Algebraic Distributed Differential Space-Time Codes with Low Decoding Complexity

G. Susinder Rajan, Student Member, IEEE, and B. Sundar Rajan, Senior Member, IEEE

Abstract—The differential encoding/decoding setup introduced by Kiran et al, Oggier-Hassibi and Jing-Jafarkhani for wireless relay networks that use codebooks consisting of unitary matrices is extended to allow codebooks consisting of scaled unitary matrices. For such codebooks to be usable in the Jing-Hassibi protocol for cooperative diversity, the conditions involving the relay matrices and the codebook that need to be satisfied are identified. Using the algebraic framework of extended Clifford algebras, a new class of Distributed Differential Space-Time Codes satisfying these conditions for power of two number of relays and also achieving full cooperative diversity with a low complexity sub-optimal receiver is proposed. Simulation results indicate that the proposed codes outperform both the cyclic codes as well as the circulant codes. Furthermore, these codes can also be applied as Differential Space-Time codes for non-coherent communication in classical point to point multiple antenna systems.

Index Terms—Algebra, cooperative diversity, low decoding complexity, space-time coding.

I. INTRODUCTION

Consider the scenario of \( R + 1 \) users wanting to communicate to a single destination using cooperative strategies. For simplicity, we consider one of the \( R + 1 \) users as the source and the remaining \( R \) users as relays. Predominantly there are two types of relaying strategies discussed in the literature, i.e., 1) amplify and forward and 2) decode and forward. In this work, we focus only on amplify and forward based relaying strategies wherein the relays are allowed to perform linear processing of the received signal. Amplify and forward based relaying is simpler and moreover does not require the relays to have knowledge of the codebook used by the source or the knowledge of the source to relay channel fading gains. Recently in [1], the idea of space-time coding for collocated MIMO (Multiple Input Multiple Output) systems has been applied in the setting of cooperative wireless relay networks in the name of distributing space-time coding, wherein coding is performed across users and time. This strategy provides each user a diversity order equal to the number of relays even though all the users are only equipped with a single antenna. The diversity thus achieved is called as cooperative diversity. However, such strategies require that the destination have complete knowledge of the fading coefficients from all the users to itself as well as that of the fading coefficients between users. Obtaining the knowledge of the fading coefficients between the users at the destination requires additional resources. To solve this problem, in [2], Kiran et al have proposed a differential encoding/decoding setup for cooperative wireless networks that does not require the knowledge of fading coefficients between the users at the destination. Such codes were named as partially coherent distributed space-time codes in [2]. In a recent work [3], it has been shown that the same strategy of [2] offers full diversity with a suboptimal receiver that does not require the knowledge of any of the fading coefficients. In an independent work [3], Jing and Jafarkhani have proposed a differential encoding/decoding setup for cooperative wireless relay networks which is more general than the setup proposed in [2], [4] and they have also provided few code constructions. We call the class of Differential Space-Time Codes (DSTCs) which can be used in a distributed manner for cooperative diversity as Distributed DSTCs (and denote by DDSTCs) to differentiate them from DSTCs for collocated MIMO systems. The problem of designing DDSTCs is more challenging than that of DSTCs for collocated MIMO systems, since in this scenario we have additional constraints to be satisfied which are due to the cooperative diversity protocol. In [5], the setup of [2], [4] has been generalized to the case when the source and destination nodes have multiple antennas. In [5], the authors propose the use of a random diagonal unitary matrix codebook in general and for certain specific number of relays (3, 6 and 9) propose the use of cyclic codes. However, a random code is not guaranteed to offer full diversity. Moreover designing good cyclic codes becomes difficult for large number of relays. In [3], the authors propose the use of Alamouti code and \( Sp(2) \) code for the specific case of 2 and 4 relays. For an arbitrary number of relays, the authors construct fully diverse DDSTCs based on circulant matrices. But, except for the Alamouti code all other DDSTC constructions in the literature [2], [3], [4], [5] have large decoding complexity. Thus, a general full diversity code construction targeting the requirements of low encoding complexity as well as low decoding complexity is not available. This issue gains significant importance especially if the number of cooperating terminals is large, which is quite expected in applications like wireless sensor networks.

In this paper we address this issue and present the following contributions:

- The notion of encoding complexity for Space-Time codes...
in terms of $g$-group encodability is introduced (Definition 1) and its significance is highlighted.

- The differential encoding/decoding setup introduced by Kiran et al. [2], Oggier et al. [5] and Jing et al. [3] for wireless relay networks that use codebooks consisting of unitary matrices is generalized to allow codebooks consisting of scaled unitary matrices. This generalization aids in reducing the encoding/decoding complexity of DDSTCs. When the codebook of scaled unitary matrices is used in the Jing-Hassibi protocol [1] for differential encoding at the source, the extra conditions involving the interrelationship between relay matrices and the codeword matrices that need to be satisfied are identified (Eqn. 4).

- Using the algebraic framework of extended Clifford algebras, a new class of DDSTCs satisfying these extra conditions (Constructions 4.3 and 4.4) is proposed which achieves full diversity with a low complexity sub-optimal receiver (Theorem 3). Explicit construction of multidimensional signal sets that lead to full diversity (Theorem 4) are also provided. To the best of our knowledge, this is the first known low decoding complexity DDSTC scheme for cooperative wireless networks which is available for all power of two number of relays.

A. Organization of the paper

Section II introduces the system model for the distributed differential encoding/decoding setup employing a differential scaled unitary matrix codebook at the source. In Section III, the notion of $g$-group encodable and $g$-group decodable space-time codes is discussed for the system model of Section II and the problem statement for DDSTCs with low encoding and decoding complexity is given. The extra conditions on the code structure imposed by the cooperative diversity protocol of [2], [3], [4], [5] are then described. In Section IV, we provide a detailed discussion on further work which comprises Sections V and VI respectively.

B. Notation

For two sets $\mathcal{A}_1$ and $\mathcal{A}_2$, $\mathcal{A}_1 \times \mathcal{A}_2$ denotes the Cartesian product of $\mathcal{A}_1$ and $\mathcal{A}_2$. For a matrix $C$, the matrices $C^*$, $C^T$ and $C^H$ denote the conjugate, transpose and conjugate transpose of $C$ respectively. For a complex number $x$, $x_I$ and $x_Q$ denote its in-phase and quadrature-phase components respectively. For a vector $a$, $a[i]$ denotes the $i^{th}$ entry of $a$. An all zero matrix of appropriate size will be denoted by $0$. A complex Gaussian vector with zero mean and covariance matrix $\Omega$ will be denoted by $\mathcal{CN}(0, \Omega)$.

