The standard noise model in gravitational wave (GW) data analysis assumes detector noise is stationary and Gaussian distributed, with a known power spectral density (PSD) that is usually estimated using clean off-source data. Real GW data often depart from these assumptions, and misspecified parametric models of the PSD could result in misleading inferences. We propose a Bayesian semiparametric approach to improve this. We use a nonparametric Bernstein polynomial prior on the PSD, with weights attained via a Dirichlet process distribution, and update this using the Whittle likelihood. Posterior samples are obtained using a blocked Metropolis-within-Gibbs sampler. We simultaneously estimate the reconstruction parameters of a rotating core collapse supernova GW burst that has been embedded in simulated Advanced LIGO noise. We also discuss an approach to deal with non-stationary data by breaking longer data streams into smaller and locally stationary components.

I. INTRODUCTION

Astronomy is entering a new and exciting era, with the second generation of ground-based gravitational wave (GW) interferometers (Advanced LIGO [1], Advanced Virgo [2], and KAGRA [3]) expected to reach design sensitivity in the next few years. Throughout history, developments in astronomy have led to deeper understandings of the universe. Each time we probe the universe with new sensors, we discover exciting and unexpected phenomena, that challenge our current beliefs in astrophysics and cosmology. GW astronomy promises to do the same, providing a new set of ears to listen to (potentially unanticipated) cataclysmic events in the cosmos.

Apart from the first direct observation of GWs, extracting astrophysical information encoded in GW signals is one of the primary goals in GW data analysis. Since observations are subject to noise, accurate astrophysical predictions rely on an honest characterization of these noise sources. At its design sensitivity, Advanced LIGO will be sensitive to GWs in the frequency band from 10 Hz to 8 kHz. The main noise sources for ground-based interferometers include seismic noise, thermal noise, and photon shot (quantum) noise [1]. Seismic noise limits the low frequency sensitivity of the detectors. Thermal noise is the predominate noise source in the most sensitive frequency band of Advanced LIGO (around 100 Hz), and arises from the test mass mirror suspensions and the Brownian motion of the mirror coatings. Photon shot noise is due to quantum uncertainties in the detected photon arrival rate, and dominates the high frequency sensitivity of the detectors.

Standard assumptions about the noise model in the GW data analysis community rely on detector noise being stationary and Gaussian distributed, with a known power spectral density (PSD) that is usually estimated using off-source data (not on a candidate signal) [1]. Real GW data often depart from these assumptions [5]. It was demonstrated in [6] that fluctuations in the PSD can moderately bias parameter estimates of compact binary coalescence GW signals embedded in LIGO data from the sixth science run (S6).

High amplitude non-Gaussian transients (or “glitches”) in real detector data invalidate the Gaussian noise assumption, and misspecifications of the parametric noise model could result in misleading inferences and predictions. A more sophisticated approach would be to make no assumptions about the underlying noise distribution by using nonparametric techniques. Unlike parametric statistical models, which have a fixed and finite set of parameters (e.g., the Gaussian distribution has two parameters: \( \mu \) and \( \sigma^2 \) representing the mean and variance respectively), nonparametric models have a potentially infinite set of parameters, allowing for much greater flexibility.

The theory of spectral density estimation requires a time series to be a stationary process. If data is not stationary (which is often the case for real LIGO data), it is important to adjust for this by introducing a time-varying PSD. It was demonstrated in [7] that the noise PSD in real S6 LIGO data is in fact time-varying. Variation in detector sensitivity was also shown in [8]. Other GW literature that discusses non-stationary noise include [9] [10]. It would be an over-simplification to assume the Advanced LIGO PSD is constant over time, and to use off-source data in characterizing this. On-source estimation of the PSD would therefore be preferable to mitigate the time-varying nature of the PSD.

There have been attempts reported in the literature to improve the modelling of noise present in GW data,
primarily concentrating on noise with embedded signals from well-modelled GW sources, such as binary inspirals [4] [11] [14], and more recently from GW bursts (un-modelled and typically short duration events) [7] [15].

Under the Bayesian framework, Röver et al [11] used a Student-t likelihood as a generalization to the commonly used Whittle (approximate Gaussian) likelihood [10]. The benefit of the Student-t set-up is two-fold: uncertainty in the noise spectrum can be accounted for via marginalization of nuisance parameters; and outliers can be accommodated due to the heavy-tail nature of the Student-t probability density. A drawback of this method is that the choice of hyperparameters can unduly influence posterior inferences.

Using the maximum likelihood approach, Röver [12] later demonstrated that the Student-t likelihood could be used as a generalization to the matched-filtering detection method commonly used in the analysis of GW signals from well-modelled sources. This approach would not be appropriate for GW bursts, since matched-filtering requires accurate signal models with well-defined parameter spaces.

Littenberg and Cornish [13] used Bayesian model selection to determine the best noise likelihood function in non-Gaussian noise. They considered Gaussian noise with a time varying mean, noise from a weighted sum of two Gaussian distributions (non-Gaussian tails), and a combination of Gaussian noise and glitches (modelled as a linear combination of wavelets).

Littenberg et al [4] demonstrated how one can incorporate additional scale parameters in the Gaussian likelihood, and marginalize over the uncertainty in the PSD to reduce systematic biases in parameter estimates of compact binary mergers in S5 LIGO data. This method requires an initial estimate of the PSD. On a related note, Vitale et al [14] highlighted a Bayesian method, similar to iteratively reweighted least squares, that analytically marginalizes out background noise and requires no a priori knowledge of the PSD. They applied this to simulated data from LISA Pathfinder.

More recently, Littenberg and Cornish [7] introduced the BayesLine algorithm in conjunction with BayesWave [15] to estimate the underlying PSD of GW detector noise. BayesLine is used to model the Gaussian noise component. They use a cubic spline to model the smooth changing broadband noise and Lorentzians (Cauchy densities) to model wandering spectral lines (due to AC supply, violin modes, etc.). BayesWave, on the other hand, models the non-Gaussian instrument “glitches” and burst sources with a continuous wavelet basis. Both methods make use of the trans-dimensional reversible jump Markov chain Monte Carlo (RJCMC) algorithm of Green [17]. BayesLine is very pragmatic and works remarkably well on real Advanced LIGO data. However, the authors did not consider statistically important notions such as the posterior consistency of the PSD [18].

Our approach to improving the GW noise model relies on developments over the past decade in the area of Bayesian nonparametrics. Since parametric modelling can lead to biased estimates when the underlying parametric assumptions are invalid, we prefer nonparametric techniques to estimate the PSD of a stationary noise time series.

A common nonparametric estimate of the spectral density of a stationary time series is the periodogram, calculated using the (normalized) squared modulus of Fourier coefficients. That is,

\[ I_n(\lambda) = \frac{1}{2\pi n} \left| \sum_{t=1}^{n} X_t \exp(-it\lambda) \right|^2, \quad \lambda \in (-\pi, \pi], \]  

where \( \lambda \) is the frequency, and \( \{X_t\} \) is a stationary time series, where \( t = 1, 2, \ldots, n \) represents discretized time. The periodogram randomly fluctuates about the true spectral density of a time series, but is not a consistent estimator, motivating methods such as periodogram smoothing and averaging [19]. Averaging of off-source periodograms from Tukey windowed simulated Advanced LIGO noise has been used in GW literature relating to reconstructing core collapse GWs [20], and predicting the important astrophysical parameters from these events [21].

