Abstract

Risk-averse model predictive control (MPC) offers a control framework that allows one to account for ambiguity in the knowledge of the underlying probability distribution and unifies stochastic and worst-case MPC. In this paper we study risk-averse MPC problems for constrained nonlinear Markovian switching systems using generic cost functions, and derive Lyapunov-type risk-averse stability conditions by leveraging the properties of risk-averse dynamic programming operators. We propose a controller design procedure to design risk-averse stabilizing terminal conditions for constrained nonlinear Markovian switching systems. Lastly, we cast the resulting risk-averse optimal control problem in a favorable form which can be solved efficiently and thus deems risk-averse MPC suitable for applications.

Key words: Risk measures; Nonlinear Markovian switching systems; Model predictive control.

1 Introduction

1.1 Background and Contributions

There exist two main ways to deal with uncertainty in model predictive control (MPC), namely, the robust and the stochastic approaches. In robust MPC, modeling errors or disturbances are modeled as unknown-but-bounded quantities and the performance index is minimized with respect to the worst-case realization (min-max approach) \cite{18}. However, such worst-case events are unlikely to occur in practice and render robust MPC severely conservative since all statistical information, typically available from past measurements, is ignored.

On the other hand, in stochastic MPC we assume that the underlying uncertainty is a random vector following some probability distribution \cite{14} and minimize the expectation of a performance index; such formulations are significantly less conservative. The driving random process is often taken to be normally and independently identically distributed \cite{12} or it is assumed that it is a finite Markov process \cite{17} and in scenario-based MPC, filtered probability distributions are estimated from data \cite{11}. However, not always can we accurately estimate a distribution from available data, nor does it remain constant in time. Stochastic MPC will guarantee mean-square stability of the closed-loop system only with respect to the nominal probability distribution, therefore, errors in the estimation of that distribution may lead to bad performance or even instability.

The theory of risk measures \cite{26} allows to interpolate between these two extreme cases. Roughly speaking, risk measures quantify the importance and effect of the right tail of a distribution of losses, that is, the impact of the occurrence of extreme events. As such they offer a mathematically elegant tool to tackle problems where we seek to avoid high effect low probability (HELP) events and can be readily used in various applications.

The first steps to risk-averse formulations can be traced back to linear-exponential-quadratic Gaussian control \cite{13} and the study of stochastic control problems under inexact knowledge of the underlying probability distribution which is often termed distributionally ro-
bust [10]. Distributionally robust control methodologies have been proposed for linear systems with probabilistic constraints assuming knowledge of some moments of the distribution [27]. The same problem was also recently addressed for Markov decision processes with uncertain transition probabilities [28].

Risk-averse MPC formulations for Markov jump linear systems (MJLS) are studied in [6, 7]. In [6] the authors formulate an MPC optimization problem employing a coherent risk measure of an uncertain cost as an objective function and give conditions under which the MPC control law is stabilizing, albeit for a system with no state-input constraints. This is extended in [7] assuming ellipsoidal state-input constraints. Building up on these results, we further improve on the state of the art by studying nonlinear systems and proposing a computationally favorable formulation for risk-averse optimization problems which leads to low computation times.

In the optimization and operations research communities, the solution of multistage risk-averse optimal control problems has been considered prohibitive as only bundle and cutting-plane methods are currently used [2, 5, 8]. Reported results are limited to short prediction horizons and linear stage cost functions. An alternative solution approach solves the dynamic programming (DP) problem using multiparametric piecewise quadratic programming [16], but its applicability is limited to systems with few states and small prediction horizons [15]. In a 2017 paper, Rockafellar proposed an algorithmic scheme for solving multistage problems using a non-composite (not nested) risk measure recognizing the difficulty of solving problems with nested typically nonsmooth operators. In Section 5 we present an algorithmic scheme for solving multistage problems by disentangling solutions of multistage risk-averse problems.

In this paper we formulate multistage risk-averse optimal control problems using Markov risk measures in a DP setting and derive Lyapunov-type risk-averse stability conditions. We study risk-averse MPC formulations for nonlinear Markovian switching systems under generally nonconvex joint state-input constraints and propose a controller design procedure for nonlinear systems with smooth dynamics and Lipschitz-continuous gradient. Lastly, we provide simulation examples to demonstrate the applicability of the proposed approach.

1.2 Notation

Let $\mathbb{R} := \mathbb{R} \cup \{+\infty\}$ be the set of extended-real numbers, $\mathbb{N}_{[k_1,k_2]}$ the integers in $[k_1,k_2]$. For $z \in \mathbb{R}^n$ let $[z]_+ = \max\{0, z\}$ (where the max is taken element-wise).

We denote by $1_n$ the vector in $\mathbb{R}^n$ with all coordinates equal to 1. We denote the sets of $n$-by-$n$ symmetric positive definite (semidefinite) matrices as $S_n^+$ ($S_n^-$). For two $n$-by-$n$ symmetric matrices $M_1, M_2$, $M_1 \succ M_2$ means that $M_1 - M_2 \in S_n^+$. We denote the transpose of a matrix $A$ by $A^T$ and the identity matrix by $I$. For a $g : \mathbb{R}^n \to \mathbb{R}^m$, its Jacobian matrix is the mapping $J_g : \mathbb{R}^n \to \mathbb{R}^{m \times n}$ defined as $J_g(x) = (\partial g_i(x)/\partial x_j)_{i,j}$, provided that the partial derivatives exist. For $\epsilon \geq 0$ we define $B_\epsilon = \{x \mid \|x\| \leq \epsilon\}$. For a set $C \subseteq \mathbb{R}^n$, we define its indicator function as $\delta_C(x) = 0$ if $x \in C$ and $\delta_C(x) = \infty$ otherwise. The domain of an extended-real-valued function $f : \mathbb{R}^n \to \mathbb{R}$ is $\text{dom} f = \{x \in \mathbb{R}^n \mid f(x) < \infty\}$. An extended-real-valued function $f : \mathbb{R}^n \to \mathbb{R}$ is called proper if its domain is nonempty; it is called lower semi-continuous (lsc) if its lower level sets are closed. An $\ell : \mathbb{R}^n \times \mathbb{R}^m \supseteq (x,u) \mapsto \ell(x,u) \in \mathbb{R}$ is called level bounded in $u$ locally uniformly in $x$ if for each $x_0 \in \mathbb{R}^n$ and $\alpha \in \mathbb{R}$, there is a neighborhood $U_{x_0}$ of $x_0$ along with a bounded set $B \subseteq \mathbb{R}^m$ such that $\{u \mid \ell(x,u) \leq \alpha\} \subseteq B$ for all $x_0 \in U_{x_0}$. The effective domain of a set-valued mapping $F : \mathbb{R}^n \rightrightarrows \mathbb{R}^m$ is defined as $\text{dom} F = \{x \in \mathbb{R}^n \mid F(x) \neq \emptyset\}$. For a nonempty set $E$ and a finite set $N$ we define $\text{finc}(E,N) = \{V : E \times N \to \mathbb{R}^n \mid V(x,i) \geq 0, V(0,i) = 0, \text{ for all } x \in E, i \in N\}$.