II. SYSTEM MODEL EMPLOYING DIFFERENTIAL SCALED UNITARY MATRIX CODEBOOK

In this section, we briefly explain the distributed differential encoding/decoding setup proposed in [2], [3], [5] with a slight modification.

We consider a network consisting of a source node, a destination node and $R$ other relay nodes which aid the source in communicating information to the destination. All the nodes are assumed to be equipped only with a single antenna and are half duplex constrained, i.e., a node cannot transmit and receive simultaneously at the same frequency. The wireless channels between the terminals are assumed to be quasi-static and flat fading. The channel fading gains from the source to the $i$-th relay, $f_i$, and from the $j$-th relay to the destination $g_j$ are all assumed to be independent and identically distributed complex Gaussian random variables with zero mean and unit variance. Moreover, we assume symbol synchronization among all the nodes.

Every transmission cycle from the source to the destination comprises of two stages. In the first stage, the source transmits a $\sqrt{\pi_1 TP}$ length vector $\sqrt{\pi_1 TP}$ which the relays receive. Here, $P$ denotes the total average power spent by all the relays and the source. The fraction of total power $P$ spent by the source is denoted by $\pi_1$. The vector $s$ satisfies $E[|s|^2] = 1$ and is a function of the information that the source intends to communicate. The exact relation of $s$ with the information sent by the source will be made precise in the sequel. The received vector at the $j$-th relay node is then given by $y_j = \sqrt{\pi_j TP} f_j s + v_j$, with $v_j \sim \mathcal{CN}(0, I_T)$. In the second half of the cycle, all the relay nodes are scheduled to transmit together. The $j$-th relay node transmits a $T$ length vector $t_j$ which is a function of $r_j$. The relays are only allowed to linearly process the received vector $r_j$ or its conjugate $r_j^*$. To be precise, the $j$-th relay node is equipped with a $T \times T$ unitary matrix $A_j$ (called relay matrix) and it transmits either $t_j = \sqrt{\pi_j P} A_j r_j$ or $t_j = \sqrt{\pi_j P} A_j r_j^*$. Without loss of generality, we may assume that $M$ relays linearly process $r_j$ and the remaining $R - M$ relays linearly process $r_j^*$. Here, $\pi_2$ denotes the fraction of total power $P$ spent by a relay. If the quasi-static duration of the channel is much greater than $2T$ time slots, then the received vector at the destination is given by

$$y = \sum_{j=1}^{R} g_j t_j + w = \frac{\sqrt{\pi_1 \pi_2 TP}}{\sqrt{\pi_1 P + 1}} X h + n \quad (1)$$

where,

$$X = \begin{bmatrix} A_{1}s & \ldots & A_{M}s & A_{M+1}s^* & \ldots & A_{R}s^* \end{bmatrix},$$

$$h = \begin{bmatrix} f_1 g_1 + \ldots + f_{M} g_{M} + \ldots + f_{R} g_{R} \end{bmatrix},$$

$$n = \sqrt{\frac{\pi_2 P}{\pi_1 P + 1}} \left( \sum_{j=1}^{M} g_j A_j v_j + \sum_{j=M+1}^{R} g_j A_j v_j^* \right) + w$$

and $w \sim \mathcal{CN}(0, I_T)$ represents the additive noise at the destination. The power allocation factors $\pi_1$ and $\pi_2$ are chosen in such a way to satisfy $\pi_1 P + \pi_2 P R = 2P$. Throughout this paper, we chose $\pi_1 = 1$ and $\pi_2 = \frac{1}{R}$ as suggested in [1].

The differential encoding is performed at the source as follows. An initial vector $s_0$ known to the destination which satisfies $s_0^H s_0 = 1$ is transmitted by the source in the first cycle. The initial vector $s_0$ should be such that the initial matrix

$$X_0 = \begin{bmatrix} A_{1}s_0 & \ldots & A_{M}s_0 & A_{M+1}s_0^* & \ldots & A_{R}s_0^* \end{bmatrix} \quad (2)$$
is unitary. The transmitted vector at the $t$-th cycle is then given as follows

$$
s_t = \frac{1}{\alpha_{t-1}} U_t s_{t-1}$$

(3) where, $U_t \in \mathbb{C}$ is the codeword containing the information at the $t$-th cycle which satisfies $U_t^H U_t = \sigma_t^2 I_T$, $\sigma_t \in \mathbb{R}$. The codebook $\mathcal{C}$ at the source consisting of scaled unitary matrices should satisfy $E[a_t^2] = 1$ in order to meet the power constraint at the source and relays. The originally proposed coding strategies in [2], [3], [5] force $\alpha_t = 1$ for all codewords. The received vector at the destination in the $t$-th cycle can then be written as $y_t = \sqrt{\frac{1}{\alpha_{t-1}}} P T X_t h_t + n_t$ where, $X_t = [ A_{1t} s_t \ldots A_{M_t} s_t \ A_{M_t+1} s^*_t \ldots A_{R_t} s^*_t ]$. If $A_i U_t = U_t A_i, \forall U_t \in \mathbb{C}, i = 1, \ldots, M$ and $A_i U_t^* = U_t A_i, \forall U_t \in \mathbb{C}, i = M + 1, \ldots, R$

(4) then, substituting for $s_t$ from (3) we get $X_t = \frac{1}{\alpha_{t-1}} U_t X_{t-1}$. If the channel remains approximately constant for $4T$ channel uses, then we can assume that $h_t = h_{t-1} - n_t$. Then,

$$
y_t = \sqrt{\frac{1}{\alpha_{t-1}}} P T X_t h_{t-1} + n_t$$

$$= \frac{1}{\alpha_{t-1}} U_t Y_{t-1} + \tilde{n}_t$$

where, $\tilde{n}_t = -\frac{1}{\alpha_{t-1}} U_t n_{t-1} + n_t$. Now we propose to decode the codeword $U_t$ as follows

$$
\hat{U}_t = \arg \min_{U_t \in \mathcal{C}} \| y_t - \frac{1}{\alpha_{t-1}} U_t Y_{t-1} \|^2
$$

(6) where, $\alpha_{t-1}$ can be estimated from the previous cycle. Note that the above decoder does not require the knowledge of the channel gains and the relay matrices $A_i, i = 1, \ldots, R$. Also, note that this decoder is not a Maximum-Likelihood (ML) decoder since the equivalent noise vector $\hat{n}_t$ is dependent on the previous codeword $U_{t-1}$ through $\alpha_{t-1}$. However, for the collocated MIMO case, it has been shown in [6], [7] that there is no significant performance loss due to this. In this setup, we call $\mathcal{C}$ a DDSTC to distinguish it from DSTCs for collocated MIMO systems.