In this paper, we implement the nonparametric Bayesian spectral density estimation method and Metropolis-within-Gibbs Markov chain Monte Carlo (MCMC) sampler presented by Choudhuri et al [22], which updates a nonparametric Bernstein polynomial prior [23] [21] on the spectral density using the Whittle likelihood to make posterior inferences. A Bernstein polynomial prior is essentially a finite mixture of Beta probability densities (see Section II C and Appendix A). It was proved that this method yields a consistent estimator for the true spectral density of a (short-term memory) stationary time series [22] — an attractive feature, absent in the periodogram. Posterior consistency in this context essentially means that the posterior probability of an arbitrary neighbourhood around the true PSD goes to 1 as the length of the time series increases to infinity. Thus, as the sample size increases, the posterior distribution of the PSD will eventually concentrate in a neighbourhood of the true PSD [18]. This is an important asymptotic robustness quality of the posterior distribution in that the choice of prior parameters should not influence the posterior distribution too much. Especially in Bayesian nonparametrics, because of the high dimension of the parameter space, many posterior distributions do not automatically possess this quality [18]. We refer the reader to Appendix C for a visual demonstration of posterior consistency.

Unlike references [4] [11] [14], we do not treat noise as a nuisance parameter to be analytically integrated out. Although the signal parameters are our primary concern, we are also interested in quantifying our uncertainty in the underlying PSD of the noise in terms of posterior probabilities and credible intervals. Knowledge of this uncertainty will allow us to make honest astrophysical
In this study, we assume that data is the sum of a GW signal embedded in noise (from all noise sources), such that
\[ y = s(\beta) + \epsilon(\theta), \] (2)
where \( y \) is the (coincident) time-domain GW data vector, \( s \) is a GW signal parameterized by \( \beta \), and \( \epsilon \) is noise parameterized by \( \theta \). Notation with a tilde on top, such as \( \tilde{y} \), refers to the frequency-domain equivalent of the same quantity, obtained by the discrete Fourier transform (DFT). Note that we are treating noise in this set-up as the conglomeration of detector noise (such as thermal noise and photon shot noise), background noise (such as seismic noise), and residual errors due to parametric statistical modelling of GW signals. An important caveat is to ensure the magnitude of the errors in the statistical model of the signal are minimized, so as to not artificially dominate the noise. Estimation of spectral lines (as done by the BayesLine algorithm [27]) is left out of the scope of this paper.

The GW signal could essentially come from any source, but in this paper we will restrict our concentration to those from rotating core collapse supernovae to simplify the problem and demonstrate the power of the method. Using the recent waveform catalogue of Abdikamalov et al [25], we conduct principal component analysis (PCA), and fit a principal component regression (PCR) model of the most important principal components (PCs) on an arbitrary rotating core collapse GW signal [20, 21, 26]. The (parametric) signal component is easily embedded as an additional Gibbs step in the Metropolis-within-Gibbs MCMC sampler of Choudhuri et al [22]. That is, we utilize a blocked Gibbs approach to sequentially sample the signal parameters \( \beta \) given the noise parameters \( \theta \), and vice versa. As the model now contains a parametric signal component as well as a nonparametric noise component, it is “semiparametric”.

To accommodate for non-stationary noise, we adapt an idea presented by Rosen et al [27], and assume a non-stationary time series can be broken down into smaller locally stationary segments. For each segment, we separately estimate the PSD using the method of Choudhuri et al [22], and look at the time-varying spectrum.

We see this work as being a complement to existing methods, with the following benefits:

- A Bayesian framework, allowing us to update prior knowledge based on observed data, as well as quantify uncertainty in terms of probabilistic statements;
- Posterior consistency of the PSD, i.e., the posterior distribution will concentrate around the true PSD as the sample size increases;
- No parametric assumptions about the underlying noise distribution (parametric models are very sensitive to misspecifications), and high amplitude non-Gaussian transients in the noise can be handled;
- Non-stationarities can be taken into account by splitting the data into smaller locally stationary segments;
- Estimation of noise and signal parameters are done simultaneously using Gibbs sampling;
- Uncertainty in astrophysically meaningful parameter estimates are honest, with less systematic bias present;
- Non-informative priors can be chosen, and the PSD does not need to be known a priori;
- Useful for any signal with a parametric statistical model (including rotating core collapse supernova GWs).

The paper is structured as follows: Section II outlines the methods and models used to simultaneously estimate signal and noise parameters in GW data; results for toy models and simulated Advanced LIGO data are presented in Section III; and in Section IV, we discuss the consequences of this work, as well as future initiatives. Supplementary material can be found in the three appendices.

II. METHODS AND MODELS

A. Parametric, Nonparametric, and Semiparametric Models

Statistical models can be classified into two groups — parametric and nonparametric. **Parametric** models have a fixed and finite set of parameters, are relatively easy to analyze, and are powerful when their underlying assumptions are correctly specified. However, if the model is misspecified, inferences will be unreliable. **Nonparametric** models have far fewer restrictions, but are less efficient and powerful than their parametric counterparts. No assumption about the underlying distribution of the data is made in nonparametric modelling, and the number of parameters are not fixed (and potentially infinite dimensional). Instead, the effective number of parameters increases with more data, providing the model structure.

For example, parametric regression (including linear models, nonlinear models, and generalized linear models) uses the following equation:
\[ y = g(x_1, x_2, \ldots, x_k|\beta) + \epsilon, \] (3)
where \( y \) is the response variable, \( g(x_1, x_2, \ldots, x_k|\beta) \) is a function of \( k \) explanatory variables (that aim to explain the variability in \( y \) given some model parameters \( \beta \)), and \( \epsilon \) is the statistical error, usually assumed to be independent and identically distributed (iid) Gaussian random
variables, with 0 mean and constant variance $\sigma^2$. Here, the functional form of $g(.)$ is known in advance, such as in linear regression, where we have

$$g(x_1, x_2, \ldots, x_k|\beta) = \beta_0 + \beta_1 x_1 + \ldots + \beta_k x_k. \quad (4)$$

Nonparametric regression has a similar set-up, but assumes that the functional form of $g(.)$ is unknown and to be learnt from the data. Function $g(.)$ could be thought of as an uncountably infinite-dimensional parameter in a nonparametric setting.

**Semiparametric** models contain both parametric and nonparametric components. The parametric regression model presented in Equations (3) and (4) is essentially the same parametric model used in this paper for GW signal reconstruction, where $(x_1, x_2, \ldots, x_k)$ are principal component (PC) basis functions. However, we model the noise $\epsilon$ nonparametrically, rather than assuming iid Gaussian noise. Since we have parametric and nonparametric components, our model is semiparametric in nature.

### B. Bayesian Nonparametrics

Bayesian nonparametrics contains the set of models on the interface between the Bayesian framework and nonparametric statistics, and is characterized by large parameter spaces and probability measures over these spaces [18]. The Bayesian statistical framework is useful for incorporating prior knowledge, and is particularly powerful when these priors accurately represent our beliefs. As mentioned in the previous section, nonparametric methods are useful for constructing flexible and robust alternatives to parametric models. A benefit of Bayesian nonparametric models is that they automatically infer model complexity from the data, without explicitly conducting model comparison.