2 Risk-averse optimal control

2.1 Measuring risk

Let $\mathcal{N} = \mathbb{N}[1,n]$ be a discrete sample space. A probability measure thereon can be identified by a probability vector $p \in \mathbb{R}^n$ with $\sum_{i=1}^n p_i = 1$, $p_i \geq 0$ for $i \in \mathcal{N}$. Let $Z : \mathcal{N} \to \mathbb{R}$ be a real-valued random variable on $\mathcal{N}$ which represents a random cost; for $i \in \mathcal{N}$ let $Z_i = Z(i)$. The vector $(Z_i)_{i \in \mathcal{N}}$ identifies the random variable $Z$.

The expectation of a random variable $Z$ with respect to the probability vector $p$ is defined as

$$\mathbb{E}_p[Z] \equiv \mathbb{E}_p[Z(i); i] = \sum_{i \in \mathcal{N}} p_i Z_i. \quad (1)$$

The notation $\mathbb{E}_p[Z; i]$ is to emphasize that the expectation is taken with respect to $i$.

A risk measure on $\mathbb{R}^n$ is a mapping $\rho : \mathbb{R}^n \to \mathbb{R}$. It is called coherent if it satisfies the following properties [26, Sec. 6.3] for $Z, Z' \in \mathbb{R}^n$, $\alpha \geq 0, \lambda \in [0,1]$

A1. Convexity, $\rho(\lambda Z+(1-\lambda)Z') \leq \lambda \rho(Z)+(1-\lambda)\rho(Z')$;

A2. Monotonicity, $\rho(Z) \leq \rho(Z')$ whenever $Z \leq Z'$;

A3. Translation equivariance, $\rho(c1_n+Z) = c + \rho(Z)$,

A4. Positive homogeneity, $\rho(\alpha Z) = \alpha \rho(Z)$.

Trivially, the expectation is a coherent risk measure and so is the essential maximum $\text{essmax}[Z] = \max\{Z_i |
\[ p_i > 0, i \in \mathcal{N} \}. \] A popular risk measure is the average value-at-risk, also known as conditional value-at-risk or expected shortfall, which is defined as
\[
AV\varrho_{\alpha}[Z] = \begin{cases} \min_{t \in \mathbb{R}} \{ t + \alpha^{-1}E_p[Z - t] \}, & \alpha \in (0, 1] \\ \\text{essmax}(Z), & \alpha = 0. \end{cases}
\]

As a result of assumptions A1–A4, coherent risk measures can be written in the following dual form [26, Thm. 6.5]
\[
\rho[Z] = \max_{\mu \in \mathcal{A}(p)} \mathbb{E}_{\rho}[Z],
\]
where \( \mathcal{A}(p) \subseteq \mathbb{R}^n \) is a compact convex set of probability vectors containing \( p \) which we shall call the ambiguity set of \( \rho \). We may think of a coherent risk measure as the worst-case expectation with respect to a probability distribution taken from a set of probability vectors. We call \( \rho \) a polytopic risk measure if \( \mathcal{A}(p) \) is a polytope, i.e., it can be described by \( \rho[Z] = \max_{\mu \in \mathcal{A}(p)} \mu^T Z \ | \ I_p \mu = 1, F(p) \mu \leq b(p) \) for some \( F(p) \in \mathbb{R}^{p \times n} \) and \( b(p) \in \mathbb{R}^q \). The expectation, the essential maximum and \( AV\varrho_{\alpha}[Z] \) are polytopic risk measures. The ambiguity set of \( AV\varrho_{\alpha}[Z] \) interpolates between the risk-neutrality expectation operator \( (AV\varrho_{\alpha}[Z] = \mathbb{E}_p[Z], \mathcal{A}(p) = \{ p \}) \) and the worst-case essential maximum \( (AV\varrho_{\alpha}[Z] = \text{essmax}) \).

### 2.2 Markovian switching systems

In this work we consider Markovian switching systems
\[
x_{k+1} = f(x_k, u_k, i_k),
\]
driven by the random parameter \( i_k \) which is a time-homogeneous Markov chain with values in a finite set \( \mathcal{N} = \mathbb{N}[1, n] \) with transition matrix \( P = (p_{ij}) \in \mathbb{R}^{n \times n} \), that is \( P[i_{k+1} = j | i_k = i] = p_{ij} \) [9]. We call the states of this Markov chain, the modes of (3). We denote the cover of each mode by \( \text{cov}(i) := \{ j \in \mathcal{N} | p_{ij} > 0 \} \). We assume that at time \( k \) we measure the full state \( x_k \) and the value of \( i_k \). As the probabilistic information available up to time \( k \) is fully described by the pair \((x_k, i_k)\), the control actions \( u_k \) may be decided by a causal control law \( u_k = \kappa_k(x_k, i_k) \). This formulation aligns with that of the classic textbook [9], but there exist formulations where \( i_k \) is not known at time \( k \) and the control law is a function of \( x_k \) only [7].