### III. Problem Statement

In this section, we describe the problem statement of designing DDSTCs with low encoding complexity and low decoding complexity.

In order to benefit from low encoding complexity and low decoding complexity, we propose to choose the DDSTC $\mathcal{C}$ to be a $g$-group encodable ($g > 1$) linear STBC.

**Definition 1:** A linear design $S(s_1, s_2, \ldots, s_K)$ of size $n \times n$ in $K$ real indeterminates or variables $s_1, s_2, \ldots, s_K$ is a $n \times n$ matrix with entries being a complex linear combination of the variables $s_1, s_2, \ldots, s_K$. To be precise, it can be written as follows:

$$
S(s_1, s_2, \ldots, s_K) = \sum_{i=1}^{K} s_i B_i
$$

where, $B_i \in \mathbb{C}^{n \times n}$ are square complex matrices called the weight matrices. A linear STBC $\mathcal{C}$ is a finite set of $n \times n$ complex matrices which can be obtained by taking a linear design $S(s_1, s_2, \ldots, s_K)$ and specifying a signal set $\mathcal{A} \subset \mathbb{R}^K$ from which the information vector $x = [ s_1 \ s_2 \ \ldots \ s_K ]$ take values, with the additional condition that $S(a) \not= S(a')$, $\forall a \not= a' \in \mathcal{A}$. A linear STBC $\mathcal{C} = \{ S(x) | x \in \mathcal{A} \}$ is said to be a $g$-group encodable ($g$-real symbol encodable or $g$-complex symbol encodable) if $g$ divides $K$ and if $\mathcal{A} = \mathcal{A}_1 \times \mathcal{A}_2 \times \cdots \times \mathcal{A}_g$ where each $\mathcal{A}_i, i = 1, \ldots, g \subset \mathbb{R}^K$.

Thus, given a $g$-group encodable STBC, it defines a natural partitioning of the real variables of its associated linear design into $g$-groups. This partitioning defines a partitioning of the set of weight matrices of $S(x)$ into $g$-groups, the $k$-th group containing $K/g$ matrices. For simplicity we assume the simplest partitioning of the information symbol vector as $x = [ x_1 T \ x_2 T \ \ldots \ x_g T ]^T$ where, $x_k = [ s_{(k-1)K+1}^{g} \ s_{(k-1)K+2}^{g} \ \ldots \ s_{kK}^{g} ]^T$. Now $S(x)$ can be written as,

$$
S(x) = \sum_{k=1}^{g} S_k(x_k) \text{ where, } S_k(x_k) = \sum_{i=(k-1)K+1}^{kK} s_i B_i.
$$

Minimizing the decoding metric corresponding to (6),

$$
\| y_t - \frac{1}{\alpha_{t-1}} S(x) Y_{t-1} \|^2
$$

(7) is in general not the same as minimizing

$$
\| y_t - \frac{1}{\alpha_{t-1}} S_k(x_k) Y_{t-1} \|^2
$$

(8) for each $1 \leq k \leq g$ individually. However if it so happens, then the decoding complexity is reduced by a large extent.

**Definition 2:** A linear STBC $\mathcal{C} = \{ S(x) | x \in \mathcal{A} \}$ is said to be a $g$-group encodable ($g$-real symbol encodable or $g$-complex symbol encodable) if it is $g$-group encodable and if its decoding metric in (7) can be simplified as in (8).

**Theorem 1:** [12] The decoding metric in (7) can be simplified as in (8) if

$$
B_i^H B_j + B_j^H B_i = 0
$$

(9) for all weight matrices $B_i$ and $B_j$ belonging to two different groups.

We illustrate the significance of the above definitions concerning encoding and decoding complexity by giving few examples.

**Example 3.1:** Consider the Golden code for 2 transmit antennas. It has 8 real variables. For the coherent MIMO channel, the signal set used is QAM for each complex variable. Hence, this code is a 8-group encodable (since QAM is a Cartesian product of two PAM signal sets) and 1-group decodable linear STBC. However, if we now impose the requirement for unitary codewords, then we will have to solve for signal sets which will yield unitary codewords inside the division algebra. This may amount to entangling all the 8-real variables which will make the code 1-group encodable and 1-group decodable. This approach was recently attempted in [9].
Example 3.2: Let us take the example of the Alamouti code for 2 transmit antennas. It has 4 real variables. If the signal set is chosen to be PSK for every complex variable, then all the codewords become unitary matrices. Hence the resulting code is 2-group encodable and 2-group decodable. However, note that if we take square QAM to be the signal set for each complex variable, then we get a 4-group encodable (since square QAM is a Cartesian product of two PAM signal sets) and 4-group decodable code, but now the codewords are scaled unitary matrices as opposed to unitary matrices. Thus relaxing the codewords to be scaled unitary matrices allows us to lower the encoding and decoding complexity.

The above two examples show that the choice of signal sets is crucial in obtaining low encoding and decoding complexity. Example 3.2 explicitly shows how allowing scaled unitary matrices as opposed to unitary matrices. Thus relaxing the constraint that each complex variable, then we get a $4\times 4$ matrix $\mathbf{C} = \mathbf{A}$, leading to full diversity for arbitrary transmission rate is provided for the linear designs given in Subsection IV-A, thus completely describing the construction of the linear STBC $\mathcal{C}$. In Subsection IV-C, we use algebraic techniques to explicitly construct the $R$ relay matrices satisfying the required conditions for arbitrary size of the codebook $\mathcal{C}$.