Bayesian nonparametrics is a relatively nascent field in statistics, and faces many challenges. The most obvious one is the mathematical difficulty in specifying well-defined probability distributions on infinite-dimensional function spaces. Constructing a prior on these spaces can be arduous, and in the case of non-informative priors, one should ensure large topological support so as not to put too much mass on a small region. Further, creating computationally convenient algorithms to sample from complicated posterior distributions presents its own set of challenges. It is also important to ensure that a Bayesian nonparametric model is statistically consistent (the truth is uncovered asymptotically), as some procedures do not automatically possess this quality [18].

Bayesian nonparametric priors (and posteriors) are stochastic processes rather than parametric distributions. Ferguson [28] provided the seminal paper for the field of Bayesian nonparametrics, introducing the Dirichlet process, an infinite-dimensional generalization of the Dirichlet distribution, now commonly used as a prior in infinite mixture models. This is a popular model (often called the Chinese Restaurant Process) for classification problems where the number of classes is unknown and to be inferred from the data. A formal definition of the Dirichlet distribution and Dirichlet process can be found in Appendix B.

Another popular prior in Bayesian nonparametrics is the Gaussian process prior, which is often used in non-linear regression contexts. In fact, one could extend the regression example in the previous section into the realm of Bayesian nonparametrics by putting a Gaussian process prior on the function $g$. Compare this to the Bayesian parametric counterpart, which puts a prior on the model parameters $\beta$.

For further discussion on Bayesian nonparametrics, we refer the reader to [18].

### C. Spectral Density Estimation

A weakly (or second order) stationary time series $\{X_t\}$ is a stochastic process that has constant and finite mean and variance over time, and an autocovariance function $\gamma(h)$ that depends only on the time lag $h$. That is, for a zero-mean weakly stationary process, the autocovariance function has the form

$$\gamma(h) = \text{E}[X_t X_{t+h}], \quad \forall t.$$  

(5)

where $\text{E}[.]$ is the expected value operator, and $t$ represents time.

Assuming an absolutely summable autocovariance function ($\sum_{h=-\infty}^{\infty} |\gamma(h)| < \infty$), the (real-valued) spectral density function $f(\lambda)$ of a zero-mean weakly stationary time series is defined as

$$f(\lambda) = \frac{1}{2\pi} \sum_{h=-\infty}^{\infty} \gamma(h) \exp(-ih\lambda), \quad \lambda \in (-\pi, \pi].$$  

(6)

where $\lambda$ is the angular frequency. Note that the spectral density function and autocovariance function are a Fourier transform pair. In this paper, we will also call this the power spectral density (PSD) function, although this term is sometimes reserved for the empirical spectrum (periodogram) in the GW literature.

For a mean-centered weakly stationary time series $\{X_t\}$ of length $n$, with spectral density $f(\lambda)$, the Whittle approximation to the Gaussian likelihood, or simply the Whittle likelihood [16] is defined as

$$L_n(x|f) \propto \exp \left( -\sum_{l=1}^{u} \left( \log \frac{f(\lambda_l)}{I_n(\lambda_l)} \right) \right).$$  

(7)

where $\lambda_l = 2\pi l/n$ are the positive Fourier frequencies, $u = (n-1)/2$, $|u|$ is the greatest integer value less than or equal to $u$, and $I_n(.)$ is the periodogram defined in Equation (4). If the PSD is known, the log $f$ term in Equation (7) is a constant and can be ignored. The Whittle
likelihood has an advantage over the true Gaussian likelihood as it has a direct dependence on the PSD rather than the autocovariance function. The Whittle likelihood is only exact for Gaussian white noise but works well under certain conditions, even when the data is not Gaussian [29]. More information about these concepts can be found in any good time series analysis textbook, such as Brockwell and Davis [33].

We now need to specify a nonparametric prior for the PSD. We will briefly introduce the spectral density estimation technique of Choudhuri et al [22], which is based on the Bernstein polynomial prior of Petrone [23] [24]. The Bernstein polynomial prior is a nonparametric prior for a probability density on [0, 1], and is based on the Weierstrass approximation theorem that states that any continuous function on [0, 1] can be uniformly approximated to any desired degree by a Bernstein polynomial. If this function is a density on [0, 1], this Bernstein polynomial is essentially a finite mixture of Beta densities. We refer the reader to Appendix A for a definition of the Bernstein polynomial and Beta density. Instead of putting a Dirichlet prior on the mixture weight vector, the weights are defined via a probability distribution putting a Dirichlet prior on the mixture weight vector, the Bernstein polynomial and Beta density. Instead of using a parametric prior for the PSD, we use a nonparametric prior for the spectral density that approximates the true PSD.

The Bernstein polynomial prior is a nonparametric prior for the probability density on [0, 1] and a Dirichlet process prior is put on the space of probability distributions on [0, 1]. Appendix B contains supplementary material on the Dirichlet process. Since the spectral density is not defined on the unit interval, we reparameterize $f_\lambda$ by the following hierarchical scheme:

- $q(\omega) = \sum_{j=1}^{k} G\left(\frac{j-1}{k}, \frac{1}{k}\right) \beta(\omega, k-j+1)$, where $G$ is a cumulative distribution function, and $\beta(\omega, a, b)$ is a Beta probability density with parameters $a$ and $b$.
- $G$ is a Dirichlet process distributed random probability measure with base measure $G_0$ and precision parameter $M$.
- $k$ has a discrete probability mass function such that $p(k) \propto \exp(-\theta_0 k^2)$, $k = 1, 2, \ldots$.
- $\tau$ has an Inverse-Gamma($\alpha_\tau, \beta_\tau$) distribution.
- $G$, $k$, and $\tau$ are a priori independent.

We use the stick-breaking construction of the Dirichlet process by Sethuraman [31], which is an infinite-dimensional mixture model (defined in Appendix B). For computational purposes, we need to truncate the number of mixture distributions to a large but finite number $L$. The choice of a large $L$ will provide a more accurate approximation but also increase the computation time. Here, we choose $L = \max\{20, n^{1/3}\}$. We therefore reparameterize $G$ to $(Z_0, Z_1, \ldots, Z_L, V_1, \ldots, V_L)$ such that

$$G = \left(\sum_{l=1}^{L} p_l \delta_{Z_l}\right) + \left(1 - \sum_{l=1}^{L} p_l\right) \delta_{Z_0},$$

where $p_1 = V_1$, $p_l = \left(\prod_{j=1}^{l-1} (1 - V_j)\right) V_l$ for $l \geq 2$, $V_l \sim \text{Beta}(1, M)$ for $l = 1, \ldots, L$, and $Z_l \sim G_0$ for $l = 0, 1, \ldots, L$. Note that $\delta_a$ is a probability density, degenerate at $a$. That is, $\delta_a = 1$ at $a$ and 0 otherwise. This yields the prior mixture of the PSD

$$f(\pi \omega) = \tau \sum_{j=1}^{k} w_{j,k} \beta(\omega|j, k-j+1),$$

with weights $w_{j,k} = \sum_{l=0}^{L} p_l I\left\{\frac{l-1}{k} < Z_l \leq \frac{l}{k}\right\}$ and $p_0 = 1 - \sum_{l=1}^{L} p_l$.

