delta \cdot t$ (there always exists such $\epsilon' > 0$ for any $l, t, \delta > 0$) and dividing the above equation by $t$, we have

$$\left| \frac{\log_2 |A^*_\epsilon|}{n} - \frac{D_R(\psi^\otimes t)}{t} \right| < \delta.$$ 

Finally, $D_R(\psi^\otimes t) \cdot t^{-1}$ approaches $D_R^\infty(\psi)$ as $t \to \infty$ by the definition of $D_R^\infty$, and it completes the proof of the theorem.

**Application of $L_D$ to general mixed states**

We discuss the application of $L_D$ to general mixed states. First, we note that the relation $E_C \leq D_R^\infty$ does not hold for general mixed states. This can be shown by taking a counter example of a bipartite state,

$$(1 - 2p)|\Phi^+\rangle\langle\Phi^+| + p|00\rangle\langle00| + |11\rangle\langle11|$$

with $|\Phi^+\rangle = \sqrt{1/2}|00\rangle + \sqrt{1/2}|11\rangle$ and $0 \leq p \leq 1/2$. The entanglement cost of the state is $E_C = H_2(1/2 + \sqrt{p(1 - p)})$ [11] where $H_2(x) = -x \log_2 x - (1 - x) \log_2 (1 - x)$, and the relative entropy of discord is $D_R^\infty = 1 - H_2(p)$. It is then straightforward to show that $E_C > D_R^\infty$ for any $0 < p < 1/2$.

For a general mixed state $\sigma$, our procedure can be applied to prepare the pure states $\psi_i$’s such that $\sigma = \sum_i p_i \psi_i$. Then, the mixed state $\sigma$ can be obtained by classically mixing them. In this case, the rate of the GHZ entanglement consumption is given by

$$R_D(\rho) = \lim_{t \to \infty} \frac{r_D(\rho^\otimes t)}{t}$$

(17)

where

$$r_D(\sigma) = \inf \{ \sum_i p_i D_R(\psi_i) : \sigma = \sum_i p_i \psi_i \}.$$ (18)

For bipartite systems, discord $D_R(\psi_i)$ in Eq. (18) is equal to the entropy of entanglement, so $R_D(\rho)$ is reduced to an entanglement measure known as the regularized entanglement of formation. It is known that the regularized entanglement of formation is equal to the entanglement cost for bipartite states [2]. The rate $R_D$ is zero if the state $\rho$ is fully separable.
