Melioidosis is a major cause of fatal community-acquired septicemia in highly endemic areas, including northeast Thailand and north Australia (1,2). Melioidosis is now known to be endemic in >45 countries across tropical regions (3). A formal modeling framework predicted the global burden to be 165,000 human melioidosis cases per year, with a case-fatality rate of 54%. The causative agent of melioidosis, the highly pathogenic gram-negative bacillus *Burkholderia pseudomallei*, is classified as a Tier 1 Select Agent by the US Centers for Disease Control and Prevention (https://www.cdc.gov/selectagent/index.html). *B. pseudomallei* intrinsically is resistant to first-line commonly available antimicrobial drugs, making a prophylactic vaccine the most desirable approach for disease control.

Growing evidence supports the effects of cellular adaptive immunity in human defense against *B. pseudomallei* infection (4–6), but additional evidence also points to the role of protective antibodies against fatal melioidosis. For instance, animal studies have demonstrated that passive transfer of antibodies specific to the bacterial lipopolysaccharide (LPS) or capsular polysaccharide (CPS) can protect mice (7–9) or a diabetic rat model (10) from intranasal or intraperitoneal challenge of *B. pseudomallei* at lethal doses. Intraperitoneal or subcutaneous immunization of mice with *B. pseudomallei* LPS, CPS (11), or CPS covalently linked to recombinant CRM197 diphtheria toxin mutant (CPS-CRM197) plus hemolysin coregulated protein 1 (Hcp1) (12) provided an optimal protective antibody response. In addition, results from studies of human melioidosis patients demonstrated that elevated levels of anti-oligo polysaccharide (OPS) II (13) and anti-LPSII IgG (14) were correlated with survival. Previous studies demonstrated that IgG1 and IgG2 are the predominant antibodies in response to the culture filtrate antigen (15,16). A recent study in a population from the same region showed differences in IgG subclass effects in response to 2 key antigens in *B. pseudomallei*, Hcp1 and OPS (17), and IgG3 responses to Hcp1 correlated with melioidosis survival. However, little data on the mechanistic effects of IgG subclasses in human melioidosis are available.

Clarifying the mechanistic role of immunoglobulin-mediated protection against melioidosis would **Role of Burkholderia pseudomallei–Specific IgG2 in Adults with Acute Melioidosis, Thailand**

Emerging Infectious Diseases • www.cdc.gov/eid • Vol. 27, No.2 February, 2021
provide crucial information for developing an effective vaccine and therapeutic monoclonal antibodies. We report on the role of *B. pseudomallei*–specific IgG2 subclass and its high binding activating Fc gamma receptor (FcγR) Ila polymorphism H131 in protection against death in human melioidosis during the acute phase.

**Materials and Methods**

**Ethics Statement**

The study was approved by the ethics committees of the Faculty of Tropical Medicine, Mahidol University (submission no. TMEC 12-014) and Sunpasithiprasong Hospital, Ubon Ratchathani (reference no. 018/2555), and by the Oxford Tropical Research Ethics Committee (reference no. 64–11). We conducted the study according to the principles of the Declaration of Helsinki 2008 (https://www.wma.net) and the International Conference on Harmonization Good Clinical Practice guidelines (https://ichgcp.net). We received written informed consent from all patients enrolled in the study.

**Serum Sample Collection**

We enrolled 200 adult inpatients with acute melioidosis ≥18 years of age at Sunpasithiprasong Hospital at a median of 5 days (range 2–13 days; interquartile range [IQR] 3–6 days) after admission, as described previously (4,18). We recruited healthy controls among donors at the hospital’s blood donation clinic. We defined melioidosis as isolation of *B. pseudomallei* from any clinical sample submitted to the laboratory, including blood, sputum, pus, urine, throat or endotracheal swabs, or bronchoalveolar lavage. Among 200 enrolled patients, 6 patients were lost to follow-up, with survival status unknown, so they were excluded from the analysis. Of 194 patients included, 61 had insufficient stored serum specimens for IgG subclass assays; hence, we analyzed serum samples from 139 subjects.

**Antigen Preparation**

We prepared whole-cell antigen from wild type strain *B. pseudomallei* K96243, an isolate from a patient in northeast Thailand, which was modified from a previous study (19,20). In brief, we grew the bacteria in rice medium at 37°C for 14 days, then heat-inactivated the bacteria at 121°C for 30 min. We centrifuged the whole-cell heat-inactivated (HIA) *B. pseudomallei* at 2,000 × g for 1 h, then used the supernatant as an antigen. We aliquoted and kept the supernatant at −20°C until used. We quantitated the protein concentration of the antigens in the supernatant by using the Pierce BCA Protein Assay Kit (Thermo Fisher Scientific, https://www.thermofisher.com) according to the manufacturer’s protocol.