Abbreviating the vector of noise parameters as $\theta = (v, z, k, \tau)$, the joint prior is therefore

$$p(\theta) \propto \left(\prod_{l=1}^{L} (1 - v_l) M^{-1}\right) \left(\prod_{l=0}^{L} g_0(z_l)\right) p(k)p(\tau),$$

and is updated using the Whittle likelihood to produce the unnormalized joint posterior.

This method is implemented as a Metropolis-within-Gibbs MCMC sampler. In Choudhuri et al [22], parameters $k$ and $\tau$ are readily sampled from their full conditional posteriors, while $V$ and $Z$ require the Metropolis algorithm with Uniform proposals. Our only variation on this implementation is our sampling of the smoothness parameter $k$. We found that a Metropolis step is faster than sampling from the full conditional. The original implementation contains a for() loop that evaluates the log posterior $k_{\text{max}}$ number of times, where $k_{\text{max}}$ is chosen (during pilot runs) to be large enough to cater for the roughness of the PSD. For most well-behaved cases, $k_{\text{max}} = 50$ will suffice, but the Advanced LIGO PSD requires many more mixture distributions (by one to two orders of magnitude) due its steepness at low frequencies. This is a significant computational burden, and a well-tuned Metropolis step can therefore outperform the original implementation.

A discussion of the Dirichlet process and stick-breaking representation can be found in Appendix B.

D. Signal Reconstruction

To reconstruct a rotating core collapse GW signal that is embedded in noise, we use the (parametric) principal component regression (PCR) method described in [20] [21] [25]. That is, let

$$\hat{y} = \hat{X} \beta + \hat{\epsilon},$$

where $\hat{X}$ is the estimated signal matrix, $\beta$ is the regression coefficients, and $\hat{\epsilon}$ is the estimated noise matrix.
where $\tilde{y}$ is the length $n$ frequency-domain GW data vector, $X$ is the $n \times d$ matrix of the $d$ frequency-domain principal component basis vectors, $\beta$ is the vector of signal reconstruction parameters (PC coefficients), and $\epsilon$ is the frequency-domain noise vector with a known PSD. We assume flat priors on $\beta$. It is important to highlight that useful astrophysical information (such as the ratio of kinetic to gravitational potential energy of the inner core at bounce, and precollapse differential rotation) can be extracted by regressing the posterior means of the PC coefficients $\beta$ on the known astrophysical parameters from the waveform catalogue, and sampling from the posterior predictive distribution [21].

We include an additional Gibbs step in the MCMC sampler described in the previous section to simultaneously reconstruct a rotating core collapse GW signal, whilst also estimating the noise power spectrum. Omitting the conditioning on the data for clarity, we sequentially sample the full set of conditional posterior densities $p(\theta | \beta)$ and $p(\beta | \theta)$, where $\theta = (v, z, k, \tau)$ are the noise parameters defined in the previous section, and $\beta$ are the signal reconstruction parameters. That is, we sample in a cycle from the full conditional posterior distribution of the signal parameters, given the PSD parameters, and the full conditionals of the PSD parameters, given the signal parameters. This set-up is called a blocked Gibbs sampler.

To sample the signal parameters, we fix the most recent MCMC sample of the PSD parameters. The conditional posterior of $\beta$ is

$$P(\beta | \theta) = N(\mu, \Sigma)$$

(13)

where $\Sigma = (\tilde{X}' D^{-1} \tilde{X})^{-1}$ and $\mu = \Sigma \tilde{X}' D^{-1} \tilde{y}$. Here $D = 2\pi \times \text{diag}(f(\lambda))$ is the noise covariance matrix, and $f(\lambda)$ is the most recent estimate of the PSD. More explicitly, at iteration $i+1$ in the blocked Gibbs sampling algorithm:

1. Create time-domain noise vector: $e^{(i+1)}|y = X\beta^{(i)}$. Due to the linearity of the Fourier transform, $\beta$ will be the same no matter if we are in the time-domain or frequency-domain.

2. Sample the PSD parameters $\theta^{(i+1)}|\beta^{(i)}$ using the method of Section II C.

3. Sample the signal parameters $\beta^{(i+1)}|\theta^{(i+1)}$ using Equation [13] (since the PSD in iteration $i+1$ is now known).

E. Non-stationary Noise

As mentioned in Section II C, stationary noise has a constant and finite mean and variance over time, and an autocovariance function that depends only on the time lag. Non-stationary noise does not meet these requirements, and has a time-varying spectrum. Stationarity of a time series can be tested using classical hypothesis tests such as the Augmented Dickey-Fuller test [22], Phillips-Perron unit root test [33], and Kwiatkowski-Phillips-Schmidt-Shin (KPSS) test [34].

To accommodate non-stationary noise, we adapt an idea presented by Rosen et al [27], that assumes a time series can be broken down into locally stationary segments. In their paper, they treat the number of stationary components of a non-stationary time series as unknown, and use RJMCMC [17] to estimate the segment breaks.

In a similar fashion, we break a non-stationary time series (or GW data stream) into $J$ equal segments. We have two requirements for the length of these segments: the segment length is large enough for the Whittle approximation to be valid; and the segments are locally stationary according to heuristics or formal stationarity hypothesis tests. This approach fits nicely into our current MCMC framework. For each segment, we estimate the PSD using the nonparametric method introduced in Section II C. A benefit of this approach is that changepoints in the PSD can be detected without using RJMCMC.

The conditional posterior density for all noise model parameters $\theta$ is the following product

$$\pi(\theta | \beta, \tilde{y}) = \prod_{j=1}^{J} \pi_j(\theta_j | \beta, \tilde{y}_j),$$

(14)

where $\pi_j(\theta_j | \beta, \tilde{y}_j)$ is the conditional posterior density of the model parameters $\theta_j$ in the $j^{th}$ segment given the signal parameters $\beta$ and the $j^{th}$ segment of data $\tilde{y}_j$.

Note that under this set-up, the PC coefficients $\beta$ do not depend on segments $j = 1, 2, \ldots, J$, since we require one set of PC coefficients (not $J$ sets) to reconstruct a rotating core collapse GW signal.

To sample $\beta | \theta$, we use the same approach presented in Section II D. The only difference is in the construction of the noise covariance matrix. This is constructed as $D = 2\pi \times \text{diag}(f_1(\lambda), f_2(\lambda), \ldots, f_J(\lambda))$, where $f_j(\lambda)$ is the PSD of the $j^{th}$ noise segment.

III. RESULTS

For the following examples, we set $L = \max\{20, n^{1/3}\}$, and use the non-informative prior set-up of Choudhuri et al [22]. That is, let $G_0 \sim \text{Uniform}[0, 1], M = 1, \alpha_\tau = \beta_\tau = 0.001$, and $\theta_k = 0.01$. We use $k_{\max} = 50$ for most examples, and $k_{\max} = 400$ for the example with simulated Advanced LIGO noise to cater for the steep drop in the PSD at low frequencies.