IV. Explicit construction of DDSTCs

In this subsection, we briefly describe a construction of a class of rate one, linear designs satisfying the conditions for four-group decodability which were first obtained using extended Clifford algebras in [10]. Extended Clifford algebras and linear designs from them are addressed in detail in [10]. However [10] chooses signal sets as applicable for coherent communication in a distributed space-time coding setup. A brief explanation of extended Clifford algebras and linear designs using them is provided in Appendix A. This algebraic framework given in Appendix A is needed to explicitly construct the relay matrices and the initial vector in Subsection IV-C.

Construction 4.1: Given a $n \times n$ linear design $\mathbf{A}(x_1, x_2, \ldots, x_L)$ in $L$ complex variables $x_1, x_2, \ldots, x_L$, one can construct a $2n \times 2n$ linear design $\mathbf{D}$ as follows:

$$
\mathbf{D} = \left[ \begin{array}{cc}
\mathbf{A}(x_1, x_2, \ldots, x_L) & \mathbf{B}(x_{L+1}, x_{L+2}, \ldots, x_{2L}) \\
\mathbf{B}(x_{L+1}, x_{L+2}, \ldots, x_{2L}) & \mathbf{A}(x_1, x_2, \ldots, x_L)
\end{array} \right]
$$

where, the linear design $\mathbf{B}(x_{L+1}, x_{L+2}, \ldots, x_{2L})$ is identical to the linear design $\mathbf{A}(x_1, x_2, \ldots, x_L)$ except that it is a design in a different set of complex variables $x_{L+1}, x_{L+2}, \ldots, x_{2L}$. We call this construction as the ‘ABBA construction’ which was first introduced in [8].

Construction 4.2: Given a $n \times n$ linear design $\mathbf{A}(x_1, x_2, \ldots, x_L)$, one can construct a $2n \times 2n$ linear design $\mathbf{S}$ as follows:

$$
\mathbf{S} = \left[ \begin{array}{cc}
\mathbf{A}(x_1, x_2, \ldots, x_L) & -\mathbf{B}(x_{L+1}, x_{L+2}, \ldots, x_{2L}) \\
\mathbf{B}(x_{L+1}, x_{L+2}, \ldots, x_{2L}) & \mathbf{A}(x_1, x_2, \ldots, x_L)
\end{array} \right]
$$

where, the linear design $\mathbf{B}(x_{L+1}, x_{L+2}, \ldots, x_{2L})$ is identical to the linear design $\mathbf{A}(x_1, x_2, \ldots, x_L)$. We call this construction as the ‘doubling construction’.

We are now ready to describe the construction of the proposed linear designs.

Construction 4.3: To obtain a linear design for $R = 2^\lambda$ relays, follow the steps given below.

Step 1: Starting with the linear design $[x]$ in complex variable $x_1$, keep applying ABBB construction iteratively on it till a $2^{\lambda-1} \times 2^{\lambda-1}$ linear design $\mathbf{D}$ is obtained.

Step 2: Apply doubling construction on $\mathbf{D}$ and scale it by $\frac{1}{\sqrt{R}}$ to obtain the linear design.

Example 4.1: Following the steps given above for $R = 8$ relays, we get
B. Construction of signal sets leading to full diversity

In this subsection, we construct signal sets for the linear designs constructed in the previous subsection that lead to full diversity STBCs. In general, the signal sets should be designed such that the resulting linear STBC ‘φ’ meets the following requirements.

1) Scaled unitary codeword matrices meeting power constraint.
2) Four-group encodable and Four-group decodable.
3) Difference of any two different codeword matrices should be full rank. We call such a code to be ‘fully diverse’.
4) The minimum determinant of the difference of any two codewords matrix should be maximized (Coding gain).

We shall first illustrate the signal set construction procedure for 4 relays and derive important insights form it. Then, we generalize the ideas thus obtained for constructing signal sets for any \( R = 2^k \) relays. The design for 4 relays according to the construction in the previous subsection is given by

\[
S = \frac{1}{\sqrt{8}} \begin{bmatrix}
1 & x_1 & x_2 & x_3 & x_4 \\
1 & x_2 & x_3 & x_4 & x_1 \\
1 & x_3 & x_4 & x_1 & x_2 \\
1 & x_4 & x_1 & x_2 & x_3
\end{bmatrix}
\]  

Let us look at \( S^H S \) shown in (12) at the top of the next page to find out the conditions on the signal sets under which the codewords are scaled unitary matrices.

From (12), we see that the signal set should be chosen such that the following condition is satisfied for all the signal points.

\[ x_1 x_2 + x_2 x_3 + x_3 x_4 + x_4 x_1 = 0. \]  

Firstly, we identify the grouping of the real variables into groups such that the corresponding weight matrices in each group satisfy (9). According to the construction, the four groups or real variables are as follows: First group: \( \{x_{11}, x_{21}\} \), Second group: \( \{x_{1Q}, x_{2Q}\} \), Third group: \( \{x_{31}, x_{41}\} \), Fourth group: \( \{x_{3Q}, x_{4Q}\} \). It is important to choose signal sets such that they do not enforce joint constraints on variables from different groups. The requirement for scaled unitary codewords as in (13) can be satisfied without disturbing 4-group encodability if all the signal points satisfy the following equation:

\[ x_{11} x_{21} = -x_{1Q} x_{2Q} = c_1, \quad x_{31} x_{41} = -x_{3Q} x_{4Q} = c_2 \]  

where, \( c_1 \) and \( c_2 \) are positive real constants. Then, the average power constraint requirement can be met by satisfying the conditions,

\[
E(x_{11}^2 + x_{21}^2) = 1, \quad E(x_{1Q}^2 + x_{2Q}^2) = 1, \\
E(x_{31}^2 + x_{41}^2) = 1, \quad E(x_{3Q}^2 + x_{4Q}^2) = 1. 
\]  

A common set of solutions for (14) and (15) can be obtained by taking points on the intersection of circles and hyperbolas. To meet the third requirement of full diversity we make use of the structure of the constructed designs. Note that

\[
|\Delta S^H S| = \frac{1}{4} \begin{bmatrix}
\Delta A^H \Delta A + \Delta B^H \Delta B & (\Delta A \Delta B - \Delta B \Delta A)^H \\
\Delta A \Delta B - \Delta B \Delta A & \Delta A \Delta B - \Delta B \Delta A
\end{bmatrix}
\]

\[
= \frac{1}{4} \begin{bmatrix}
\Delta A^H \Delta A + \Delta B^H \Delta B & 0 \\
0 & \Delta A \Delta B - \Delta B \Delta A
\end{bmatrix}
\]

\[
\geq \frac{1}{4} \max(|\Delta A|^2, |\Delta B|^2) |\Delta S^H S| \]  

where, the notation \( \Delta \) has been used to denote the difference matrix which will have the same form as the associated linear design. The second equality in (16) follows because the linear designs \( A \) and \( B \) commute. This can be proved as follows. Let

\[
A = \begin{bmatrix}
W & X \\
X & W
\end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix}
W' & X' \\
X' & W'
\end{bmatrix}.
\]