**ELISA**

We used ELISA to measure serum levels of IgM and IgG specific to *B. pseudomallei*. We added whole cells of HIA *B. pseudomallei* to wells of Nunc MaxiSorp flat bottom 96-Well immunoplates (Thermo Fisher Scientific) at a concentration of 200 ng/well and incubated the plates overnight at 4°C. Between each step, we washed the ELISA plate 3 times with 300 µL of washing buffer consisting of 0.05% Tween-20 in phosphate buffered saline (PBS; Sigma-Aldrich, https://www.sigmaaldrich.com). After blocking with 5% skimmed milk in PBS for 2 h at 37°C, we diluted the serum 1:100 and added it to the plate in duplicate, then incubated for 1 h. We diluted the horseradish peroxidase (HRP) enzyme–conjugated antihuman IgM or IgG (Sigma-Aldrich) 1:2,000 and then added it to the ELISA plate before incubating for 1 h. We developed the ELISA by using 3,3′,5,5′-tetramethylbenzidine (TMB; Thermo Fisher Scientific) substrate and determined the absorbance value (optical density = 450 nm) by using a Multiskan GO microplate spectrometer (Thermo Fisher Scientific).

For IgG subclasses, we blocked the overnight precoated ELISA plate with 1% bovine serum albumin (BSA) in PBS for 2 h. We then diluted the serum 1:100 for detecting IgG1, IgG3, and IgG4 or 1:2,000 for detecting IgG2, and then added the serum to the ELISA plate. After 1-h incubation, we diluted the biotin-conjugated antihuman IgG1, IgG2, IgG3, or IgG4 1:1,000 and added them to the plate before incubating for 1 h. Then we added streptavidin-HRP (Mabtech, https://www.mabtech.com) to the plate and incubated for 1 h and developed by using TMB as we described in the previous paragraph.

**Genomic Methods**

We extracted genomic DNA from blood samples by using the QIAamp DNA Blood Midi kit (QIA-GEN, https://www.qiagen.com) according to the manufacturer’s instructions, then stored at −20°C. We genotyped the *FCGR2A* c.535A>G (rs1801274) single nucleotide variant (SNV) by using the TaqMan SNP genotyping assay (Applied Biosystems, https://www.thermofisher.com) on a CFX96 Touch Real-Time PCR Detection System (Bio-Rad, http://www.bio-rad.com). The SNV context sequence was AATGGAAATCCCCAGAATTTCTCCCA(A/G) TTTGGATCCCACCCTTCCATCCCA.
Antibody-Dependent Cellular Phagocytosis
We labeled the bacteria by incubating with fluorescein isothiocyanate (FITC) for 30 min in the dark at room temperature, then washed the bacteria with PBS and immediately used the bacteria in the assay. We incubated FITC-labeled B. pseudomallei with HIA serum samples (10% vol/vol) or Roswell Park Memorial Institute (RPMI) 1640 medium (Sigma-Aldrich) as a control at 37°C for 1 h. We then added opsonized FITC-labeled B. pseudomallei to human monocyte cell lines, THP-1 (FcyRIIa-R-H131 genotype) or U937 (FcyRIIa-R131 genotype), at a multiplicity of infection (MOI) of 5 CFUs/cell. After incubation at 37°C for 30 min, we immediately transferred cells to ice to stop phagocytosis. We washed the cells twice with cold PBS. We then added cold trypan blue (Sigma-Aldrich) to the cells and incubated for 10 min on ice to quench the FITC signal of bound B. pseudomallei on cell surface. Next, we washed the cells twice with cold PBS and incubated with BD Cytofix Fixation Buffer (Becton Dickinson, https://www.bd.com) cold fixative buffer at 4°C for 15 min. We then washed the cells twice with cold MACSQuant Running Buffer (Miltenyi Biotec, https://www.miltenyibiotec.com), and analyzed the cells by using the MACSQuant Analyzer 10 (Miltenyi Biotec). We expressed results as fold-change in enhancement of phagocytosis calculated by dividing the percentage of infected cells in the presence of serum by those in the absence of serum samples in the RPMI-1640 control.