Each \( f(\cdot, \cdot, i) : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \rightarrow \mathbb{R}^{n_x}, i \in \mathcal{N} \), is assumed to be continuous and satisfy \( f(0, 0, i) = 0 \). MJLS are a special case of (3) with \( f(x, u, i) = A_i x + B_i u, i \in \mathcal{N} \). System (3) is subject to the joint state-input constraints
\[
(x_k, u_k) \in Y_{i_k},
\]
and we shall assume that for all \( i \in \mathcal{N}, Y_i \) are nonempty, closed sets containing the origin.

### 2.3 Markov risk measures

Consider the space of pairs \((i, j) \in \Omega := \mathcal{N} \times \mathcal{N} \) equipped with the \( \sigma \)-algebra \( \mathcal{F} = 2^\Omega \) and the probability measure \( P[\{(i, j)\}] = p_{ij} \). The conditional probability conditioned by the knowledge of \( i \) can be identified with the probability vector \( P_i = \{ p_{ij} \}_1^\mathcal{N} \) — the \( i \)-th row of \( P \). For a random variable \( Z : \Omega \rightarrow \mathbb{R} \), the conditional expectation of \( Z \) conditioned by \( i \), denoted as \( \mathbb{E}_i[Z; j] \), is a random variable on \( \mathcal{N} \), that is \( \mathcal{N} \ni i \mapsto \mathbb{E}_i[Z; j] \in \mathbb{R} \), with
\[
\mathbb{E}_i[Z; j] := \mathbb{E}_i[P_i[Z; j] = \sum_{j \in \mathcal{N}} p_{ij} Z(i, j). \]

We may extend this definition to define conditional variants of risk measures. Following (5), we give the following definition

**Definition 1 (Markov risk measure)** Given a coherent risk measure \( \rho \) with ambiguity set \( \mathcal{A} \) and a probability transition matrix \( P \) of a Markov chain, we define the Markov risk measure \( \rho_i[Z; j] \) as
\[
\rho_i[Z; j] = \max_{\mu \in \mathcal{A}(P_i)} \sum_{j \in \mathcal{N}} \mu_j Z(i, j),
\]
for all random variables \( Z : \Omega \rightarrow \mathbb{R} \).

This definition falls into the general framework of [21]. This way, with every \( i \) we associate the coherent risk measure \( \rho_i[Z; j] \). As with the expectation, the notation \( \rho_i[Z; j] \) is to emphasize that the risk is computed with respect to \( j \).

### 2.4 Risk-averse optimal control and dynamic programming

Consider a stage cost function \( \ell \in \text{fcns}(\mathbb{R}^{n_x} \times \mathbb{R}^{n_u}, \mathcal{N}) \) and a terminal cost \( \ell_N \in \text{fcns}(\mathbb{R}^{n_x}, \mathcal{N}) \). Functions \( \ell \) are extended-real-valued, therefore, they can encode constraints such as (4) by taking \( \text{dom} \ell(\cdot, \cdot, i) = Y_i, i \in \mathcal{N} \). Likewise, \( \ell_N \) can encode constraints on the terminal state of the form \( x_N \in X_i^T \) by taking \( \text{dom} \ell_N(\cdot, i) = X_i^T, i \in \mathcal{N} \), where \( X_i^T \) contain the origin in their interiors. We may now introduce the following finite-horizon risk-averse optimal control problem

\[
\begin{align*}
\text{minimize} \quad & \ell(x_0, u_0, i_0) + \rho_{i_0} \left[ \inf_{u_1} \ell(x_1, u_1, i_1) + \rho_{i_1} \left[ \inf_{u_2} \ell(x_2, u_2, i_2) + \cdots + \rho_{i_{N-1}} \ell_N(x_N, i_N) \right] \right]_{i_1}^{i_2} \\
& + \rho_{i_1} \left[ \inf_{u_2} \ell(x_2, u_2, i_2) + \cdots + \rho_{i_{N-1}} \ell_N(x_N, i_N) \right]_{i_2}^{i_1},
\end{align*}
\]

where $x_{k+1} = f(x_k, u_k, i_k)$, for all $k \in \mathbb{N}_{[0,N-1]}$. As it will become evident in what follows, each one of the infima at stage $k$ in (7) is parametric in $x_k$ and $i_k$, that is, the minimization takes place over causal control laws $u_0, \ldots, u_{N-1}$. Note that under assumptions A1 and A2, we may interchange the Markov risk measures with the infima [26, Prop. 6.60] leading to risk-averse multistage formulations presented in [26, Sec. 6.8.4].

Problem (7) can be described by a DP recursion. Inspired by [26, Sec. 6.8.4], for a $V \in \text{fcns}(\mathbb{R}^{n_x}, \mathcal{N})$ we define the DP operator $T : \text{fcns}(\mathbb{R}^{n_x}, \mathcal{N}) \rightarrow \text{fcns}(\mathbb{R}^{n_x}, \mathcal{N})$ so that

$$(TV)(x,i) = \inf_u \{\ell(x, u, i) + \rho_i[V(f(x, u, i), j)]\} = \inf_u \ell(x, u, i) + \max_{\mu \in A(P_i)} \mu_j V(f(x, u, i), j).$$

Let $(SV)(x,i)$ be the corresponding set of minimizers for the optimization problem involved in the definition of $(TV)(x,i)$. This defines the following DP recursion

$V^*_k = TV^*_k,$  \hspace{1cm} (8a)

$U^*_k = SV^*_k,$ \hspace{1cm} (8b)

for $k \in \mathbb{N}_{[0,N-1]}$ with $V^*_0(x, i) := \ell_N(x, i), i \in \mathcal{N}$. For $C = \{C_i\}_{i \in \mathcal{N}}$ with $C_i \subseteq \mathbb{R}^{n_x}$ we define the mode-dependent predecessor operator $R(C) = \{R_i(C)\}_{i \in \mathcal{N}}$ with $R_i(C) = \{x \in \mathbb{R}^{n_x} | \exists u \in \mathbb{R}^{n_u}, (x, u) \in X_i, f(x, u, i) \in \bigcap_{j \in \text{cov}(i)} C_j\}$. Next, we present some fundamental properties of the DP operator $T$.