For the examples with a signal embedded in noise, we use a Uniform($-\infty, \infty$) prior on the signal reconstruction parameters $\beta$, and let $d = 25$ PCs. For a discussion on the optimal choice of PCs, we refer the reader to [21]. We also scale the signals to a signal-to-noise ratio (SNR) of $\phi = 50$. Here SNR (for $n$ even) is defined as

$$\phi = \sqrt{\frac{2}{n/2+1} \sum_{j=0}^{n/2+1} \frac{|\tilde{s}(\lambda_j)|^2}{|\tilde{e}(\lambda_j)|^2}},$$

(15)
where \( \lambda_j \) are the positive Fourier frequencies, \( \tilde{s}(.) \) is the Fourier transformed signal, and \( \xi(.) \) is the Fourier transformed noise series. Note that for the zero and Nyquist frequencies, the factor of 2 in Equation \( (15) \) becomes a factor of 4.

The value of \( \rho = 0.5 \) is physically motivated, as we would expect to see an SNR of approximately 50 to 170 for rotating core collapse supernova GWs at a distance of 10 kpc. We therefore demonstrate how the method works for the lower end of this range.

The units for frequency in most examples are radians per second (rad/s). In the example using simulated Advanced LIGO noise, we rescale to kilohertz (kHz). PSD units are the inverse of the frequency units, and the PSD figures are scaled logarithmically. GW strain amplitude is unitless.

For all examples, we run the MCMC sampler for 100,000 iterations, with a burn-in period of 50,000 and thinning factor of 10. This results in 10,000 samples retained.

A. Estimating the PSD of Non-Gaussian Coloured Noise

To demonstrate how our model is capable of dealing with non-Gaussian transients in the data (or glitches as they are sometimes called in GW data analysis), we provide an illustrative toy example, using coloured noise generated from a first order autoregressive process, abbreviated to AR(1).

A mean-centered AR(1) process \( \{X_t\} \) is defined as

\[
X_t = \rho X_{t-1} + \epsilon_t, \quad t = 1, 2, \ldots, n, \tag{16}
\]

where \( \rho \) is the first order autocorrelation, and \( \epsilon_t \) is a white noise process (not necessarily Gaussian), with zero mean and constant variance \( \sigma^2 \). With this formulation, we see how the current observation at time \( t \) depends on the previous observation at time \( t - 1 \) through \( \rho \), as well as some white noise \( \epsilon_t \), often referred to as innovations or the innovation process in time series literature.

The AR(1) model is a useful example here since it has a well-defined theoretical spectral density that we can compare our results against. Assuming \( |\rho| < 1 \), the AR(1) process is stationary and has spectral density

\[
f(\lambda) = \frac{\sigma^2}{1 + \rho^2 - 2\rho \cos 2\pi \lambda}, \quad \lambda \in (-\pi, \pi]. \tag{17}
\]

As seen in Equation \( (17) \), the AR(1) process has a PSD that is not flat, and the noise in our toy example is coloured (non-white), with correlations between frequencies — typical of what we would expect with real Advanced LIGO noise. As the AR(1) process has a coloured spectrum, and white noise has a flat spectrum, we will call use the term innovations to refer to the white noise component of the model to avoid confusion.

For our example, rather than using Gaussian innovations, which is the most common innovation process used in autoregressive models, we use Student-\( t \) innovations with \( \nu = 3 \) degrees of freedom. The choice of \( \nu = 3 \) degrees of freedom is the smallest integer that results in a Student-\( t \) model with finite variance (a requirement for the innovation process \{\( \epsilon_t \)\} of an AR(1) model). This model has wider tails than that of the Gaussian model (and in fact the widest tails possible whilst maintaining the finite variance requirement), meaning we can expect extreme values in the tails of the distribution to occur more often. This will be our proxy for glitches.

We refer the reader to a relevant time series analysis textbook such as Brockwell and Davis \cite{32} for further information on AR(1) processes.

For this example, we generate a length \( n = 2^{12} \) AR(1) process with \( \rho = -0.9 \) and Student-\( t \) innovations with \( \nu = 3 \) degrees of freedom. Let this (stationary) time series have sampling interval \( \Delta_t = 1/2^{14} \) (the same as Advanced LIGO). The data set-up can be seen in Figure \( \ref{fig:1} \).

![FIG. 1: Simulated stationary AR(1) process with first-order autocorrelation \( \rho = -0.9 \), and Student-\( t \) innovations (\( \nu = 3 \) degrees of freedom).](image)

We can see the effect of using \( \nu = 3 \) degrees of freedom in Figure \( \ref{fig:1} \). Notice how there are transient high amplitude non-Gaussian events. These are a result of the wide-tailed nature of the Student-\( t \) density. It would be very unlikely to see these high amplitude events if the innovation process was Gaussian.

We now run the noise-only algorithm of Section II C to demonstrate that we can accurately characterize a non-Gaussian noise PSD.
The estimated point-wise posterior median log PSD in Figure 2 is very close to the true log PSD, and the 90% credible region generally contains the true log PSD. This demonstrates that even if there are non-Gaussian transients in the data (which is certainly the case for real LIGO data), this PSD estimation method performs well. This is however not surprising as the Whittle likelihood gives a good approximation to Gaussian and some non-Gaussian likelihoods [29].

B. Extracting a Rotating Core Collapse Signal in Stationary Coloured Noise

In this example, we aim to extract a rotating GW signal from noisy data using the blocked Gibbs sampler described in Section II D. We embed the A1O12.25 rotating core collapse GW signal from the Abdikamalov et al [25] test catalogue (i.e., a signal not part of the base catalogue used to create the PC basis functions) in AR(1) noise with $\rho = 0.9$. For clarity, let this process have a Gaussian white noise innovation process with $\sigma^2 = 1$. Let the time series be length $n = 2^{12}$, which corresponds to 1/4 s of data at the Advanced LIGO sampling rate. The signal is scaled to have a SNR of $\varrho = 50$. The reconstructed signal can be seen in Figure 3.

The rotating core collapse GW signal in Figure 3 is reconstructed particularly well during the collapse and bounce phases (the first few peaks/troughs). The post-bounce ring-down oscillations are usually poorly estimated due to stochastic dynamics [21] [25], but are acceptable for this particular example.

In this example, the signal parameters were simultaneously estimated with the noise PSD using the blocked Gibbs sampler described in Section II D. We now compare the performance of the estimated noise PSD with and without a signal present. That is, we compare the noise PSD estimates between the algorithms presented in Section II C (noise-only model) and Section II D (signal-plus-noise model), using the same noise series for both models.

We can see in Figure 4 that both models (noise-only and signal-plus-noise) perform similarly when estimating the PSD of coloured Gaussian noise. The posterior median log PSDs are approximately equal, and are very close to the true log PSD of an AR(1) process with $\rho = 0.9$. This is a useful robustness check, and demonstrates that we are successfully decoupling the signal from the noise.
C. Comparing Input and Reconstruction Parameters

As there is no analytic form linking the astrophysical parameters of a rotating core collapse stellar event to its GW signal, we can only approximate the GW signal using statistical methods. We do this using PCR, but this means that there are no true input parameters that we can compare with the estimated signal reconstruction parameters. However, if one were to create a fictitious signal as a known linear combination of PCs, we could demonstrate the algorithm’s performance in estimating the signal reconstruction parameters.