Then, we have

\[
\begin{bmatrix}
w & x \\
x & w
\end{bmatrix} = \begin{bmatrix}
w' & x' \\
x' & w'
\end{bmatrix} = \begin{bmatrix}
w w' + x x' & w' x' + x w' \\
x w' + x x' & x x' + w w'
\end{bmatrix},
\]

\[
\begin{bmatrix}
w' & x' \\
x' & w'
\end{bmatrix} = \begin{bmatrix}
w w' + x x' & w' x' + x w' \\
x w' + x x' & x x' + w w'
\end{bmatrix}.
\]

Thus we observe that linear designs \( A \) and \( B \) commute if their constituent sub-matrices commute. Applying this argument recursively, the claim follows.

Thus \( S \) is fully diverse, i.e., \( |\Delta S| \neq 0 \) if either of the submatrices \( A \) or \( B \) is fully diverse. For the example of 4 relays, we have

\[
|\Delta S| = \begin{bmatrix}
\Delta x_1 & \Delta x_2 \\
\Delta x_2 & \Delta x_1
\end{bmatrix} = (\Delta x_1 + \Delta x_2)(\Delta x_1 - \Delta x_2).
\]

Hence we can guarantee full diversity by ensuring that \( \Delta x_1 \neq \pm \Delta x_2 \) and \( \Delta x_3 \neq \pm \Delta x_4 \). Just like before, we should be careful not to disturb 4-group encodability in the process. We take care of that requirement also by satisfying the following conditions:

\[
\Delta x_{11} \neq \pm \Delta x_{21}, \quad \Delta x_{1Q} \neq \pm \Delta x_{2Q}, \\
\Delta x_{31} \neq \pm \Delta x_{41}, \quad \Delta x_{3Q} \neq \pm \Delta x_{4Q}.
\]  

Putting together all the conditions that need to be met, we have to choose constellation points satisfying (14), (15) and (17). The solution can be found simply by finding the intersection of points on the unit circle \( x^2 + y^2 = 1 \) with a hyperbola \( xy = c \), where \( c < 1 \) on the two dimensional \( xy \) plane. This is illustrated in Fig. 1.

Observe from Fig. 1 that the hyperbola intersects the circle at four different points. But the full diversity criterion demands that \( \Delta x \neq \pm \Delta y \). After enforcing this condition, only two points survive out of the four points. They can be either the set of points marked A or the set of points marked B in Fig. 1. Thus we have obtained a signal set containing 2 points. Supposing that we need more than two points, we can draw more circles (centered at origin) with radii such that the average power constraint is met and then find those.
the constants illustrated in Fig. 2 shown at the top of the next page. Implementing these two suggestions makes the signal the case of the desired signal set for the variables $x_1, x_2$ and $x_3, x_4$. More precisely, to get the points intersecting with the hyperbola $xy = c$ where, $c$ is a positive number less than $1$. In this manner we can get the desired signal set for the variables $x_{11}, x_{22}$ and $x_{33}, x_{44}$. The signal set for the variables $x_{1Q}, x_{2Q}$ and $x_{3Q}, x_{4Q}$ can be obtained by considering a different hyperbola. This is illustrated in Fig. 2 shown at the top of the next page.

Based on empirical studies, we propose to choose points in the set $A$ and set $B$ alternatively on each circle. Also, choosing the constants $c_1 = c_2 = 0$ seems to give the largest coding gain. Similar observations have also been made in [7] for another class of linear STBCs applicable in co-located MIMO systems. Implementing these two suggestions makes the signal identical for all the 4-groups and the resulting signal set for the case of 8 points is shown in Fig. 2. Note that the proposed signal set construction is far from general and the most general solution would correspond to the following equations:

$$x_{11}x_{22} = -x_{1Q}x_{2Q} = c_1, \ x_{33}x_{44} = -x_{3Q}x_{4Q} = c_2,$$

$$E(x_{11}^2 + x_{22}^2) = d_1, \ E(x_{1Q}^2 + x_{2Q}^2) = d_2,$$

$$E(x_{33}^2 + x_{44}^2) = d_3, \ E(x_{3Q}^2 + x_{4Q}^2) = d_4,$$

$$\Delta x_{11} \neq \pm \Delta x_{22}, \ \Delta x_{1Q} \neq \pm \Delta x_{2Q},$$

$$\Delta x_{33} \neq \pm \Delta x_{44}, \ \Delta x_{3Q} \neq \pm \Delta x_{4Q}.$$

In general, we need to choose the parameters $c_1, c_2, d_1, d_2, d_3, d_4, r_1, r_2, \ldots, r_m$ and the solution points such that the coding gain is maximized.

$^1$This condition is necessary since otherwise the hyperbola will not intersect the circle with least radius.

Based on the detailed illustration of signal set construction for 4 relays antennas, a natural generalization of it to higher dimensions is given in Construction 4.4 as follows.

**Construction 4.4:** Suppose that we want a $Q$ points signal set $\mathbb{R}^{2^{Q-1}}$ for the constructed design for $R = 2^h$ relays. Then the resulting signal set $\subset \mathbb{R}^{2^{Q-1}}$ should be a Cartesian product of 4 signal sets in $\mathbb{R}^{2^{Q-1}}$ since we insist on 4-group encodability. In our case, we choose all the four sets to be identical and each will contain $\sqrt{Q}$ points. Let the signal points in $\mathbb{R}^{2^{Q-1}}$ be labeled as $p_i$, $i = 1, \ldots, \sqrt{Q}$. If $i = 2q+r$, for some integers $q$ and $r$ where $1 \leq r \leq 2$, then $p_i$ is given by

$$p_i[q \mod 2^{Q-1} + 1] = +r_{q+1}, \text{ if } r = 1$$

$$p_i[q \mod 2^{Q-1} + 1] = -r_{q+1}, \text{ if } r = 2$$

where, $r_i, \ i = 1, \ldots, \sqrt{Q}$ are positive real numbers such that $r_{i+1} > r_i, \ \forall i = 1, \ldots, \sqrt{Q} - 1$ and $\sum_{i=1}^{\sqrt{Q}} r_i^2 = \sqrt{Q}$.