**Proposition 2** If $\ell_N \cdot, i$ is proper, lsc and $\ell_i \cdot, i$ are proper, lsc and level bounded in $u$ locally uniformly in $x$ for all $i \in \mathcal{N}$, then for all $i \in \mathcal{N}$:

(i) $TV \in \text{fcns}(\mathbb{R}^{n_x}, \mathcal{N})$ for $V \in \text{fcns}(\mathbb{R}^{n_x}, \mathcal{N})$,

(ii) $V^*_k \cdot, i$ are lsc,

(iii) $\text{dom} V^*_k \cdot, i = \text{dom} U^*_k \cdot, i \neq \emptyset$,

(iv) $U^*_k$ is compact-valued, $\forall \text{dom}(V^*_k+1) = R(\text{dom}(V^*_k))$.

**PROOF.** The proof goes along the lines of [17, Thm. 11a] using [20, Prop. 1.17, Prop. 1.26(a)].

We may easily verify the monotonicity property $TV \leq TV'$, for all $V, V'$ with $V \leq V'$, following [4]. An observation that will prove useful in what follows is that if $T\ell_N \leq \ell_N$, then $V^*_{k+1} \leq V^*_k$. The above risk-averse optimal control problem leads naturally to the statement of a risk-averse MPC problem where control actions are computed by a control law $\kappa_N^*(x,i) \in U^*_N(x,i)$. In Section 3 we state an appropriate risk-based notion of stability and provide conditions on $\ell_N$ for the MPC-controlled system $x_{k+1} = f(x_k, \kappa_N^*(x_k, i_k), i_k)$ to be stable.

### 3 Risk-averse stability

Consider the following Markovian switching system which is controlled by some control law $u_k = \kappa(x_k, i_k)$

$x_{k+1} = f^*(x_k, i_k) := f(x_k, \kappa(x_k, i_k), i_k),$  \hspace{1cm} (9)

subject to the constraints $(x_k, i_k) \in X^* \equiv \{(x, i) \mid (x, \kappa(x, i)) \in Y_i\}$. For convenience, we introduce the notation $X^*_i = \{x \mid (x, \kappa(x, i)) \in Y_i\}$, for $i \in \mathcal{N}$. Let $i(t) = (i_0, i_1, \ldots, i_k)$ denote an admissible path of length $k$ of the Markov chain $\{i_t\}_{t \in \mathbb{N}}$, that is, $i_{k+1} \in \text{cov}(i_t)$ for $t \in \mathbb{N}_{[0,k-1]}$. For a given initial state $x_0$, the solution of (9) at time $k$ is denoted as $\phi(k, x_0, i_{[k-1]})$.

In order to be able to define risk-based notions of stability, we must first introduce an appropriate notion of invariance for Markovian switching systems [17].

**Definition 3 (Uniform invariance)** Let $X = \{X_i\}_{i \in \mathcal{N}}$ be a collection of nonempty closed subsets of $\mathbb{R}^{n_x}$ and $X_i \subseteq X^*_i$. $X$ is called uniformly invariant (UI) for (9) subject to constraints $x \in X^*_i$ if $f^*(x, i) \in \bigcap_{j \in \text{cov}(i)} X_j$, whenever $x \in X_i$ for all $i \in \mathcal{N}$.

For the controlled system (9), the predecessor operator is now defined as $R_i(C) = \{x \in X^* \mid f^*(x, i) \in \bigcap_{j \in \text{cov}(i)} C_j\}$. Have that $C$ is UI if and only if $C_i \subseteq R_i(C)$ for all $i \in \mathcal{N}$ [17].

Given a coherent risk measure $\rho$ and a random variable $\psi(i_0, i_1, \ldots, i_k)$, let $\bar{\rho}_i[\psi] = \rho_u[\psi(i_0, i_1, \ldots, i_k); i_1]$ and recursively define $\bar{\rho}_k = \bar{\rho}_{k-1} \circ \bar{\rho}_{k-1} \cdots \bar{\rho}_{i_1}$, that is $\bar{\rho}_k[\psi] = \rho_u[\psi(i_0, i_1, \ldots, i_k); i_1] \cdots \rho_u[i_2; i_1]$ [26, Sec. 6.8.2].

We may now give the following stability notion [6].

**Definition 4 (Risk-square exponential stability)** We say that the origin is risk-square exponentially stable (RSES) for system (9) over a set $X = \{X_i\}_{i \in \mathcal{N}}$ if $X$ is UI and for $x_0 \in X_{i_0}$

$$\bar{\rho}_{k-1}[\|\phi(k, x_0, i_{[k-1]}\|)^2] \leq \lambda \rho^k \|x_0\|^2,$$

for all $k \in \mathbb{N}$, for some $\beta \in (0, 1)$, $\lambda \geq 0$.

RSES entails that the origin is exponentially mean-square stable for system (9) not only for the nominal probability distribution, but also for those probability distributions in the ambiguity set of the risk measure. In the unconstrained case, RSES corresponds to the notion of uniform global risk-sensitive exponential stability which is defined using the notion of dynamic risk measures [6]. If the underlying risk measure is the expectation operator, then RSES reduces to mean-square
The proof can be found in the appendix.

In Thm. 6 we show that \( V_N^\star \) is a mode-dependent risk-averse Lyapunov function over compact uniformly invariant subsets of \( \text{dom} V_N^\star \). We shall use this result in the following sections to design risk-averse stabilizing MPC controllers for MJLS as well as nonlinear Markovian switching systems. Note that Condition (iv) in Thm. 6 holds if the following assumption is satisfied (see [18, Prop. 2.15])

**Assumption 7 (Local boundedness of \( V_N^\star \))** For all \( i \in N \), functions \( \ell(\cdot, \cdot, i) \) and \( \ell_N(\cdot, i) \) are continuous on their domains, and the sets \( U_i(x) := \{ u \in \mathbb{R}^{n_u} | (x, u) \in Y_i \} \) are compact and bounded uniformly in \( x \).

Additionally, because of the monotonicity property of \( T \) and since \( T \ell_N \leq \ell_N \), condition (10) implies \( V_{k+1}^\star \leq V_k^\star \), thus \( \text{dom}(V_k^\star) \subseteq \text{dom}(V_{k+1}^\star) = R(\text{dom} V_k^\star) \) (Prop. 2), thus \( \text{dom} V_k^\star \) is UI.