Consider the following fictitious rotating core collapse GW signal

\[ y = \sum_{i=1}^{d} \alpha_i x_i, \tag{18} \]

where \( y \) is the length \( n \) signal, \((x_1, x_2, \ldots, x_d)\) are the \( d \) PC basis vectors of length \( n \), and \((\alpha_1, \alpha_2, \ldots, \alpha_d)\) are the “true” weights, or PC coefficients. To randomize the weights, we randomly sample each from the standard normal distribution.

In this example, we embed the fictitious length \( n = 2^{12} \) GW signal in AR(1) noise with \( \rho = 0.9 \) and Gaussian innovations with \( \sigma = 1 \). We set \( d = 10 \). We rescale the signal to have SNR \( \varrho = 50 \), and after the algorithm has run, we rescale our estimated PC coefficients back to the original level for comparison.

![FIG. 5: Posterior median PC coefficients (blue square) and “true” PC coefficients (orange triangle) for the 10 PCs of a fictitious GW signal embedded in AR(1) noise. The error bands are the 95% credible intervals.](image)

It can be seen in Figure 5 that the “true” PC coefficients are generally contained within the 95% credible intervals, demonstrating that the algorithm can estimate a signal’s input parameters well in the presence of stationary coloured noise. Notice also that the credible intervals widen as the principal component number increases. This is due to the fact that higher numbered PCs explain lower amounts of variation in the waveform catalogue, resulting in lower amplitude waves. We would therefore be more uncertain about these PCs embedded in noise.

D. Extracting a Rotating Core Collapse Signal in Time-Varying Coloured Noise

Non-stationary noise has a time-varying spectrum. To illustrate how our method can handle non-stationarities (or change-points in the spectral structure), we simulate a noise series with \( J = 2 \) locally stationary components of equal length \( n_1 = n_2 = 2^{12} \). The first segment of the noise series is generated from an AR(1) process with \( \rho = 0.5 \). The second noise segment comes from an AR(1) process with \( \rho = -0.75 \). Both segments use a Gaussian innovation process with variance \( \sigma^2 = 1 \) for clarity. We embed part of the A108.25 waveform from the Abdikamalov et al catalogue [25]. This waveform is in the test set, not included in the construction of PC basis functions. The data set-up can be seen in Figure [6].

![FIG. 6: Snapshot of the signal superimposed on signal plus noise. The noise series has length \( n = n_1 + n_2 = 2^{13} \) and is segmented into two equal parts. The first half of the noise is generated from an AR(1) with \( \rho = 0.5 \), and the second half is generated from an AR(1) with \( \rho = -0.75 \). Both segments use a Gaussian innovation process with variance \( \sigma^2 = 1 \). The A108.25 rotating core collapse GW signal from the Abdikamalov et al test catalogue [25] is embedded in this noise with a SNR of \( \varrho = 50 \).](image)

The aim here is to simultaneously estimate both noise PSDs, as well as reconstructing the embedded GW signal using the method described in Section II E. Here we are assuming the change-point between the two noise series is known, though we will demonstrate in the next section that our method can locate unknown change-points.

Notice the difference between the first half of the noise series compared with the second half. Each segment has a different dependence structure, and are therefore coloured differently in the frequency-domain. This results in a different time-domain morphology. Estimates of the noise PSDs can be seen in Figures [7] and [8].
FIG. 7: Spectral density estimate of the first noise segment ($\rho = 0.5$) from Figure 6. 90% credible region (shaded pink), posterior median log PSD (dashed blue), and theoretical log PSD (solid black).

FIG. 8: Spectral density estimate of the second noise segment ($\rho = -0.75$) from Figure 6. 90% credible region (shaded pink), posterior median log PSD (dashed blue), and theoretical log PSD (solid black).

FIG. 9: Reconstructed rotating core collapse GW. 90% credible region (shaded pink) and posterior median signal (dashed blue), superimposed with true A1O8.25 GW signal from the Abdikamalov et al [25] test catalogue (solid black). The first half of the signal was embedded in AR(1) noise with $\rho = 0.5$, and the second half had AR(1) noise with $\rho = -0.75$. Both noise segments had Gaussian white noise with $\sigma^2 = 1$.

The 90% credible region for the reconstructed GW signal in Figure 9 generally contains the true signal, and has performed particularly well during collapse and bounce. Again, the post-bounce ring-down oscillations usually have the poorest reconstruction through the time series, but has performed remarkably well in this example, regardless of the slight imperfections of the PSD estimates.

The 90% credible region for the reconstructed GW signal in Figure 9 generally contains the true signal, and has performed particularly well during collapse and bounce. Again, the post-bounce ring-down oscillations usually have the poorest reconstruction through the time series, but has performed remarkably well in this example, regardless of the slight imperfections of the PSD estimates.

E. Detecting a Spectral Change-Point

Consider a change-point problem similar to that of the previous section, where a time series exhibits a change in its spectral structure somewhere in the series. A valuable consequence of the algorithm presented in Section II E is its ability to detect change-points regardless of whether the change-point occurs within a segment or on the boundary. For the following examples, let $n = 2^{12}$ and break this into $J = 32$ equal length segments. For clarity, assume the time series does not contain an embedded GW signal.

First consider the case where the change-point occurs on the boundary of two noise series. Let $n_1 = n_2 = 2^{11}$ be the lengths of each noise series, and let the first half of the time series be generated from an AR(1) with $\rho = 0.5$, and the second half from an AR(1) with $\rho = -0.75$. Both AR(1) processes have additive Gaussian innovations with $\sigma^2 = 1$. In this example, the change-point occurs exactly halfway through the series. Figure 10 shows a time-frequency map of the estimated log PSDs for each segment.
FIG. 10: Time-frequency map showing the estimated posterior median log PSDs for 32 segments of 1/4 s of AR(1) noise. The change-point in spectral structure occurs exactly halfway through the series.

It is obvious that a change-point occurs halfway through Figure 10 as there is a sheer change in the spectral structure at this point between segments 16 and 17. The first half of the time-frequency map exhibits stronger low-frequency behaviour, whereas the second half has more power in the higher frequencies.

Now consider the case where the change-point occurs during a segment rather than on the boundary. Here, let each segment have the same set-up as before, but instead set \( n_1 = 2^{11} - 2^6 \) and \( n_2 = 2^{11} + 2^6 \) such that a change-point occurs halfway through segment 16. A time-frequency map of the estimated log PSDs can be seen in Figure 11.

These examples demonstrate that we can detect potentially unknown change-points in a time series. It is important to note that if more segments are used, the time duration within each segment becomes smaller, and our accuracy in detecting the change-point increases. That is, the time at which the change-point occurs becomes more resolved if the segment durations are smaller. However, one must also ensure that the segment durations are long enough for the Whittle approximation to be valid.

