Phase transition between quantum and classical regimes for the escape rate of a biaxial spin system

(Received xxx)

Employing the method of mapping the spin problem onto a particle one, we have derived the particle Hamiltonian for a biaxial spin system with a transverse or longitudinal magnetic field. Using the Hamiltonian and introducing the parameter \( p(\equiv (U_{\text{max}} - E)/(U_{\text{max}} - U_{\text{min}})) \) where \( U_{\text{max}} \) (\( U_{\text{min}} \)) corresponds to the top (bottom) of the potential and \( E \) is the energy of the particle, we have studied the first- or second-order transition around the crossover temperature between thermal and quantum regimes for the escape rate, depending on the anisotropy constant and the external magnetic field. It is shown that the phase boundary separating the first- and second-order transition and its crossover temperature are greatly influenced by the anisotropy constant as well as the transverse or longitudinal magnetic field.

PACS numbers: 75.45.+j, 75.50.Tt

In recent years, quantum-classical escape rate transition in the spin system has emerged as good candidates to display first- or second-order transition (FST). Such a system is a single domain ferromagnetic particle with the magnetization \( \mathbf{M} \) whose direction is subject to the magnetocrystalline anisotropy. In this situation the direction \( \hat{M} \) has at least two equivalent stable orientations separated by an energy barrier \( U \). Even though \( \hat{M} \) is initially directed along one of these equivalent orientations, \( \hat{M} \) can be changed by thermal activation whose rate is proportional to \( \exp(-U/kT) \) at high temperature, and by quantum tunneling at a temperature low enough to neglect the thermal activation. In general, since the tunneling rate is dominated by \( \exp(-U/h\omega) \) where \( \omega \) characterizes the width of the parabolic top of the barrier hindering the tunneling process, there is a crossover temperature \( T_0 \) from the thermally activated to the quantum tunneling process. Whether the transition about the crossover temperature is first- or second-order one is determined by the external magnetic field and the magnetic anisotropy constant. By controlling the field and choosing the anisotropy constant in an appropriate way, we expect that there exists the crossover temperature \( T_0^{(c)} \) at the phase boundary between first- and second-order transition.

Theoretical studies of the system have been around for some time. Affleck and Larkin and Ovchinnikov demonstrated that a second order transition from thermal to quantum regimes can occur at the crossover temperature by using the standard instanton technique. Later, Chudnovsky discussed the criterion to determine FST based on the behavior of the period of oscillations in the inverted potential. Since then, based upon the mapping of a spin problem onto a particle one Chudnovsky, Garanin and Martínez suggested the spin system with the uniaxial crystal symmetry which shows FST in the presence of a transverse and longitudinal field. A biaxial spin model without an applied field has been considered by J.-Q. Liang et al. who demonstrated that FST is determined from the ratio of the transverse to the longitudinal anisotropy constant by using the periodic instanton method. Even though they presented the analytical results without field, their approach could not be simply extended to the situation in the presence of field. Very recently, in an effort to treat FST of the biaxial spin system with a longitudinal field, Garanin and Chudnovsky used a perturbation approach and obtained the phase boundary between the first- and the second-order transition which is numerically corrected by the Liang et al.’s exact value in the absence of the field. Thus, relevant approach to treat a biaxial spin system with a transverse or longitudinal field has been highly required for FST. In fact, complete analytical solution of the problem seems to be considerably important for the possibility of FST in molecular magnetic systems as well as a single domain ferromagnetic particle with many spins. In this paper, employing the method of mapping of a spin problem onto a particle one, we obtain the particle Hamiltonian of the biaxial spin problem with a transverse or longitudinal field, which has not been obtainable from the previous studies. Actually, such a mapping is not a regular procedure and its form strongly depends on the form of the spin Hamiltonian. Using the Hamiltonian and introducing the dimensionless energy variable \( p \), we will study the first- or second-order transition around the crossover temperature between thermal and quantum regimes for the escape rate, depending on the anisotropy constant and the external magnetic field, and present the ana-
lytic form of the phase boundary separating first- from second-order transition and the crossover temperature at the phase boundary.

