Introduction

Sleep-disordered breathing (SDB) may lead to cardiovascular morbidity due to repetitive episodes of complete or partial upper airway obstruction [1,2]. The mechanisms underlying such adverse cardiovascular effects are complex and are attributed, in part, to increased cardiac (stretch or) transmural pressure generated during occluded breathing, hypoxemia, and increased sympathetic activity (due to hypoxemia and arousals from sleep) [3]. Such pathophysiological mechanisms can also stimulate the secretion of natriuretic hormones [4] and thereby cause nocturia.

Although previous case series and reports have reported nocturia as a manifestation of SDB [5,6,7,8,9,10], a comprehensive and systematic study of the association between nocturia and SDB in a large community-based population has not been performed.

Moreover, nocturia per se may be associated with morbidity and mortality, rather than merely reflecting a consequence of adverse cardio-respiratory interactions [11]. Specifically, nocturia has been independently associated with falls, hypertension, and all-cause mortality in a study of elderly patients [12,13,14]. However, in such cohorts assessing the relationship between nocturia and hypertension, the investigators did not perform polysomnography...
Participants were queried as to how often in the prior year, did they awaken to go to the bathroom: never, rarely (1/month or less), sometimes (2–4/month), often (5–15/month), and almost always (16–30/month). Moreover, cohort studies have demonstrated an association between SDB and all cause mortality [20,21,22,23,24]. Hence, it is unclear as to whether nocturia is independently associated with hypertension, or whether such association may be attributable to residual confounding by co-existent SDB.

Our primary aim was to determine the cross-sectional associations between nocturia and cardiovascular morbidity exists (hypertension, coronary artery disease, heart failure, and stroke) that is independent of SDB in the Sleep Heart Health Study (SHHS) cohort. We hypothesized that self-reported frequency of nocturia is associated with prevalent hypertension and prevalent cardiovascular disease after adjusting for co-existent SDB. An additional aim was to determine whether nocturia is independently associated with SDB. We hypothesized that SDB is independently associated with self-reported frequency of nocturia in a large cohort of middle-aged and older individuals.

### Methods

#### Study Population

This report uses data from the Sleep Heart Health Study (SHHS), a prospective multi-center cohort study that was performed to assess whether SDB is a risk factor for cardiovascular disease in middle-age and older adults. The SHHS had been approved by the institutional review board at each participating site. Informed written consent was obtained from all participants. Details regarding the design and methodology are available elsewhere [25,26]. Briefly, participants were recruited from ongoing cohort studies, that included the Cardiovascular Health Study [27], the Framingham Heart Study

### Table 1. Participant Characteristics.

| Variable                | Nocturia | No nocturia | P value |
|-------------------------|----------|-------------|---------|
| Age (years)             | 64.2±10.5| 61.2±11.3   | <0.0001 |
| Men (proportion)        | 56.7%    | 57.6%       | 0.49    |
| Body Mass Index (Kg/m²) | 28.7±5.5 | 28.3±5.2    | 0.007   |
| FEV1 (Liters)           | 2.62±0.80| 2.77±3.3    | 0.02    |
| Alcohol consumption     |          |             |         |
| (drinks per night)      | 0 (0, 3) | 0 (0, 4)    | 0.49    |
| Diuretic intake (proportion) | 17.0% | 13.4% | 0.0001 |
| Diabetes Mellitus (proportion) | 11.4% | 10.0% | 0.08   |
| Alpha blockers (proportion) | 6.1% | 2.8% | <0.0001 |
| AHI (4% hypopnea)       | 4.6 (1.6, 11.1) | 5.7 (1.9, 13.9) | 0.0001 |
| Patients with AHI >15 events/hr | 23.2% | 17.4% | <0.0001 |
| Patients with AHI >10 events/hr | 33.9% | 27.3% | <0.0001 |
| Patients with AHI >5 events/hr | 39.8% | 48.2% | <0.0001 |
| Diabetes Mellitus *     | 0.11 (0.05) | 0.034 | 0.0008, 0.20 |