**Example 4.2:** Let $R = 2^3 = 8$ and $Q = 16^4$. Thus the rate of transmission of this code will be $\frac{\log Q}{8} = 2$ bits per channel use. The design is given in (10). The corresponding four dimensional signal set is described below.
that the designs given in Construction 4.3. The partition-
sets for the designs given in Construction 4.3.

Theorem 2: Construction 4.3 provides fully diverse signals
sets for the designs given in Construction 4.3.

Proof: The constructed designs for 2L complex variables
has the structure as shown in Construction 4.2. The partition-
ing of the real variables into four groups is as follows.
1) First group: \{x_{11}, x_{21}, \ldots, x_{LL}\}
2) Second group: \{x_{1Q}, x_{2Q}, \ldots, x_{LQ}\}
3) Third group: \{x_{(L+1)1}, x_{(L+1)2}, x_{(L+2)1}, x_{(L+2)2}\}
4) Fourth group: \{x_{(L+1)Q}, x_{(L+2)Q}, \ldots, x_{2LQ}\}

The signal set is a Cartesian product of four smaller
dimensional signal sets $\mathbb{R}^L$. Since
$$S^H S = A^H A + B^H B$$
and because the designs A and B are identical, it is sufficient to show
that the design $A(x_1, x_2, \ldots, x_L)$ gives rise to fully diverse
scaled unitary codewords for the chosen signal set. Let the
given signal set be denoted by $\Lambda \subset \mathbb{R}^L$. Then the following
properties are satisfied $\forall x, y \in \Lambda, x \neq y$.
$$x[i] x[j] = 0, 1 \leq i \neq j \leq L$$
$$|\{i \mid (x - y)[i] \neq 0\}| \leq 2$$
$$(x - y)[i] \neq \pm (x - y)[j], i \neq j$$
The design $A(x_1, x_2, \ldots, x_L)$ can be obtained by
repeatedly applying ABBA construction on the linear
design $[x_1]$. The off-diagonal entries of the matrix
$A(x_1, x_2, \ldots, x_L)^H A(x_1, x_2, \ldots, x_L)$ are sum of
terms like $x^*_i x_j + x^*_j x_i, i \neq j$. But we have,
$x^*_i x_j + x^*_j x_i = 2(x_{1i} x_{2j} + x_{1i} Q x_{2j} Q)$ which is
equal to zero for the signal set $\Lambda$ by virtue of 20. Thus we are
guaranteed of scaled unitary codewords.

Due to the ABBA structure of the linear design
$A(x_1, x_2, \ldots, x_L)$, the determinant can be obtained in an
iterative manner. Let $A(x_1, x_2, \ldots, x_K) = \begin{bmatrix} A_1 & A_2 & A_2 & A_1 \end{bmatrix}$.

Then we have
$$|A| = \begin{bmatrix} 1 & 0 & A_1 & A_2 \\ 1 & 1 & A_2 & A_1 \\ 0 & A_2 & A_1 + A_2 \end{bmatrix} = (A_1 + A_2) (A_1 - A_2)$$

The above equation suggests that $|A(x_1, x_2, \ldots, x_L)|$
can be computed recursively. For $L = 2$, $A(x_1, x_2) = (x_1 + x_2)(x_1 - x_2)$. Using this, we can easily
show that $|A(x_1, x_2, \ldots, x_L)|$ is a product of $L$ terms. A
typical term in the product looks like $(x_1 \pm x_2 \pm \cdots \pm x_L)$. Thus to ensure $(\Delta A(x_1, x_2, \ldots, x_L)) \neq 0$, each term
in the product should not equal zero. Thus we need
$(\Delta x_1 \pm \Delta x_2 \pm \cdots \pm \Delta x_L) \neq 0$. Let us look at the real part
of this expression. We get \((\Delta x_{1I} \pm \Delta x_{2I} \pm \cdots \pm \Delta x_{LI})\). For the given signal set \(A\), from (21) and (22), we have \((\Delta x_{1I} \pm \Delta x_{2I} \pm \cdots \pm \Delta x_{LI}) \neq 0\). Thus the theorem is proved.

C. Construction of Relay Matrices and Initial vector

**Theorem 3:** For the linear designs given by Construction 4.3 there exist \(R\) relay matrices satisfying condition (3) for arbitrary signal sets. Moreover, if the initial vector \(s_0 = [1\ 0\ \ldots\ 0]\), then the initial matrix \(X_0\) given in (2) becomes unitary.

**Proof:** See Appendix B.

Example 4.3: Let \(R = 4\). Then the DDSTC \(C\) is obtained using the design shown in (11) and the signal set given in Construction 4.4. The signal set is a Cartesian product of four 2-dimensional signal sets. The relay matrices are given as follows:

\[
A_1 = I_4, \quad A_2 = \begin{bmatrix}
0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 1 & 0
\end{bmatrix}, \quad A_3 = \begin{bmatrix}
0 & 0 & -1 & 0 \\
0 & 0 & 0 & -1 \\
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0
\end{bmatrix}, \quad A_4 = \begin{bmatrix}
0 & 0 & 0 & -1 \\
0 & 0 & -1 & 0 \\
0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0
\end{bmatrix}.
\]

The initial vector \(s_0 = [1\ 0\ \ldots\ 0]^T\) and the initial matrix \(X_0 = I_4\). This DDSTC is single complex symbol decodable (or 2 real symbol decodable).