F. Simulated Advanced LIGO Noise

In this example, we simulate Advanced LIGO noise and embed the A1O10.25 rotating core collapse GW signal from the Abdikamalov et al. catalogue in it, scaled to an SNR of \( \varrho = 50 \). We assume a one detector set-up, with linearly polarized GW signal (zero cross polarization). The Advanced LIGO sampling rate is \( r_s = 2^{14} \) Hz, with a Nyquist frequency of \( r_* = 2^{13} \) Hz. Let \( n = 2^{12} \), which corresponds to quarter of a second of data.

The simulated noise is Gaussian, and coloured by the Advanced LIGO design sensitivity PSD. Generating this noise blindly results in a perfect matching of the end-points and their derivatives, due to the simplified frequency-domain model. This is not realistic, since real data will often not have matching end-points. In order to make the noise generation more realistic, we internally generated a longer frequency-domain series (ten times longer), inverse discrete Fourier transformed it, and returned a fraction of it with a random starting point. This is referred to as “padding” the data.

FIG. 11: Time-frequency map showing the estimated posterior median log PSDs for 32 segments of 1/4 s of AR(1) noise. The change-point in spectral structure occurs in the middle of segment 16 just before the halfway point.

Figure 11 demonstrates that there is a noticeable change-point roughly halfway through the series. There is a smoother transition from one PSD structure to the other than in the previous example since the true change-point occurs in the middle of a segment rather than on the boundary.

These examples demonstrate that we can detect potentially unknown change-points in a time series. It is important to note that if more segments are used, the time duration within each segment becomes smaller, and our accuracy in detecting the change-point increases. That is, the time at which the change-point occurs becomes more resolved if the segment durations are smaller. However, one must also ensure that the segment durations are long enough for the Whittle approximation to be valid.

F. Simulated Advanced LIGO Noise

In this example, we simulate Advanced LIGO noise and embed the A1O10.25 rotating core collapse GW signal from the Abdikamalov et al. catalogue in it, scaled to an SNR of \( \varrho = 50 \). We assume a one detector set-up, with linearly polarized GW signal (zero cross polarization). The Advanced LIGO sampling rate is \( r_s = 2^{14} \) Hz, with a Nyquist frequency of \( r_* = 2^{13} \) Hz. Let \( n = 2^{12} \), which corresponds to quarter of a second of data.

The simulated noise is Gaussian, and coloured by the Advanced LIGO design sensitivity PSD. Generating this noise blindly results in a perfect matching of the end-points and their derivatives, due to the simplified frequency-domain model. This is not realistic, since real data will often not have matching end-points. In order to make the noise generation more realistic, we internally generated a longer frequency-domain series (ten times longer), inverse discrete Fourier transformed it, and returned a fraction of it with a random starting point. This is referred to as “padding” the data.

FIG. 12: Estimated log PSD for simulated Advanced LIGO noise. 90% credible region (shaded pink) and posterior median (dashed blue) overlaid with log periodogram (solid grey).

Figure 12 shows the estimated log PSD and the 90% credible region, overlaid with the log periodogram. The method performs remarkably well, particularly at higher frequencies. Even though we will not be able to resolve frequencies below \( \sim 10–20 \) Hz at the Advanced LIGO design sensitivity, it is still interesting to see how this method performs at lower frequencies. Here, the low
frequency estimates are slightly off, but not by much. We believe this to be due to two factors: 1/4 s of simulated Advanced LIGO noise is actually a non-stationary series, and we did not adjust for non-stationarities (simulated Advanced LIGO data is not stationary for more than 1/16 s based on the Augmented Dickey-Fuller test, Phillips-Perron unit root test, and KPSS test); and the Bernstein polynomial basis functions are notoriously slow to converge to a true function. These factors considered, the method still provides a reasonable approximation.

The resultant reconstructed GW signal can be seen in Figure 13. The estimated signal here is very close to the true signal during the collapse and bounce phases, as well as during the ring-down oscillations. The 90% credible region contains most of the true GW signal.

We chose $d = 25$ PCs to reconstruct a rotating core collapse GW signal, but this could be too many or too few basis functions. Model selection methods similar to [21] were not investigated in the current study, and even though Figures 3 and 13 demonstrated good estimates during all phases (including ring-down), there is a demand for improved reconstruction methods.

We then accommodated for non-stationarities in detector noise by breaking the series into smaller and locally stationary components, and looked at the resulting time-varying spectrum. This can be seen in Figure 14. Rather than choosing $J = 32$ as in Section III E, non-stationarities in the Advanced LIGO noise become more apparent if we slice the noise series into fewer segments, each with longer duration. Instead, consider splitting the data into $J = 8$ equal length segments ($n_j = 2^8$). Here, the Whittle approximation is valid, and the segments look locally stationary.

Figure 14 illustrates that the Advanced LIGO PSD is changing over time. Notice that lower frequencies are gaining more power over time. Assuming that each segment is locally stationary (which should be the case since the duration of each segment is less than 1/16 s), it is important to accommodate for the changing nature of the PSD since the Choudhuri et al. [22] PSD estimation technique is based on the theory of stationary processes. If we did not adjust for non-stationarities, estimates of astrophysically meaningful parameters could become biased.

**IV. DISCUSSION AND OUTLOOK**

This study was motivated by the need for an improved model for PSD estimation in GW data analysis. The assumptions of the standard GW noise model are too restrictive for Advanced LIGO data. GW data is subject to high amplitude non-Gaussian transients, meaning that the Gaussian assumption is not valid. If the noise model is incorrectly specified, we could make misleading inferences. The stationarity assumption is also not valid, as simulated Advanced LIGO noise is not stationary for much longer than 1/16 s according to classical statistical hypothesis tests. Using off-source data to estimate the PSD is problematic since the PSD will naturally drift over time, and is not necessarily the same as on the GW source.

The primary goal of this study was to develop a statistical model that allows for on-source estimation of the PSD, while making no assumptions about the underlying noise distribution. We also wanted a method capable of accounting for non-stationary noise. Although we restricted our attention to GWs from rotating core collapse stellar events in this paper, our approach is perfectly valid for any GW signal embedded in noise.

A secondary goal of this paper was to highlight to the GW community the rich and active area of Bayesian nonparametrics (and semiparametrics). We believe this...
framework will be a very powerful toolbox going forward, particularly in the analysis of GW bursts, since accurate parametric models for these types of signals are limited. Further, our future research efforts regarding rotating core collapse events involves Bayesian nonparametric regression models to construct GWs from their initial conditions. Regularization methods, such as the Bayesian LASSO [37], are also being considered.

In this paper, we have assumed linearly polarized GWs to be detected by one interferometer. A relatively simple extension of this work is to include a network of detectors, as well as GWs with non-zero cross polarization. Another extension would be to assume an unknown signal arrival time, as done in [20, 21]. These extensions can be expected in the second generation of the algorithm.

The noise in our model was assumed to come from all sources, including detector noise, environmental noise, and statistical noise from parametric modelling of the signal. The statistical noise is the residual difference between the true and fitted signals. An important factor to consider was whether statistical noise artificially dominated the noise. We do not believe this to be a dominating contributor to the overall noise.