Kg/m² = kilogram/meter²; FEV1 = forced expiratory volume; hr = hour; proportions compared by Chi square; Mann-Whitney test for non-parametrics (presented as median and interquartile range); unpaired t-test for parametric variables (presented as mean ± SD); AHI = apnea-hypopnea index. doi:10.1371/journal.pone.0030969.t001

### Table 2. Variables Associated With Presence Of Nocturia.†

| Variable               | B (S.E.) | P value | 95% CI  |
|------------------------|----------|---------|---------|
| AHI                   | 0.008 (0.001) | <0.0001 | 0.005, 0.01 |
| AHI >15               | 0.18 (0.04) | <0.0001 | 0.12, 0.27 |
| AHI >10               | 0.17 (0.04) | <0.0001 | 0.10, 0.24 |
| AHI >5                | 0.14 (0.03) | <0.0001 | 0.07, 0.20 |

Figure 1. Proportions and numbers of patients with reported frequency of nocturia. Participants were queried as to how often in the prior year, did they awaken to go to the bathroom: never, rarely (1/month or less), sometimes (2–4/month), often (5–15/month), and almost always (16–30/month). doi:10.1371/journal.pone.0030969.g001
the Tucson Epidemiologic Study of Obstructive Airways Disease [29], the Strong Heart Study [30], the Atherosclerosis Risk in Communities Study [31], the Health and Environment Cohort Study in Tucson, as well as three New York City cohorts undergoing evaluation for the impact of psychosocial risk factors on cardiovascular disease. Inclusion criteria included age ≥ 40 years and not having received positive airway pressure treatment for sleep apnea, a tracheostomy, or supplemental oxygen. Participants underwent unattended PSG at home between December 1995 and January 1998.

Polysomnography
Polysomnography (PSG) was performed in an unattended setting at home (Compumedics PS-2 system; Compumedics Pty. Ltd, Abbotsville, Australia). Recordings included electroencephalogram (C3/A1 and C4/A2), right and left electrooculograms, submental electromyogram, nasal/oral airflow recorded by thermocouple (Protech, Woodenville, WA), rib cage and abdominal movement recorded by inductive plethysmography, oxyhemoglobin saturation (SpO2) by pulse oximetry (Nonin, Minneapolis, MN), and electrocardiogram. Leg movements were not recorded. Standardized techniques for sensor attachment and quality assurance were used and have been previously described [25].

PSG Scoring and Sleep Parameters
Scoring of sleep stages followed the guidelines of Rechtschaffen and Kales and were performed at a centralized location [32]. Apnea was defined as complete or almost complete cessation of airflow (<25% of baseline) and associated with 4% desaturation or more. Hypopnea was defined as a decrease to less than 70% of baseline on either inductance plethysmography channel or thermocouple channels, for 10 seconds or longer and associated with 4% desaturation or more. The apnea hypopnea index (AHI) was calculated by computing the average number of apneas plus hypopneas per hour of sleep.

Health and Demographic Data
Demographic information was obtained from the parent cohorts. Participants’ weight was measured using a calibrated scale at the time of PSG. Participants’ height was taken from parent study data obtained within 3 years of the sleep study and used to calculate the body mass index (BMI) [kg/m²]. Health information was derived from several sources. Data related to chronic medical conditions (such as diabetes mellitus) was obtained from the parent cohorts. Current medications were recorded on the night of the PSG. The SHHS Sleep Habits Questionnaire incorporated the Epworth Sleepiness Scale.

An interviewer administered health interview on the night of the PSG was used to obtain information pertaining to self-reported prevalent cardiovascular disease, smoking and caffeine use. In the Sleep Heart Health Study (SHHS), the interviewer asked if a doctor had ever told the participant that she or he had angina, heart attack, heart failure, or stroke and if the participant ever underwent coronary artery bypass surgery or coronary angioplasty. An “unsure” response was allowed for each item. We then defined prevalent cardiovascular disease as a positive response to one or more of the afore-mentioned conditions or procedures.