Consider the biaxial spin model in a transverse field $H_x$ described by the Hamiltonian

$$\mathcal{H} = -K_{||}S_x^2 + K_{\perp}S_y^2 - H_xS_x,$$  \hspace{1cm} (1)

where $K_{||}$ and $K_{\perp}$ are the longitudinal and transverse anisotropy constants, respectively. This Hamiltonian can be mapped onto a particle problem which describes the exact correspondence between the spin wave function $\psi$ where

$$\psi = \sum_{M=-S}^S a_M \left[ \frac{(S+M)!(S-M)!}{(2S)!} \right]^{1/2} |SM\rangle,$$  \hspace{1cm} (2)

where $|SM\rangle$ are the eigenstates of $S_z^2$ and the particle wave function $\Psi(x) = \exp(-\gamma(x)) \sum_M a_M \exp(Mx)$ where

$$\frac{d\gamma(x)}{dx} = \tilde{S}h_x(1-k) \sinh(x) + (\tilde{S} - 1)k \sinh(2x) \over 1 + k \cosh(2x),$$  \hspace{1cm} (3)

$\tilde{S} = S + 1/2$, $k = k_1/(2 + k_1)$, $k_1 = K_{\perp}/K_{||}$ and $h_x = H_x/(2\tilde{S}K_{||})$. The particle Hamiltonian is

$$\mathcal{H} = -\frac{1}{2m(x)} \frac{d^2}{dx^2} + U(x),$$  \hspace{1cm} (4)

where $1/m(x) = K_{||}(2 + k_1)[1 + k \cosh(2x)]$, $U(x) = \tilde{S}^2 K_{||} u(x)$, and

$$u(x) = \frac{1}{(1-k)[1 + k \cosh(2x)]} \left[ \frac{h_x^2 \sinh^2(x)(1-k)^2}{2h_x(1-k) \cosh(x)} \right]$$

$$+ (\cosh^2(x) - \cosh(2x) + 4)/(4\tilde{S}^2) \right] \right].$$  \hspace{1cm} (5)

Here we notice that the potential and the mass without transverse anisotropy are reduced to the results in Ref. However, even though $\tilde{S}$ appears in the potential, the terms associated with $\tilde{S}$ can be neglected in the large $S$ limit including $S = 10$. So, we will not include the terms with $1/(4\tilde{S}^2)$ in the subsequent consideration.

In the quasiclassical approximation the transition rate becomes

$$\Gamma \sim \int dE W(E) \exp[-(E - U_{\min})/T],$$  \hspace{1cm} (6)

where $W(E)$ is the probability of tunneling at an energy $E$. Since this is defined via the imaginary-time action

$$W(E) \sim e^{-S(E)},$$

the transition rate is approximately given by

$$\Gamma \sim \exp(-F_{\min}/T),$$  \hspace{1cm} (7)

where $F_{\min}$ is the minimum of the effective “free energy” $F \equiv E + TS(E) - U_{\min}$ with respect to $E$. Then, writing $F(E)/T = \int_{-1/2T}^{1/2T} d\tau [(m(x)/2)(dx/d\tau)^2 + U(x) - E_{\min}]$, the imaginary time action is given by

$$S(E) = 2 \int_{-x_1(E)}^{x_1(E)} dx \sqrt{2m(x)U(x) - E},$$  \hspace{1cm} (8)

where $\pm x_1(E)$ are the turning points for the particle with energy $-E$ in the inverted potential $-U(x)$. We note that the mass is coordinate dependent, which is crucial in changing the boundary between first- and second-order transition, as will be seen. In order to determine FST in the crossover regime, we need to consider the behavior of $S(E)$ near the top of the barrier. Since the potential in Eq. (8) is even, we expand the integrand in Eq. (8) near $x = 0$ which corresponds to the top of the barrier. Introducing dimensionless energy variable $\tilde{p}(\equiv (U_{\max} - E)/(U_{\max} - U_{\min}))$ where $U_{\max}$ ($U_{\min}$) corresponds to the top (bottom) of the potential, the action becomes near the top of the barrier

$$S(E) = \frac{\pi \Delta U}{\sqrt{U_2(K_{||} + K_{\perp})}} [p + \beta \tilde{p}^2 + O(p^3)],$$  \hspace{1cm} (9)

where $U_2 = -\tilde{S}^2 K_{||} u_0^2(0)/2$, $U_4 = \tilde{S}^2 K_{||} u_4(0)/4!$, and

$$\beta = \frac{3}{8} \left[ \frac{U_4 \Delta U}{U_2^2} \right] \left[ 1 - \frac{2}{3} \left( \frac{k}{1 + k} \right)^2 \times \left( \frac{U_2}{U_4} \right) \right].$$  \hspace{1cm} (10)

Here $\Delta U = U_{\max} - U_{\min}$ and the second term in the bracket comes from the coordinate dependence of the mass. Using the analogy with the Landau theory of phase transitions and the general conditions for first- and second-order quantum-classical transition of the escape rate discussed in Refs. and , the factor in front of $p^2$ in Eq. (8) determines the boundary between the first- and second-order transition.