V. SIMULATION RESULTS

In this section, we compare the error performance of the proposed DDSTC in Example 4.3 with that of the circulant codes in [3] and the cyclic codes in [5] for transmission rates of 1 bit per channel use (bpcu) and 1.5 bpcu. The signal set chosen for the proposed code is as given by Construction 4.4 with parameters \(r_1 = \frac{1 + \sqrt{3}}{2},\ r_2 = \sqrt{2}\) for a transmission rate of 1 bpcu and for the case of rate=1.5 bpcu, the signal set parameters are \(r_1 = 0.378,\ r_2 = 0.8452,\ r_3 = 1.1339\) and \(r_4 = 1.3628\). The circulant code of [3] is given by \(\{u_1A_1, u_2A_2, u_3A_3, u_4A_4| u_i \in \mathcal{F}, i = 1, \ldots, 4\}\). The relay matrices \(A_i\) are taken to be powers of the \(4 \times 4\) circulant matrix. The signal set \(\mathcal{F}\) is chosen to be \(\theta_i\) radians rotated version of 64-PSK for a transmission rate of 1 bpcu and 1024-PSK for a rate of 1.5 bpcu. The rotation angles are chosen as follows to guarantee full diversity: \(\theta_1 = 0,\ \theta_2 = 1.5,\ \theta_3 = 3,\ \theta_4 = 4.5\). Another reference for comparison is the cyclic codes proposed in [5] whose codewords for rate=1 bpcu and rate=1.5 bpcu are given as follows:

\[
\begin{bmatrix}
\zeta_{256} & 0 & 0 & 0 \\
0 & \zeta_{128} & 0 & 0 \\
0 & 0 & \zeta_{64} & 0 \\
0 & 0 & 0 & \zeta_{32}
\end{bmatrix}^i, \quad i = 0, \ldots, 255
\]

\[
\begin{bmatrix}
\zeta_{4096} & 0 & 0 & 0 \\
0 & \zeta_{2048} & 0 & 0 \\
0 & 0 & \zeta_{1024} & 0 \\
0 & 0 & 0 & \zeta_{512}
\end{bmatrix}^i, \quad i = 0, \ldots, 4095
\]

where, \(\zeta_{256} = e^{\frac{2\pi i}{256}}\) and \(\zeta_{4096} = e^{\frac{2\pi i}{4096}}\). For simulations, we have assumed a block fading channel which is quasi-static for 800 channel uses and varies independently from one block to another.

Fig. 5 shows the error performance curves of the proposed codes in comparison with those of [3], [5]. It can be observed from Fig. 5 that for a transmission rate of 1 bpcu, the proposed code outperforms the cyclic code by about 5 dB and the circulant code by more than 10 dB. Similarly for a transmission rate of 1.5 bpcu, it can be observed that the proposed code outperforms the cyclic code by about 5 dB and the circulant code by more than 25 dB. It is worthwhile to
note that for rate=1 bpcu, the decoding search space for
the proposed code is only 4 whereas it is 256 for the other
two codes. Similarly for rate=1.5 bpcu, the decoding search
space for the proposed code is only 8 whereas it is 4096 for the
other two codes. Because of the exponential growth of decoding
search space with increasing transmission rate for the codes
in [3], [5], it takes a prohibitively large time to complete a
error performance simulation for higher rates.

VI. DISCUSSION

We have thus constructed a class of four group decodable
DDSTCs for any power of two number of relays using
algebraic techniques. It is important to note that relaxing
the unitary matrix codebook to scaled unitary matrix codebook
has aided us in obtaining decoding complexity benefits.
A limitation of this algebraic method is that it is available only
for power of two number of relays. Extending this method to
obtain g-group decodable DDSTCs for g > 4 appears to be
difficult for two reasons:

1) The rate of the known linear designs in the literature
for g > 4 fall below 1 and obtaining R unitary relay
matrices satisfying Condition [3] is difficult and it is not
clear to the authors whether such matrices exist at all.
For example, constructing the relay matrices satisfying
Condition [3] for orthogonal designs is difficult.

2) Even if the relay matrices are obtained, an initial vector
satisfying Condition [4] may not exist for the chosen
relay matrices.

For the specific case of g = 4, things were possible because the
linear designs correspond to left regular matrix representation
of an algebra over C and hence using algebraic techniques,
it was possible to construct the relay matrices and the initial
vector satisfying all the required conditions.

Optimizing the signal sets for coding gain might be possible
for small number of relays and for small number of points.
However it becomes difficult for larger number of relays and/or
larger number of points because it involves many parameters
and a general closed form solution is difficult. Hence optimizing
the signal sets for coding gain is an important direction
for further work.

APPENDIX A

CONSTRUCTION USING EXTENDED CLIFFORD ALGEBRA

Definition 3: Let \( L = 2^n, n \in \mathbb{N} \). An Extended Clifford
algebra denoted by \( \text{Cliff}_n^L \) is the associative algebra over \( \mathbb{R} \) generated
by \( n + a \) objects \( \gamma_k, k = 1, \ldots, n \) and \( \delta_i, i = 1, \ldots, a \)
which satisfy the following relations:

- \( \gamma_k^2 = -1, \forall k = 1, \ldots, n; \gamma_k \gamma_j = -\gamma_j \gamma_k, \forall k \neq j \)
- \( \delta_i^2 = 1, \forall k = 1, \ldots, a; \delta_i \delta_j = \delta_j \delta_i, \forall 1 \leq k, j \leq a \)
- \( \delta_k \gamma_j = \gamma_j \delta_k, \forall 1 \leq k \leq a, 1 \leq j \leq n \)

The classical Clifford algebra, denoted by \( \text{Cliff}_n \), is obtained
when only the first two relations are satisfied and there are no \( \delta_i \).
Thus \( \text{Cliff}_n \) is a sub-algebra of \( \text{Cliff}_n^L \). Let \( \mathcal{S}_n \) be the natural
\( \mathbb{R} \) basis for this sub-algebra.

\[ \mathcal{S}_n^L = \mathcal{S}_n \cup \{ \delta_i | i = 1, \ldots, a \} \]

\[ \cup_{m=2}^{n+1} \mathcal{S}_n \{ \prod_{i=1}^{m} \delta_i | 1 \leq k_i \leq k_{i+1} \leq a \} \]

Then a natural \( \mathbb{R} \) basis for \( \text{Cliff}_n^L \) is:

\[ \mathcal{S}_n = \{ 1 \} \cup \{ \gamma_1 | 1 = 1, \ldots, n \} \]

\[ \cup_{m=2}^{n} \{ \prod_{i=1}^{m} \delta_i | 1 \leq k_i \leq k_{i+1} \leq n \} \]

We need a unitary matrix representation for the symbols
\( 1, \gamma_1, \gamma_2, \gamma_1 \gamma_2, \delta_1, k = 1, \ldots, a, \)
\( \cup_{m=2}^{n+1} \prod_{i=1}^{m} \delta_i | 1 \leq k_i \leq k_{i+1} \leq a \) in the algebra \( \text{Cliff}_n^L \).
Such matrices are naturally provided by the left regular
representation.