Figure 2. Association between nocturia and presence of sleep-disordered breathing based upon different apnea-hypopnea index (AHI) thresholds are shown as odds ratio (symbol) and 95% confidence intervals (y-error bars). Odds ratios and respective confidence intervals that were adjusted for confounders (left panel) and unadjusted for confounders (right panel) are shown. The x-axis of each panel represents nocturia expressed as a dichotomous categorical variable (nocturia present or absent) by progressively increasing the threshold level of collapse from ‘rarely’ to ‘always’ to yield four different dichotomous variables for nocturia. The cluster of three symbols with corresponding error bars for each definition of nocturia correspond to variable AHI thresholds for nocturia from left-to-right (>15, >10 and >5 per hour, respectively). For nocturia defined as greater than rarely (closed triangle) only one adjusted odds ratio is shown (left panel) because multivariate regression was performed only if univariate regression was significant at P<0.05 (see methods).

doi:10.1371/journal.pone.0030969.g002
Relationship between nocturia and SDB

Univariate logistic regression identified the following covariates associated with nocturia: greater age, higher body mass index, lower forced expiratory volume in one second, ingestion of any diuretic agents or alpha-blockers (likely for prostatism). In 6342 participants (age 63±11 [SD] years, 53% women) self-reported levels of nocturia are depicted in Figure 1. In Table 2, increasing severity of nocturia — expressed as an ordinal variable — was associated with increasing severity of SDB, increasing age, increasing BMI, greater alcohol consumption, diuretic intake, presence of diabetes mellitus, lower lung function (measured as forced expiratory volume in 1 second [FEV1]), greater sleep fragmentation (time awake after sleep onset and arousals per hour of sleep), and alpha-blocker ingestion. After adjusting for such confounders, the association between nocturia and SDB remained (Table 2). Collapsing the ordinal variable differently — in order to identify the threshold level of nocturia frequency that was most strongly associated with SDB — yielded two threshold levels (at least 5 nights per month or at least 16 nights per month) that were significantly associated with SDB (Figure 2). Using the former definition (at least 5 nights per month), 3625 (57.1%) patients were classified as having nocturia (Figure 1).

Results

The characteristics of the patients with and without nocturia are shown in Table 1. Patients with nocturia were older, had greater body mass index (BMI), and were more likely to be receiving diuretic agents or alpha-blockers (likely for prostatism). In 6342 participants (age 63±11 [SD] years, 53% women) self-reported
diuretic, ingestion of alpha blocker agents, and the presence of SDB based on a thresholds of 5, 10, or 15 events per hour for the AHI (P<0.05) (Table 3). Presence of diabetes mellitus and ingestion of alcohol also had a tendency to be associated with nocturia (P = 0.08; Table 3).

Multiple logistic regression, with nocturia as the dependent variable, revealed that after adjusting for age, body mass index, ingestion of diuretics, alcohol consumption, diabetes mellitus, and alpha blocker agents, and FEV1, the presence of SDB was independently associated with nocturia using all 3 cutoffs for AHI (5, 10, or 15 per hour) with hypopneas requiring ≥4% oxygen desaturation. However, statistical significance was not achieved for AHI >3 per hour (Table 3).

Relationship between nocturia, hypertension, and cardiovascular disease

Univariate logistic regression identified the following covariates were associated with hypertension: nocturia, greater severity of SDB (AHI with 4% oxygen desaturation; continuous variable), greater age, higher body mass index, ethnicity, cigarette smoking, time awake after sleep onset, arousals per hour of sleep, alcohol ingestion, neck circumference, and waist-hip ratio (Table 4). Using multiple logistic regression, nocturia was independently associated with hypertension after adjusting for age, body mass index, ethnicity, cigarette smoking, alcohol ingestion, neck circumference, and waist-hip ratio, diuretics and severity of SDB (AHI with hypopneas requiring at least 4% oxygen desaturation; Table 4).