### 4.2 Risk-averse MPC design for MJLS

Here we provide RSES conditions and design guidelines for risk-averse MPC of MJLS [9], that is \( f(x, u, i) = A_i x + B_i u \), using a quadratic stage cost \( \ell(x, u, i) = x^\top Q_i x + u^\top R_i u + \delta_{Y_i}(x, u) \), with \( Q_i \in S^{n_x}_+, R_i \in S^{n_u}_+ \), and \( Y_i \) are polytopes with the origin in their interiors. The terminal cost function is taken to be \( \ell_N(x) = x^\top P_i x + \delta_{X_i}(x) \) with \( P_i \in S^{n_x}_+ \) and \( X_i \). We shall derive conditions on \( P_i \) and \( X_i \) so that the stabilizing conditions of Thm. 6 are satisfied. Condition \( T \ell_N \leq \ell_N \) is equivalent to

\[
\text{dom}(T \ell_N) \supseteq \text{dom} \ell_N \iff R(X) \supseteq X^\star,
\]

where \( x^\star = f(x, u, i) \) and the minimization in (11a) is over the space of admissible causal control laws \( u = \kappa(x, i) \) so that \( (x, i) \in X^\star \). An upper bound to the left hand side of (11a) is obtained by parametrizing \( u = K_i x \). We introduce the shorthand notation \( A_i = A_i + B_i K_i \) and \( Q_i = Q_i + K_i^\top R_i K_i \), for \( i \in N \). Condition (11b) means that \( X^\star \) is a UI set for the system \( x_{k+1} = (A_k + B_k K_k)x_k \) under the prescribed constraints. Such a set can be determined by the fixed-point iteration \( \bigcap_{k=1}^\infty (O_k) \) with \( O_0 = \{ (x, i) | (x, K_i x) \in Y_i \} \). If this iteration converges in a finite number of iterations — a sufficient condition for which is given in [17, Lem. 21] — to a set \( O_\infty \), this is a polytopic UI set.

Assuming that \( \rho \) is a polytopic Markov risk measure with ambiguity set \( A(\rho) = \text{conv} \{ \mu_i | i \in N_{[1,i]} \} \) and using its dual representation, condition (11a) becomes \( \rho + \frac{1}{\rho} \rho + \frac{1}{\rho} \rho = \rho + \frac{1}{\rho} \rho = 1 \), and the terminal cost function is taken to be \( \ell_N(x) = x^\top P_i x + \delta_{X_i}(x) \) with \( P_i \in S^{n_x}_+ \) and \( X_i \). We shall derive conditions on \( P_i \) and \( X_i \) so that the stabilizing conditions of Thm. 6 are satisfied. Condition \( T \ell_N \leq \ell_N \) is equivalent to

\[
\text{dom}(T \ell_N) \supseteq \text{dom} \ell_N \iff R(X) \supseteq X^\star,
\]
\[ \sum_{j \in \text{cov}(i)} H_{ij}^l (\bar{A}_i^l P_i^l \bar{A}_i^l) \preceq P_i^l \text{ for all } i \in \mathcal{N} \text{ and } l \in \mathbb{N}_{[1,n_i]}. \] 

This condition can be cast as a linear matrix inequality (LMI) by a change of variables \((P_i^l)^{-1} = M_i, \ K_i = Y_i M_i^{-1}, F_i^l = [\sqrt{\mu_i^1} \ell_{ij}, \ldots, \sqrt{\mu_i^n} \ell_{ij}] \text{ and } M = \text{blkdiag}(M_1, \ldots, M_n): \)

\[
\begin{bmatrix}
m_i (A_i M_i + B_i Y_i)^T & M_i Q_i^{1/2} Y_i^{1/2} \\
* & M \\
* & * \\
* & * & 0 \\
* & * & * & -1
\end{bmatrix} \succeq 0, \tag{12}
\]

for all \(i \in \mathcal{N} \text{ and } l \in \mathbb{N}_{[1,n_i]} \). The left hand side of (12) is a symmetric matrix, therefore, we show only its upper block triangular part and replace the lower block triangular part by asterisks (*) to simplify the notation. Solving this LMI for \(M_i \in \mathcal{S}_{n_i}^+ \) and \(Y_i \in \mathbb{R}^{n_i \times n_i} \) yields the linear gains \(K_i \) and the cost matrices \(P_i^l \). LMI (12) has to be solved once offline to determine matrices \(P_i^l \).

### 4.3 Risk-averse MPC design for nonlinear Markovian switching systems

For nonlinear systems, an obvious choice for the terminal cost function would be \(\ell_N(x,i) = \delta_{[0]}(x) \) — meaning, \(X_i^f = \{0\} \) for \(i \in \mathcal{N} \) — but that would lead to a very conservative design. Here we exploit the system linearization at the origin to determine a terminal cost function and terminal constraints which render the MPC-controlled system RSES. We shall first draw the following assumption for the nonlinear dynamics:

**Assumption 8** For each \(i \in \mathcal{N}, f(\cdot, \cdot, i) \) is differentiable with \(L_i\)-Lipschitz Jacobian.

We use a parametric controller of the form \(\kappa(x,i) = K_i x \) and define the associated closed-loop function \(f^\kappa(x,i) = f(x,K_i x,i), i \in \mathcal{N} \). Function \(f^\kappa(\cdot, \cdot, i) \) can be written as a composition of \(f(\cdot, \cdot, i) \) with the linear mapping \(W_i : (x,u) \mapsto (x,K_i x) \), therefore, its Jacobian matrix will be Lipschitz-continuous with Lipschitz constant \(L_i\|W_i\|^2 \) which is bounded above by

\[
\beta_i := L_i (1 + \|K_i\|^2). \tag{13}
\]