For the model without transverse field we have $U_2 = 2\tilde{S}^2 K_{||} k/(1 + k)$ and $U_4 = -2\tilde{S}^2 K_{||} k(1 - 5k)/[3(1 + k)^2]$ from Eq. (9). If the mass does not depend on the coordinate, the sign of the factor of $U_4$ determines whether the system becomes the first- or the second-order transition due to the anharmonicity of the potential. However, as has been already noticed from Eq. (8), the mass is a function of $x$. So, we cannot simply obtain the phase boundary from the anharmonicity of the potential near the top of the barrier. Now, using $\Delta U = \tilde{S}^2 K_{||}$, the action (8) is given by

$$S(E) = (\pi \tilde{S}/\sqrt{k_1}) [p + \beta \tilde{p}^2 + O(p^3)],$$  \hspace{1cm} (11)

where $\beta = (1 - 1/k_1)/8$. Thus the critical value of $k_1$ is 1 implying that smaller values of $k_1$ lead to the first-order transition which is consistent with the result in Ref. In case of the second-order transition the crossover occurs at temperature $T_0^{(2)} = \omega_0/(2\pi)$ where $\omega_0$ is oscillation frequency near the bottom of the inverted potential. To estimate the frequency, we set up the Euclidean Euler-Lagrange equation $m(x)\ddot{x} + m'(x)\dot{x}^2/2 - U'(x) = 0$, and insert $x = x_b + \delta x$ into the equation, where $x_b$ is $x$-coordinate of the barrier. Expanding to second order in