Nocturia was independently associated with cardiovascular disease and stroke after adjusting for SDB and other known confounders for cardiovascular disease, whereas, nocturia was associated with a reduced odds ratio for presence of heart failure (Table 5). History of coronary artery disease was not associated with presence of nocturia (table 5).

Polysomnographic changes and Sleepiness

Patients with nocturia displayed greater derangement of polysomnographic measures than patients without nocturia.

Table 6. Those with nocturia had less total sleep time, sleep efficiency and proportion of REM sleep, but had a higher arousal index and were more hypoxic. They also were subjectively more sleepy on the basis of their Epworth Sleepiness Score. 

Discussion

Nocturia was independently associated with SDB in a large community-based sample of middle-aged and older subjects. Although previous reports had identified nocturia as a manifestation of SDB, such studies had used either a much smaller sample size (ranging from 5 to 138 subjects) [5,6,7,8,9,34,35] or had studied a sleep lab-based population [6,7,8,9,10,34,35]. Our study findings are therefore more generalizable as we studied a large community-based sample of middle-aged to older population. Moreover, our cross-sectional study revealed a robust relationship between nocturia and SDB after adjustment for many potential confounders. The association with SDB has important implications to patient care and research. Primary care physicians and urologists should consider SDB in the differential diagnosis of patients who present with nocturia. In addition, the mechanistic underpinning for the relationship between nocturia and SDB, viz., natriuretic peptides and the stimulus for release of such natriuretic peptides by the adverse cardio-respiratory effects of SDB (hypoxia, increased respiratory effort [increased transmural pressure], and

arousals from sleep) and rostral fluid shifts may be worthy of further research [36].

In our study, we also show that nocturia was independently associated with prevalent hypertension, cardiovascular disease, and stroke. Such an association was independent of co-existent SDB measured by the AHI (Tables 4 and 5). Previous studies have demonstrated an association between nocturia and cardiovascular morbidity, however, none of these studies measured or adjusted for co-existent SDB [12,15,16,17,18,19]. Therefore, prior to this report, whether nocturia was associated with hypertension independent of co-existent SDB was unclear.

The association between nocturia and cardiovascular morbidity raises some intriguing questions. First, what is the mechanism underlying the association between nocturia and cardiovascular morbidity? When considering this question, we should note that the association between hypertension and nocturia was also independent of the effects of diuretics (Table 4). One potential postulated mechanism for the association between nocturia and cardiovascular morbidity has been the adverse hemodynamic changes associated with the stress of nocturnal awakenings [37]. It is conceivable that nocturia, by virtue of disrupting sleep and causing insufficient sleep, may lead to adverse cardiovascular effects. There is an evolving, large body of literature concerning the effects of poor or insufficient sleep on increased blood pressure, glucose intolerance, and inflammation, which, may in turn, lead to adverse cardiovascular morbidity [38]. In our report, however, while sleep duration and efficiency were statistically lower in subjects experiencing nocturia (when compared to subjects without nocturia) the difference was small (Table 6). Such data would suggest that mechanisms other than insufficient sleep may be responsible for the association between nocturia and cardiovascular morbidity. Moreover, the multivariate regressions revealed that nocturia was associated with cardiovascular disease independent of sleep fragmentation measured as time awake after sleep onset or arousals per hour of sleep (Tables 4 and 5). Such findings would
suggest that the association between nocturia and cardiovascular disease is independent of known associations between adequate sleep and cardiovascular disease [39].