Since the “theoretical” PSD of Advanced LIGO at its design sensitivity has a very steep decrease at low frequencies until it reaches a minimum at roughly 230 Hz, it is difficult for our algorithm to perfectly characterize the shape at low frequencies without increasing computation significantly. This is due to the well-known slow convergence of Bernstein basis functions to a true curve. That is, many Bernstein polynomials (on order \( k = 1000 \)) are required to accurately characterize the PSD of Advanced LIGO. Compare this to more well-behaved noise sources, such as those from autoregressive processes, which require \( k < 50 \). We are currently developing a second generation of this algorithm, using a mixture of B-spline densities (normalized to the unit interval), rather than Beta densities. B-splines have much faster convergence rates than Bernstein polynomials [33, 36]. An additional benefit of changing the basis functions to B-splines is that, like BayesLine [7], we will be able to account for spectral lines by peak-loading knots at a priori known frequencies that these occur at. We have left estimation of spectral lines out of the scope of this paper, but believe that a change of basis functions from Bernstein polynomials to normalized B-spline densities could work well. Another interesting approach would be to model spectral lines with informative priors using a similar approach to Macaro [38].

We used non-informative priors in this analysis. It may be possible to translate the known shape of the Advanced LIGO design sensitivity PSD into a prior. This may also aid in improving PSD estimates at lower frequencies.

We discussed a simplified method for estimating the time-varying PSD of non-stationary noise. Our approach assumed that a time series is split into equal length segments, and at known times. We demonstrated that it is possible to identify change-points in a time series and its spectrum using this method, and that there is no need to estimate the locations of the segment splits. Thus, a fixed grid of known segment placements suffices, and no RJMCMC is required. RJMCMC would have slowed the algorithm down significantly, and created an entirely new set of complications.

There is much work to be done on PSD estimation. As the Advanced LIGO and Advanced Virgo interferometers swiftly approach design sensitivity, it is important that we continue to focus not only on parameter estimation techniques, but also on modelling detector noise. PSD estimation is as important as parameter estimation, since we want to make honest statements about our observations based on rigorous statistical theory. It is hoped that in the near future, we can converge on a PSD estimation method that is less strict than the standard noise model, works well on real detector data, and is based on good statistical theory. We believe that the methods presented in this paper are definitely a step in the right direction.

Appendix A: Bernstein Polynomials and the Beta Density

To define the Bernstein polynomial, we first need to discuss the Bernstein basis polynomials. There are \( k + 1 \) Bernstein basis polynomials of degree \( k \), having the following form

\[
b_{j,k}(x) = \binom{k}{j} x^j (1-x)^{k-j}, \quad j = 0, 1, \ldots, k. \tag{A1}\]

A Bernstein polynomial is the following linear combination of Bernstein basis polynomials

\[
B_k(x) = \sum_{j=0}^{k} \beta_j b_{j,k}(x), \tag{A2}\]

where \( \beta_j \) are called the Bernstein coefficients.

As mentioned in Section II C, the Bernstein polynomial prior is a finite mixture of Beta probability densities. We use the following parameterization for the Beta probability density function

\[
f(x|\alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1-x)^{\beta-1}, \tag{A3}\]

\[
\propto x^{\alpha-1}(1-x)^{\beta-1}, \tag{A4}\]

where \( x \in (0, 1) \), the shape parameters are positive real numbers (i.e., \( \alpha > 0 \) and \( \beta > 0 \)), and \( \Gamma(.) \) is the gamma function defined as the following improper integral

\[
\Gamma(u) = \int_{0}^{\infty} x^{u-1} \exp(-x) dx. \tag{A5}\]

Appendix B: The Dirichlet Distribution, Dirichlet Process, and Stick-breaking Construction

The Dirichlet distribution is a multivariate generalization of the Beta distribution (defined in Appendix A)
with a probability density function defined on the $K$-dimensional simplex

$$
\Delta_K = \left\{ (x_1, \ldots, x_K) : \ x_i > 0, \ \sum_{i=1}^{K} x_i = 1 \right\}.
$$

The probability density function of the Dirichlet distribution is defined as

$$
f(x|\alpha) = \frac{\Gamma\left(\sum_{i=1}^{K} \alpha_i\right)}{\prod_{i=1}^{K} \Gamma(\alpha_i)} \prod_{i=1}^{K} x_i^{\alpha_i-1},
$$

where $\alpha_i > 0, i = 1, \ldots, K$.

The Dirichlet process is an infinite-dimensional generalization of the Dirichlet distribution. It is a probability distribution on the space of probability distributions, and is often used in Bayesian inference as a prior for infinite mixture models. One of the many representations of the Dirichlet process is Sethuraman’s stick-breaking construction \[13,31\]. This is useful for implementing MCMC sampling algorithms.

Let $G \sim DP(M, G_0)$, where $G_0$ is the center measure, and $M$ is the precision parameter (larger $M$ implies a more precise prior). The Sethuraman representation is

$$
G = \sum_{i=1}^{\infty} p_i \delta_{Z_i},
$$

$$
p_i = \left( \prod_{j=1}^{i-1} (1 - V_j) \right) V_i,
$$

$$
Z_i \sim G_0,
$$

$$
V_i \sim Beta(1, M).
$$

Consider a stick of unit length. The weights $p_i$ associated with points $Z_i$ can be thought of as breaking this stick randomly into infinite segments. Break the stick at location $V_1 \sim Beta(1, M)$, assigning the mass $V_1$ to the random point $Z_1 \sim G_0$. Break the remaining length of the stick $1 - V_1$ by the proportion $V_2 \sim Beta(1, M)$, assigning the mass $(1-V_1)V_2$ to the random point $Z_2 \sim G_0$. At the $i^{th}$ step, break the remaining length of the stick $\prod_{j=1}^{i-1} (1 - V_j)$ by the proportion $V_i \sim Beta(1, M)$, assigning the mass $\left( \prod_{j=1}^{i-1} (1 - V_j) \right) V_i$ to the random point $Z_i \sim G_0$. This process is repeated infinitely many times.

**Appendix C: Demonstration of Posterior Consistency**

It was proved in \[22\] that under very general conditions on the prior, the PSD estimation method used in this paper has the property of posterior consistency. We provide an illustrative example of this in Figure 15.

![Figure 15: Illustration of posterior consistency. The true log PSD (dashed black) overlaid with point-wise posterior median log PSDs of varying sample sizes.](image)

We generated AR(1) processes (with $\rho = 0.9$ and Gaussian white noise) of varying sample sizes, and compared their performance. It can be seen in Figure 15 that as the sample size of the time series increases, the point-wise posterior median log PSD gets closer to the true log PSD, thus demonstrating posterior consistency.

**ACKNOWLEDGMENTS**

We thank Neil Cornish for a thorough reading of the manuscript and for providing insightful comments, Claudia Kirch and Sally Wood for helpful discussions on stationary and locally stationary time series, and Blake Seers for advice on data visualization. We also thank the New Zealand eScience Infrastructure (NeSI) for their high performance computing facilities, and the Centre for eResearch at the University of Auckland for their technical support. RM’s and ME’s work is supported by the University of Auckland staff research grant 420048358, and NC’s work by NSF grants PHY-1204371 and PHY-1505373. This paper has been given LIGO Document Number P1500057. All analysis was conducted in R, an open-source statistical software available on CRAN (cran.r-project.org). We acknowledge the ggplot2, grid, codah, and bspec packages.