$$F(E)/T = \int_{-1/2T}^{1/2T} d\tau [(m(x)/2)(dx/d\tau)^2 + U(x) - E_{\min}],$$
δx, we have δx + ω₀δx = 0, where ω₀ = √(U''(0))/m(0).
This yields the crossover temperature given by \( T_{0}^{(2)} = \frac{\sqrt{2k} - \xi}{1 - k} \), which leads to the crossover temperature at the phase boundary, \( T_{0}^{(c)} = \frac{\sqrt{2k}}{1 - k} \).
For the first-order transition the approximate form of the crossover temperature for small k can be analytically calculated from the relation \( T_{0}^{(1)} \approx \Delta U/S(E_{min}) \). At the bottom of the barrier, \( S/E_{min} \) can be calculated directly from the integral expression [3] or following from [3],
\[
S(E) = 4\tilde{S}\sqrt{\frac{2k - E}{1 - k}}|K(q) - \alpha^2\Pi(\alpha^2, q)|, \tag{12}
\]
which is derived from the Eqs. [3] and [3]. Here \( E = E/\tilde{S}^2K \), and \( K \) and \( \Pi \) are complete elliptic integrals of the first and third kind with \( q^2 = (z_1 - 1)/(z_1 + 1) \), \( \alpha^2 = q^2(1 - k)/(1 + k) \), and \( z_1 = \left[k(k - 1) + E]/[k(k - 1) - K^2] \).
This yields \( T_{0}^{(1)} \approx (\sqrt{2k}/2)\ln [(1 + \sqrt{1 - k^2})/k] \), which is approximate form for the first-order transition in the region of small k.
We now consider the model with a transverse magnetic field. Expanding the potential [3] in powers of \( x \), we obtain
\[
U_2 = [\tilde{S}^2K_1/(1 + k_t)](h_x + k_t)(1 - h_x), \tag{13}
U_4 = [\tilde{S}^2K_1/[12(1 + k_t)^2]][4(1 - 5k_t)(1 - k)h_x^2 + (1 + 3k_t)h_x - 8k(1 - 5k)], \tag{14}
\]
and \( \Delta U = \tilde{S}^2K_1(1 - h_x)^2 \). It is noted that the condition in which the barrier does not vanish is \( U_2 > 0 \), i.e., \( h_x < 1 \). Then, the action near the top of the barrier becomes from Eq. [3],
\[
S(E) = \pi\tilde{S}\sqrt{\frac{(1 - h_x)^{3/2}}{h_x + h_x^{1/2}}}[\beta + O(\beta^2)], \tag{15}
\]
where
\[
\beta = \frac{(1 - k_t)}{8(h_x + k_t)^2}(h_x + h_x^2)(h_x - h_x^3), \tag{16}
\]
\[
h_x^\pm(k_t) = \frac{1}{\beta} - 14k_t + k_t^2 \pm \sqrt{(1 + k_t)^2 - 34k_t + k_t^2}, \tag{17}
\]
As is shown in Fig. [3], the behavior of \( h_x^\pm \) shows that β is negative for \( k_t < 1 \) and \( h_x < h_x^\pm \) which corresponds to the first-order transition. As is shown in Fig. [3] in the absence of the transverse anisotropy, \( h_x = 1/4 \) is the critical value for FST and in the presence of very small transverse anisotropy we have \( h_x^\pm \approx (1 + 7k_t)/4 \) in which the boundary becomes wider for \( 0 \leq k_t < 0.2 \). As \( k_t \) continues to increase, the region where a first-order transition occurs, is smaller for the biaxial model than for the uniaxial model. This is intuitively understood that, since the transverse anisotropy drives the decay of the metastable state, it plays the role of the transverse field in the uniaxial case and so, for a given small transverse field the region for the first-order transition decreases as the transverse anisotropy increases. It is also noted that \( h_x^0 \) decreases linearly for \( k_t < 1 \), i.e., just as \( h_x^0 \approx (1 - k_t)/\beta \).
Continuing in the present case as without transverse case, we have the crossover temperature for the second-order transition
\[
T_{0}^{(2)}(k_t, h_x) = \sqrt{\frac{k_t + h_x}/(1 - h_x)}, \tag{18}
\]
Using Eq. [17] for \( h_x^0 \), the crossover temperature at the phase boundary between the first- and second-order transition is written as
\[
T_{0}^{(c)} = \sqrt{\frac{S}{(2\pi)}[\sqrt{2}/(4\pi)](1 + k_t)} \tag{19}
\]
which is illustrated in Fig. [3]. We note that \( T_{0}^{(c)} \approx \tilde{S}K_1(\sqrt{3}/(4\pi))(1 + 3k_t) \) for small \( k_t \) and \( T_{0}^{(c)} \approx |\tilde{S}K_1(\sqrt{2}/2\pi)| \) for \( k_t \lesssim 1 \).
In case of the first-order transition the crossover temperature as a function of \( k_t \) for small \( h_x \) is approximately estimated from the ground-state tunneling expression given by Eq. [3] or the direct integral expression [3] and \( \Delta U \) considered above, which gives
\[
T_{0}^{(1)}(k_t, h_x) \approx \tilde{S}K_1(1 - h_x)^2/[2g(k_t, h_x)], \tag{20}
\]
where
\[
g(k_t, h_x) = \ln \left[\sqrt{1 + k_t + \sqrt{1 - h_x^2}}\right] - 2\frac{h_x}{\sqrt{k_t + h_x}} \times \arctan \left[\sqrt{h_x/[1 + k_t}\sqrt{1/h_x^2 - 1}]\right]. \tag{21}
\]
Simple analysis for the crossover temperature shows that there exists a maximum of the crossover temperature \( T_0^{\text{max}} \) in the regime of the second-order transition, which from Eq. [18] gives \( T_0^{\text{max}} = |\tilde{S}K_1(\sqrt{2}/\pi)|(1 + k_t) \) at \( h_x = (1 - k_t)/2 \). It is noted that this is the asymptotic form of \( T_0 \) for \( k_t \lesssim 1 \) discussed previously. As the transverse anisotropy increases, \( T_0^{\text{max}} \) decreases linearly, (Fig. [3]) while \( T_0^{\text{max}} \) increases linearly, (Fig. [3]) and shown in Table [3] as \( k_t \) increases, the difference between \( T_0^{\text{max}} \) and \( T_0 \) decreases and becomes zero at \( k_t = 1 \) which is the critical value in the fieldless case.
In the presence of a longitudinal field of the spin model \( H = -K_1S^z + K_1S^z - H_zS^z \), we can proceed the consideration, similarly and so, we will briefly discuss the essential points. In order to obtain the relation between \( h_z = (H_z/(2\tilde{S})) \) and \( k_t \) at the phase boundary, we need to have the coefficient of \( p^2 \) in the action, i.e., \( \beta \) including \( U_3 \) and \( m(x_0) \) as well as \( U_2 \) and \( U_4 \) where \( x_0 \) is the position of the barrier, because the potential given by
\[
u(x) = \frac{1}{\beta} \left\{ \frac{1}{1 - k_t} \left[1 + k_t \cosh(2x) \right] \left[h_x^2 (1 - k_t)^2 - k_t h_z (1 - k_t) \sinh(2x) - 1 + \cosh(2x) - 5 \cosh(2x) - \left(4\tilde{S}^2\right) \right] + k_t \cosh(2x) - 1 + \left(4\tilde{S}^2 - \cosh(2x) + 4\right)/(4\tilde{S}^2) \right\}, \tag{22}
\]
is not an even function. Following the procedure discussed previously, we have the boundary between first- and second-order transition