The linearization of the nonlinear system at the origin is an MJLS \(\dot{x}_{k+1} = f(x_k, u_k, i_k) := A_{i_k} x_k + B_{i_k} u_k \) with \(A_{i_k} \) and \(B_{i_k} \) given by the Jacobian matrices, with respect to \(x \) and \(u \) respectively, of \(f \) at the origin. That is, \(A_i = J_x f(0,0,0), B_i = J_u f(0,0,0) \). For notational convenience, we define the following quantities:

\[
\begin{align*}
\dot{f}^\kappa(x,i) & := (A_i + B_i K_i) x, \\
\mathcal{L}_N(x,i) & := \rho_i [\ell_N(f^\kappa(x,i), j); j] - \ell_N(x,i), \\
\mathcal{L}'_N(x,i) & := \rho_i [\ell_N(f^\kappa(x,i), j); j] - \ell_N(x,i), \\
\Delta(x,i) & := \mathcal{L}_N(x,i) - \mathcal{L}'_N(x,i).
\end{align*}
\]

According to Thm. 9, one first needs to select \(m_i > 0 \) for each \(i \in \mathcal{N} \) such that (14) holds true. In the most common case where \(\ell \) and \(\ell_N \) are quadratic functions, this is precisely an LMI of the form (12) with \(Q_i + m_i I \) in place of \(Q_i \) solving which we obtain matrices \(K_i \) and \(P_i^l \) and determine the constants \(\beta_i \) and find \(\delta_i > 0 \) so that (15) holds. The last step is to determine a UI set \(X_i^f \) for the nonlinear system \(x_{k+1} = f^\kappa(x_k, i_k) \). We may cast the nonlinear system as a linear one with bounded additive disturbance \(x_{k+1} = \bar{A}_{i_k} x_k + e(x_k, i_k) \) — indeed, as we show in the proof of Thm. 9, \(\|e(x,i)\| \leq \beta_i/2 \|x\|^2 \). We may follow the approach of [25] in order to determine a polytopic robustly invariant set.
5 Computationally tractable formulation of risk-averse optimal control problems

Starting from an initial state $x_0$ and initial mode $i_0$ and computing control actions according to a causal control law $u_k$, the future states of the Markovian system, up to some future time $N$, span a scenario tree — a tree-like structure such as the one shown in Fig. 1. Note that the state at a node $t$, the input and mode leading to that node are denoted as $x^t$, $u^t$ and $i^t$ respectively.

The possible realizations of the system state at time $k$ define the nodes of the tree. The set of all nodes at stage $k$ defines the set $\Omega_k$. The set of nodes in $\Omega_{k+1}$ which are reachable from a node $t \in \Omega_k$ is called the set of children of $t$ and is denoted by $\text{ch}(t)$ which is a subset of $\Omega_{k+1}$. The space $\text{ch}(t)$ becomes a probability space with $P[\eta] = p_{c,v}$ for $\eta \in \text{ch}(t)$. As illustrated in Fig. 1, the system dynamics on the scenario tree is described by $x^n = f(x^t, u^t, i^n)$, for $\eta \in \text{ch}(t)$ and $x^0 = x_0, i^1 = i_0$.

On the scenario tree, we define a process $\Phi$ as follows: for $t \in \Omega_N$ we define $\Phi^t = \rho_t [\ell_N(x^t, i^n; \eta) = \max_{\mu^t \in A(P_r)} \sum_{\eta \in \text{ch}(t)} \mu^t_{\eta,i^n} \ell_N(x^t, i^n)]$. Moreover, $\ell_N(x, i) = \inf_{t_N(x,i) \leq \tau} \tau$. When the underlying risk measure is polytopic with $A(p) = \{ \mu \in \mathbb{R}^n | \sum_{i=1}^n \mu_i = 1, F(p) \mu < b(p) \}$, then

$$\Phi^t = \max_{\mu^t \in A(P_r)} \inf_{\ell \in \text{ch}(t)} \ell_N(x^t, i^n; \eta) \sum_{\eta \in \text{ch}(t)} \mu^t_{\eta,i^n} \ell^t_{\eta} \eta^t$$

$$= \inf_{\ell_N(x^t, i^n; \eta) \leq \tau^t} \max_{\mu^t \in A(P_r)} \sum_{\eta \in \text{ch}(t)} \mu^t_{\eta,i^n} \ell^t_{\eta} \eta^t$$

$$= \inf_{\tau^t, u^t, y^t \geq 0, \lambda^t \in \mathbb{R}, \ell^t(x^t, i^n; x^t, u^t, y^t) \leq \tau^t} \inf_{\ell \in \text{ch}(t)} b(P_r)^{\top} y^t + \lambda^t$$

$$\tau^t = F(P_r)^{\top} y^t + \lambda^t$$

where in the first equation we interchanged $\max$ with $\inf$ using [3, Prop. 2.6.4] using the fact that the level sets of the mapping $\tau^t \mapsto \max_{\mu^t \in A(P_r)} \sum_{\eta \in \text{ch}(t)} \mu^t_{\eta,i^n} \ell^t_{\eta} \eta^t$ are bounded because $A(P_r)$ is compact. The last equality is because of LP duality. Traversing indices $k$ from $N-1$ back to 1, we define $\Phi^t := \rho_t [\ell^t(x^t, u^t, i^n; \eta) + \Phi^t_{i^n}; \eta]$, which boils down to

$$\Phi^t = \inf_{\tau^t, y^t \geq 0, \lambda^t \in \mathbb{R}, \ell^t(x^t, u^t, i^n; x^t, y^t) \leq \tau^t} \inf_{\ell \in \text{ch}(t)} b(P_r)^{\top} y^t + \lambda^t$$

$$\tau^t = F(P_r)^{\top} y^t + \lambda^t$$

for $t \in \Omega_k$. This formulation allows us to deconvolve the nested Markov risk measures. Indeed, $V^*_k(x_0, i_0)$ is the optimal value of the following minimization problem

$$\begin{align*}
\text{minimize} & \quad \ell(x_0, u^1, i_0) + b(P_r)^{\top} y^1 + \lambda^1 \\
\text{subject to} & \quad \ell_N(x^t, i^n) \leq \tau^t_{i^n}, \eta \in \text{ch}(t), t \in \Omega_N, \\
& \quad \tau^t = F(P_r)^{\top} y^t + \lambda^t \\
& \quad \ell(x^t, u^t, i^n) + b(P_r)^{\top} y^t + \lambda^t \leq \tau^t_{i^n}, \\
& \quad x^n = f(x^t, u^t, i^n), \\
& \quad \eta \in \text{ch}(t), t \in \Omega_k, k \in \mathbb{N}_{[0, N]}.
\end{align*}$$