Statistics
We reported nonnormally distributed continuous data as median and IQR. We analyzed the statistical significance of differences by using Mann-Whitney U-test for 2 groups and the Kruskal-Wallis 1-way ANOVA to test the mean difference among 3 groups in GraphPad Prism Version 6 (GraphPad Software Inc., https://www.graphpad.com). We calculated the percentage of coefficient of variation (CV) in ELISA by dividing SD of measurement by mean of measurement multiplied by 100. The cutoff was 10% intra-assay CV and 15% for inter-assay CV. We performed univariable and multivariable logistic regression adjusting for age, diabetes, pre-existing renal disease, and neutrophil counts by using Stata version 14.0 for Windows (StataCorp LLC, https://www.stata.com).

Results

Elevated IgG2 Levels in Patients Who Survived Melioidosis
The characteristics of patients with acute melioidosis enrolled in the study were previously described (4,18). Among 194 patients in the cohort, median age was 56 years (range 19–89 years; IQR 46–63 years); 129 (66.5%) were men and 65 (33.5%) were women. Underlying conditions among patients included diabetes (57.7%), renal disease (17.5%), and heart disease (11.8%) (Table 1). Forty-nine (25%) persons died within 28 days despite receiving appropriate antimicrobial drug treatment.

Serum levels of IgM specific to whole-cell HIA B. pseudomallei were not statistically significantly different between survivors (median 0.28, IQR 0.13–1.00) and nonsurvivors (median 0.31, IQR 0.08–0.52; p = 0.18) (Figure 1, panel A). Similarly, anti–HIA B. pseudomallei IgG levels were not different between survivors (median 2.32, IQR 1.10–2.94) and nonsurvivors (median 2.12, IQR 1.42–2.50; p = 0.29) (Figure 1, panel B). As expected, HIA B. pseudomallei–specific IgM and IgG levels in patients with melioidosis, including those who died and survived, were much higher than those in healthy controls (Figure 1, panels A, B).

We then measured anti–HIA B. pseudomallei IgG subclasses in serum samples from melioidosis patients to determine whether IgG subclasses are associated with survival. We found statistically significantly higher IgG2 levels (median 1.30, IQR 0.45–2.04) against whole-cell heat-killed B. pseudomallei in serum from survivors than in serum from nonsurvivors (median 0.18) (Figure 1, panel A). Similarly, anti–HIA B. pseudomallei–specific IgM and IgG levels in patients with melioidosis, including those who died and survived, were much higher than those in healthy controls (Figure 1, panels A, B).

Table 1. Baseline demographic characteristics of patients with acute melioidosis, Thailand

| Characteristic                             | No. patients (%), n = 194 |
|--------------------------------------------|----------------------------|
| Deaths                                     | 49 (25.3)                  |
| Median age, y (IQR)                        | 56 (46–63)                 |
| Sex                                        |                            |
| M                                          | 129 (66.5)                 |
| F                                          | 65 (33.5)                  |
| Underlying conditions                      |                            |
| Diabetes                                   | 112 (57.7)                 |
| Renal disease                              | 34 (17.5)                  |
| Heart disease                              | 23 (11.8)                  |
| Chronic liver disease                      | 7 (3.6)                    |
| Previous melioidosis                       | 5 (2.6)                    |
| Clinical manifestation                     |                            |
| Bacteremia                                 | 99 (51.0)                  |
| Pneumonia                                  | 48 (24.7)                  |

IgG2 Level Associated with Protection against Death
In a univariable model, we found that increasing IgG2 levels in serum samples was statistically significantly associated with survival (odds ratio [OR] 0.63, 95% CI 0.43–0.92). In previous studies of the same cohort, we found that age, pre-existing renal disease, and neutrophil count were associated with a 28-day mortality rate of 26% (4,18). We next tested the association of the IgG2 levels with death by using a multivariable
model adjusting for age, diabetes, pre-existing renal disease, and neutrophil count (Table 2). Our results demonstrate that elevated IgG2 levels correlate with survival (OR 0.50, 95% CI 0.30–0.83).

Serum from Survivors Enhanced Phagocytosis in THP-1 Human Monocytic Cells
IgG2 has the least functional potency of the subclasses due to low affinity binding between its Fc region and activating FcγRs expressed on effector innate immune cells (21,22). A single-nucleotide polymorphism (SNP) resulting in a histidine (H) residue instead of an arginine (R) at position 131 improves affinity for human IgG2 and affects effector function (23). We performed antibody-dependent cellular phagocytosis (ADCP) assays by using 2 monocyte cell lines: U937 cells, containing a homozygous low-affinity FcγRIIa-R131 phenotype, and THP-1 cells, containing heterozygous intermediate-affinity FcγRIIA-H/R131 alleles of FcγRIIa.