We first view \( \text{Cliff}_n^L \) as a vector space over \( \mathbb{C} \) by thinking of
\( \gamma_1 \) as the complex number \( i = \sqrt{-1} \). A natural \( \mathbb{C} \) basis for
\( \text{Cliff}_n^L \) is given by:

\[ \mathcal{B}_n^L = \{ 1, \gamma_2 \} \cup \{ (1, \gamma_2) \delta_i | i = 1, \ldots, a \} \]

\[ \cup_{m=2}^{n} \{ (1, \gamma_2) \prod_{i=1}^{m} \delta_i | 1 \leq k_i \leq k_{i+1} \leq a \} \]

Thus the dimension of \( \text{Cliff}_n^L \) seen as a vector space over \( \mathbb{C} \) is
\( 2^{n+1} - a - 1 \). We have a natural embedding of \( \text{Cliff}_n^L \) into \( \text{End}_\mathbb{C}(\text{Cliff}_n^L) \),
the (set of all \( \mathbb{C} \)-linear maps from \( \text{Cliff}_n^L \) to itself) given by left
multiplication as shown below.

\[ \phi : \text{Cliff}_n^L \rightarrow \text{End}_\mathbb{C}(\text{Cliff}_n^L) \]

\[ \phi(x) = L_x : y \mapsto xy \]

Since \( L_x \) is \( \mathbb{C} \)-linear, we can get a matrix representation of
\( L_x \) with respect to the natural \( \mathbb{C} \) basis \( \mathcal{B}_n^L \). Left regular
representation yields unitary matrix representations for the
required symbols in the algebra. The resulting linear designs
are precisely those given by Construction [3, 5]. This has been
explicitly shown in more detail in [10].

APPENDIX B

PROOF OF THEOREM [3]

Proof: Let us prove the theorem assuming that all the
complex variables of the linear design take values from the
entire complex field. We use the fact that the linear design for
\( R = 2^n \) relays was obtained as a matrix representation of the
Extended Clifford algebra \( \text{Cliff}_n^L \). Thus \( a = \lambda - 1 \). We choose
\[ M = 2^n = \frac{q}{2}. \]

The \( M \) relay matrices are explicitly given by the union of the elements of the sets \( \{\phi(1), \phi(\delta_1), \ldots, \phi(\delta_a)\} \) and \( \{\prod_{k=1}^{m} \phi(\delta_k) \mid 1 \leq k_1 \leq k_{i+1} \leq a\} \). By virtue of the property that \( \phi \) is a ring homomorphism, these matrices are guaranteed to commute with all the codewords because they are matrix representations of elements belonging to the center of the algebra \( \mathbb{H}_2^{2^{p-1}} \). To obtain the remaining \( R - M \) relay matrices, we need to find unitary matrices which satisfy

\[ A_iC^* = CA_i, i = M + 1, \ldots, R \]

(23)

where, \( C \) is any codeword. But the codeword \( C \) is simply a matrix representation of some element belonging to the Extended Clifford algebra. One method to get these relay matrices is to take them from within the Extended Clifford algebra itself. By doing so, we can translate the condition in (23) into a condition on elements of the algebra which will then provide us a handle on the problem. Towards that end, we first identify a map in the algebra which is the analogue of taking the conjugate of the matrix representation of an element. Note from Appendix A that we used the fact that \( \gamma_1 \) can be thought of as the complex number \( i = \sqrt{-1} \). When we take the conjugate of a matrix, we simply replace \( i \) by \( -i \). Hence the analogue of this action in the algebra is to replace \( \gamma_1 \) by \( -\gamma_1 \). Thus, the analogous map \( \sigma \) in the algebra is defined as follows:

\[ \sigma : x \mapsto \bar{x} \]

(24)

where, the element \( \bar{x} \) is obtained from \( x \) by simply replacing \( \gamma_1 \) by \( -\gamma_1 \) in the expression of \( x \) in terms of the natural \( \mathbb{R} \)-basis of Extended Clifford algebra. Now the problem is to find \( R - M \) distinct elements denoted by \( a_i, i = M + 1, \ldots, R \) of the algebra \( \mathbb{H}_2^{2^{p-1}} \) which satisfy \( a_i \bar{x} = x a_i, \forall x \in \mathbb{H}_2^{2^{p-1}} \). The elements of the union of the following two sets satisfy the above required condition.

\[ \{\gamma_2 \{1, \delta_1, \ldots, \delta_a\}\}, \{\gamma_2 \left\{ \bigcup_{m=2}^{a} \prod_{i=1}^{m} \delta_k \mid 1 \leq k_1 \leq k_{i+1} \leq a \right\}\} \]

This can be proved by using the anti-commuting property, i.e., \( \gamma_2(-\gamma_1) = \gamma_1(\gamma_2) \). Hence the matrix representation of these specific elements gives the unitary relay matrices \( A_i, i = M + 1, \ldots, R \). Suppose we plug in these relay matrices to form a linear design

\[ X = [A_1 s \ldots A_M s A_{M+1} s^* \ldots A_R s^*] \]

where, \( s = [x_1 \; x_2 \; \ldots \; x_R]^T \), it turns out that we get exactly the same linear design which is used at the source. Thus the initial vector choice of \( s_0 = [1 \; 0 \; \ldots \; 0]^T \) guarantees that the initial matrix \( X_0 \) is an identity matrix.

However, we would like to point out that there are also other elements of the algebra which satisfy \( a_i \bar{x} = x a_i, \forall x \in \mathbb{H}_2^{2^{p-1}} \). For example, consider the union of the elements of the sets \( \{\gamma_1 \gamma_2 \{1, \delta_1, \ldots, \delta_a\}\} \) and \( \{\gamma_1 \gamma_2 \left\{ \prod_{m=2}^{a} \prod_{i=1}^{m} \phi(\delta_k) \mid 1 \leq k_1 \leq k_{i+1} \leq a \right\}\} \).

ACKNOWLEDGMENT

The authors thank Prof. Hamid Jafarkhani, Dr. Yindi Jing and Dr. Frédérique Oggier for providing us with preprints of their recent works [3, 4, 5, 9]. The authors are grateful to the anonymous reviewers for providing constructive comments which helped in improving the presentation of this paper.