Note that this formulation does not require the enumeration of the vertices of $A(p)$ which, for instance, in the case of AV@R, increases exponentially with the number of modes. The above optimization problem is solved at every time instant with $x_0, i_0$ being the current state and mode of the system. Solving this problem yields the optimal control actions $u^t_{\ast}$ at each node of the scenario tree. The first value, $u^1_{\ast}$, defines the risk-averse MPC controller $\kappa^N_{i}(x, i) = u^\ast(x, i)$. Note that in the particular case of an MJLS where stage-wise and terminal costs are quadratic and the constraints are polyhedral and/or ellipsoidal, we obtain a quadratically constrained quadratic program (QCQP) which can be solved very efficiently online as we show in Section 6. The above reformulation can be applied to risk measures whose ambiguity set is described by a set of conic inequalities (using conic duality) such as the entropic value-at-risk [1].

6 Illustrative example

Here we demonstrate the design of stabilizing risk-averse MPC controllers for a nonlinear system. We consider the following nonlinear Markovian switching system with three modes:

$$\begin{align*}
\begin{bmatrix} x_{k+1} \\ y_{k+1} \end{bmatrix} &= A_{i_k} \begin{bmatrix} x_k \\ y_k \end{bmatrix} + c_{i_k} \begin{bmatrix} 1 - r_{i_k} y_k \\ 1 - e_{i_k} \end{bmatrix} + B_{i_k} u_k. 
\end{align*}$$

(16)

The system matrices are

$$A_1 = \begin{bmatrix} 0.2 & 0.1 \\ 0.5 & 0.5 \end{bmatrix}, \quad A_2 = \begin{bmatrix} 0.1 & -0.5 \\ 0.5 & 0.5 \end{bmatrix}, \quad A_3 = \begin{bmatrix} 0.6 & -0.6 \\ 0.1 & 0.1 \end{bmatrix},$$

$$B_1 = \begin{bmatrix} 1.6 \\ 0.9 \end{bmatrix}, \quad B_2 = \begin{bmatrix} 0.1 \\ 0.9 \end{bmatrix}, \quad B_3 = \begin{bmatrix} 1 \end{bmatrix},$$

and parameters $c_1 = 0.2, c_2 = -0.1, c_3 = -0.3$. Stage-wise cost matrices are $Q_i = I$ and $R_i = 100 \cdot i$ for $i \in \{1, 2, 3\}$. The nominal and actual transition matrices are given by

$$P = \begin{bmatrix} 0.4 & 0.6 & 0.6 \\ 0.6 & 0.4 & 0.4 \\ 0.4 & 0.6 & 0.0 \end{bmatrix}, \quad P' = \begin{bmatrix} 0.33 & 0.0 & 0.67 \\ 0.56 & 0.0 & 0.44 \\ 0.33 & 0.67 & 0.0 \end{bmatrix}.$$

The nonlinear system is constrained to be inside the box $Y_1 = [-2.5, 2.5]^2 \times [-0.5, 0.5]$ for all three modes. Using $m = 0.5$ we compute the controller design parameters of Thm. 9 which are shown in Table 1. We take the terminal sets to be ellipsoidal $X^f_i = \{x \mid p_i x \leq r_i \}$ Finally, we simulate the system for different values of parameter $\alpha$ of AV@R, after we formulate the problem as described.
A similar effect is observed when inspecting the distribution of $\ell(x_k, u_k, i_k)$ for three MPC controllers. MPC controllers with higher $\alpha$ (closer to stochastic MPC) allow for higher costs, albeit with low probability. On the other hand, the risk-averse controller with $\alpha = 0.5$ (closer to minimax MPC) tends to produce cost distributions with shorter right tails. Interestingly, the point $x_0$ is not feasible for the worst case controller ($\alpha = 0$). The cost distributions are shown in Fig. 3.

![Trajectories of the closed-loop system with risk-averse MPC](image1)

Fig. 2. Trajectories of the closed-loop system with risk-averse MPC for $N = 6$ with (Left) $\alpha = 0.9$ and (Right) $\alpha = 0.5$. The green lines correspond to 1000 random simulations.

![Distribution of $\ell(x_k, u_k, i_k)$](image2)

Fig. 3. Distribution of $\ell(x_k, u_k, i_k)$ estimated using 1000 randomly generated switching sequences. The cost of trajectories corresponding to higher $\alpha$ values are more spread out compared to $\alpha = 0.5$ and have a noticeably longer right tail.

### 7 Conclusions

We proposed a control methodology for constrained nonlinear Markovian switching systems. The proposed stability analysis framework hinges on dynamic programming and leads to the formulation of risk-based Lyapunov-type conditions. These conditions can be translated into an LMI when the dynamics is linear, while, when the system is nonlinear a design methodology was proposed. In the case of MJLS, the resulting optimization problem can be formulated as a QCQP and can be solved efficiently online enabling its use in embedded applications.

We believe that risk-averse problems possess a favorable structure which can be further exploited to lead to parallelizable implementations akin to ones already developed for stochastic optimal control problems [22–24]. We plan to investigate risk-constrained formulations where we impose acceptable risk of violating the constraints instead of hard state/input constraints. This has a potential to make the overall design much less conservative.