Second, different cardiovascular morbidities expressed divergent relationships with the presence of nocturia. Nocturia was associated with an increased risk for hypertension, cardiovascular disease, and stroke, whereas, presence of nocturia appeared to be protective against heart failure (Table 5). Conceivably, nocturia could reduce circulating blood volume and reduce cardiac preload in patients with heart failure. However, such reasoning would be at odds with data suggesting that the up-regulation of the neurohormonal process underlying generation of nocturia – natriuretic peptides – is associated with increased cardiovascular mortality [40,41]. Such data may in turn be reconciled by evidence suggesting that certain polymorphisms in natriuretic peptides may be associated with reduced bioactivity of such natriuretic hormones and consequently can influence outcomes in heart failure [42]. We realize that the effects of residual confounding cannot be excluded as a potential cause for such an association. Clearly, the relationship between natriuretic peptides, nocturia, and cardiovascular outcomes is complex and needs more research.

The findings of this report should be considered in light of a number of limitations. First, the association between nocturia and SDB does not necessarily imply a cause-effect relationship based on our data. However, other studies have demonstrated the improvement of nocturia following continuous positive airway pressure therapy and can attribute nocturia – at least in part – to SDB [34,35,43]. Second, our study did not consider concomitant measures relevant to nocturia such as daily water intake or diurnal variation in urine production. Conceivably, greater ingestion of fluids in patients with SDB who suffer from dry throat sensation may play a role in the observed association between nocturia and SDB. Third, we used AHI as the primary measure of the insults imposed by SDB and did not consider a composite index that included hypoxia and arousals – both mechanistically implicated in the causation of nocturia by SDB. However, arousals alone have not always been shown to be closely associated with cardiovascular morbidity. Fourth, our report could have been strengthened by accounting for the confounding influence of kidney disease, which, through the loss of renal concentrating ability may lead to polyuria and accompanying nocturia. However, in the SHHS study, while the individual sub-cohorts had different measures relating to kidney function that were obtained at different points in time, there was not a uniform measure of kidney function for the entire SHHS cohort obtained at the same time relative to the SHHS protocol. We did find that measures of hypoxemia (number of oxygen desaturations per hour and time spent below 90%) were indeed associated with nocturia (data not shown). However, as anticipated, such hypoxemia variables and the AHI were closely correlated. Therefore we chose to only use the measure with the stronger association with nocturia in our regression models – viz., apnea-hypopnea index. Lastly, the study variables regarding nocturia and cardiovascular disease were based upon self-reported cross-sectional data obtained at enrollment. Nocturia was not measured from urine volume and the presence of cardiovascular disease (other than hypertension) was not cross-referenced against patient medical records. However, because of the difficulty in measuring overnight nocturnal urine production, nocturia has been defined quite simply by international consensus as just waking at night to void [33].

In conclusion, nocturia is independently associated with sleep-disordered breathing. After adjusting for SDB, there remained an association between nocturia and cardiovascular morbidity. Such results support screening for SDB in patients with nocturia, but the mechanisms underlying the relationship between nocturia and cardiovascular morbidity require further study. These data suggest that clinicians should be cognizant of the association between nocturia and SDB, and consider screening for SDB in patients with recalcitrant nocturia.

**Acknowledgments**

The authors are indebted to the SHHS participants who contributed their time to this study. The authors are grateful for diligent work performed by the technical staff at the clinical sites for collecting the data. The authors are thankful to the reading center for analyzing and coding the sleep studies. SP and SQF had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

SHHS acknowledges the Atherosclerosis Risk in Communities Study, the Cardiovascular Health Study, the Framingham Heart Study, the Cornell/Mt. Sinai Worksite and Hypertension Studies, the Strong Heart Study, the Tuscon Epidemiologic Study of Airways Obstructive Diseases (TESAOD), and the Tuscon Health and Environment Study for allowing their cohort members to be part of the SHHS and for sharing such data for the purposes of this study. SHHS is particularly grateful to the members of these cohorts who agreed to participate in SHHS as well. SHHS further recognizes all the investigators and staff who have contributed to its success. A list of SHHS investigators, staff, and their participating institutions is available on the SHHS website (www.jhsph.edu/shhs).