\[ k_t = (1 - h_z^2)/(1 + 2h_z^2). \]  

(23)

The ratio of two anisotropy constants, \( k_t \), decreases parabolically for \( h_z \ll 1 \), as \( k_t \simeq 1 - 3h_z^2 \), and linearly for \( h_z \lesssim 1 \), as \( k_t \simeq (2/3)(1 - h_z) \). This can be understood from the fact that, since the height of barrier decreases as \( h_z \) increases, the first-order transition is expected for the larger width of the barrier which comes from the smaller value of the transverse anisotropy. The crossover temperature \( T_0^{(c)} \) at the phase boundary can be obtained by using Eq. (23) and \( T_0^{(2)}(k_t, h_z) = (1/2\pi)\sqrt{|U''(x_b)|/m(x_b)} \) in the second order transition, which leads to

\[ T_0^{(c)} = (\tilde{S}K_1/\pi)(1 - h_z^2)/\sqrt{1 + 2h_z^2}. \]  

(24)

Simple analysis shows that our results are consistent with the ones deduced from the correction of the perturbative calculation performed in Ref. 2 up to the numerical factors. Even though the perturbative approach is less justified at large value of the transverse anisotropy constant, its boundary and crossover temperature are strikingly the same trend as our analytical results obtained from the quasiclassical method.

In this paper we have considered the quantum-classical escape rate transition of a biaxial spin system in the presence of a transverse or longitudinal field by using the particle Hamiltonian mapped from the spin system. The coordinate dependence of the particle mass was crucial in changing the boundary between the first- and second-order transition and its boundary was greatly influenced by the transverse anisotropy constant and external field, whose effect is expected to observe in future experiment including Fe₈ molecular magnet. 14

9. Actually, based on the periodic instanton method, Lee et al. studied the phase transition in the biaxial spin system with a transverse magnetic field. In order to obtain the effective Lagrangian, they expanded the quantity \( s \sin \theta (= \sqrt{s^2 - p^2}) \) of the magnetic field term of the Hamiltonian in \( p \) up to quadratic terms (the \( x - y \) approximation). However this approximation often used for planar magnet, breaks down in the presence of a field perpendicular to the \( z \)-axis in their Hamiltonian because such a field forces the spins to move out of the \( x - y \) plane. Correspondingly, their starting effective Lagrangian is valid for \( \lambda \ll 1 \). Thus, in our understanding, it is not appropriate to discuss the quantum-classical transition depending on the whole magnitude of the parameter \( \lambda = K_2/K_1 \) because \( \lambda \) was initially very small in the Lagrangian.

12. D. A. Garanin and E. M. Chudnovsky, cond-mat/9808037.
13. We check this point numerically and confirm that, up the small numerical values which can be neglected, there is no difference of \( u(x) \) between with and without \( 1/(4\xi^2) \)-terms in the integration range from \( -\lambda_z \) to \( \lambda_z \) in Eq. 8.
14. Since the Hamiltonian \( H = K_1S^2_x + K_2S^2_y \) is used in Ref. 1, our anisotropy constants are related by \( K_1 = K_2 \) and \( K_2 = K_1 - K_2 \). This yields \( k_t = -1 + 1/\lambda \), in which \( k_t = 1 \) corresponds to \( \lambda = 1/2 \).
15. We have also performed the calculation for the action in the whole range of \( E \). In this case the formula is very complicated and we do not present them here. We checked that the formula in the bottom of the potential agrees with the result obtained from the action at the ground-state tunneling.