Proof of Lemma 5. Define $V_k := V(x, k, i_k)$ and, for fixed $x_0 \in \text{dom} V^*_N(x, i_0)$ let $x_t := \phi(t, x_0, i_{t-1})$. We have
\[
\tilde{\rho}_k \left[ V_k - V_0 + c \sum_{t=0}^{k-1} \| x_t \|^2 \right] = \tilde{\rho}_k \left[ \sum_{t=0}^{k-1} \left( V_{t+1} - V_t + c \| x_t \|^2 \right) \right] \\
\leq \sum_{t=0}^{k-1} \tilde{\rho}_k \left[ V_{t+1} - V_t + c \| x_t \|^2 \right] \\
= \sum_{t=0}^{k-1} \tilde{\rho}_k \left[ V_{t+1} - V_t + c \| x_t \|^2 \right],
\]
(A.1)
where the inequality is because of the subadditivity of $\tilde{\rho}$ (A1 and A4) and the last equality is because $V_{t+1} - V_t + c \| x_t \|^2$ is independent of $t_{t+1}, \ldots, i_k$. In light of Cond. (ii) and given that $\tilde{\rho}_{t+1}[V_{t+1} - V_t + c \| x_t \|^2] = \rho_{i_0} \circ \ldots \circ \rho_{i_k} [V_{t+1} - V_t + c \| x_t \|^2; i_{t+1}] = \rho_{i_0} \circ \ldots \circ \rho_{i_k} [V(f^N(x_{t+1}, i_{t+1}) - V(x, t, i_t) + c \| x_t \|^2; i_{t+1}] \leq 0$, and because of (A.1) and property A2 we have that $\tilde{\rho}_k[V_k - V_0 + c \sum_{t=0}^{k-1} \| x_t \|^2] \leq \tilde{\rho}_k[V_k - V_0 + \sum_{t=0}^{k-1} \| x_t \|^2] \leq 0$. Using properties A3 and A4, $\tilde{\rho}_k[\sum_{t=0}^{k-1} \| x_t \|^2] \leq V_0/c$ which proves the first part of Lemma 5.

By Cond. (ii), $\rho_{i_k} [V_{k+1} - V_k; i_{k+1}] \leq -c \| x_k \|^2 \leq -c_0 \| x_k \|^2 \leq -c_0 \| V_k \|_{\alpha_0}$ for some $\eta \in (0, 1)$, so $\rho_{i_k} [V_{k+1}; i_{k+1}] \leq \beta V_k$ with $\beta := 1 - \eta \in (0, 1)$. We have $\rho_{i_0}[V_{i_0}; i_0] \leq \beta V_0$ and $\rho_{i_2}[V_{2}; i_2] \leq \beta V_1$, so $\rho_{i_0}[\rho_{i_2}[V_{2}; i_2]; i_1] \leq \beta \rho_{i_0}[V_{1}; i_1] \leq \beta^2 V_0$. Then, $\rho_{i_2}[V_2] \leq \beta^2 V_0$ and recursively
\[
\rho_k[V_k] \leq \beta^k V_0.
\]
(A.2)

By the left hand side of Cond. (iii), $\| x_k \|^2 \leq 1/\alpha_k V_k$ and applying $\tilde{\rho}_k$ and using (A.2) and subsequently the right hand side of Cond. (iii), $\rho_k[\| x_k \|^2] \leq \rho_k[V_k/\alpha_k] \leq 1/\alpha_k \tilde{\rho}_k[V_k] \leq 1/\alpha_k \beta^k V_0 \leq 2 \alpha_k \beta^k \| x_k \|^2$.

Proof of Theorem 6. Let $\tilde{X} \subseteq \text{dom} V^*_N$ be a compact UI set. By (8), $V^*_N(x, i) = \rho_i \left[ V^*_{N-1}(f^N(x, i), j); j \right] + \ell(x, \kappa^*_N(x, i), i)$. Then, for $(x, i) \in \tilde{X}$,
\[
\rho_i \left[ V^*_{N-1}(f^N(x, i), j); j \right] - V^*_N(x, i) \\
= \rho_i \left[ V^*_{N-1}(f^N(x, i), j); j \right] - \ell(x, \kappa^*_N(x, i), i) \\
- \rho_i \left[ V^*_{N-1}(f^N(x, i), j); j \right] \\
\leq - \ell(x, \kappa^*_N(x, i), i) \leq -c \| x \|^2.
\]

The first inequality is because $V^*_N \leq V^*_{N-1}$ and property A2. We have that $V^*_N(x, i) \leq \ell_N(x, i) \leq d \| x \|^2$ for all $x \in \tilde{X}$. Because of Cond. (iii), we may find $\epsilon > 0$ such that $B_\epsilon \subseteq \tilde{X}$ for $i \in N$. By Cond. (iv), there is an
$M > d c^2$. Then, for all $x \in X_i \setminus X_i^f$, $M \epsilon^2 \|x\|^2 \geq M \geq V_N^*(x, i)$. Because of Cond. (i) and the definition of $T$, we have that $V_N^*(x, i) \geq c \|x\|^2$ for all $(x, i) \in \text{dom} V_N^*$ for $t \in \mathbb{N}[1, N]$. The proof is complete since $V = V_N^* + \delta_x$ satisfies all conditions of Lemma 5.

**Proof of Theorem 9.** Define $e(x, i) = f^\kappa(x, i) - \hat{f}^\kappa(x, i)$. By Assumption 8 and since $f^\kappa(0, i) = 0$ for all $i \in N$, $\|e(x, i)\| \leq \beta_i/2 \|x\|^2$. It is $\Delta(x, i) = \rho_i [f^\kappa(x, i)^T P_j f^\kappa(x, i); j] - \rho_i [x^T \bar{A}_i^T P_j \bar{A}_i x; j]$. Since $\rho_i [\cdot]$ is convex and monotone, it is nonexpansive with respect to the infinity norm [26, p. 302], thus for $x \in X_i^f$

$$|\Delta(x, i)| \leq \max_{j \in \text{cov}(i)} |f^\kappa(x, i)^T P_j f^\kappa(x, i) - x^T \bar{A}_i^T P_j \bar{A}_i x|$$

$$= \max_{j \in \text{cov}(i)} |e(x, i)^T P_j e(x, i) + 2x^T \bar{A}_i^T P_j e(x, i)|$$

$$\leq \max_{j \in \text{cov}(i)} \|P_j\| (\beta_i^2 \|x\|^4 + \beta_i \|\bar{A}_i\| \|x\|^3) \leq \sigma_i \|x\|^2$$

Therefore, $L\ell_N(x, i) = L'\ell_N(x, i) + \Delta(x, i) \leq -x^T (\bar{Q}_i + (m_i - \sigma_i)) x \leq -\ell(x, \kappa(x, i), i)$, for all $x \in X_i^f$ and since $X_i^f$ is UI, $T\ell_N \leq \ell_N$. The assertion follows from Thm. 6. □