The ADCP activities of antibodies were not statistically significantly different between serum from survivors (median 37.63, IQR 19.88–82.62) and nonsurvivors (median 45.34, IQR 21.51–93.67) in U937 containing the low-affinity FcγRIIa-R131 phenotype (p = 0.68) (Figure 2, panel A). In contrast, we did find a statistically significant difference in phagocytic activity between survivors (median 89.66, IQR 69.03–120.30) and nonsurvivors (median 52.43, IQR 37.14–105.10) when we used THP-1 expressing intermediate-affinity FcyRIIA-H/R131 allele (p<0.001) (Figure 2, panel B).

Association between Enhanced Phagocytosis in THP-1 and Bacteremia
When we used U937 cells, we did not see a statistically significant difference in ADCP activity between patients without bacteremia (median 60.95, O}}
IQR 18.18–93.38) and those with bacteremia (median 30.68, IQR 20.22–76.03; p = 0.12) (Figure 3, panel A). Furthermore, the ADCP activity in THP-1 of serum from patients without bacteremia (median 90.18, IQR 61.62–135.5) was higher than in those with bacteremia (median 75.38, IQR 41.39–106.80), but this difference did not reach statistical significance (p = 0.07) (Figure 3, panel B).

**FcγRIIa Genotype Distribution among Cohort Patients**

The genotype distribution was 63.4% FcγRIIa-H131/H131, 29.3% FcγRIIa-H131/R131, and 7.3% FcγRIIa-R131/R131 and exhibited a 9:4:1 ratio in our melioidosis cohort. The frequency of the FcγRIIIa-H131 allele overall in our cohort was 78%. However, we did not find a substantial association between this FcγRIIa polymorphism and death, bacteremia, diabetes status, or preexisting renal disease in our cohort (data not shown).

**Discussion**

Our major finding in this study is the elevated level of serum IgG2 against whole-cell HIA *B. pseudomallei* lysate in melioidosis patients who survived the disease compared with fatal cases. We confirmed the association between elevated IgG2 level and survival in a multivariable logistic regression analysis adjusting for age, diabetes, preexisting renal disease, and neutrophil count. Some studies provide evidence for a role of IgG2 in protection against various microorganismal infections, including *Plasmodium falciparum* malaria (24), and encapsulated bacteria, including *Streptococcus pneumoniae* (25,26), *Haemophilus influenza* (26,27), and *Neisseria meningitidis* (28). The IgG2 in those studies mainly recognized CPS epitopes that are highly repeated T-independent antigens. Previous work did not show a correlation between IgG2 responses to Hcp1 or OPS and survival (14), so the IgG2 responses to whole-cell *B. pseudomallei* in our study are likely to be against other antigens yet to be tested. Ongoing work also will address whether protective IgG2 also bind to carbohydrate epitopes on the outside surface of *Burkholderia* spp.

A large body of literature supports IgG2 having no or lower relative binding affinity for activating FcγRs when compared with other IgG subclasses (21,29). Nevertheless, IgG2 has been shown to possess opsonophagocytosis capacity in some studies (27,28,30). These conflicting results might be explained by the presence of a guanine to adenine SNP resulting in replacement
of arginine (R) with histidine (H) at residue 131 of FcγRIIa. The product of FcγRIIa-H131, which has been reported in 67% of persons with Chinese ethnicity (31), 45% of White populations, and 41% of Black populations (32), were found to bind IgG2-immune complex more efficiently than those of R131 (33,34), hence enhancing phagocytosis. Therefore, the considerable association between elevated IgG2 and protection against death in this cohort could be partly due to an increase of IgG2-mediated phagocytosis of the bacteria to effector innate immune cells via FcγRIIa, which 78% of our cohort possessed.

We used 2 types of human mononcytic cells expressing different FcγRIIa phenotypes to compare ADCP activity between patients who survived the disease and those who did not. U937 cells are homozygous for low-affinity FcγRIIa-H/R131 phenotype, whereas THP-1 cells are heterozygous for intermediate-affinity FcγRIIa-H/R131 phenotype. We demonstrated that serum from survivors with much higher levels of IgG2 subclass could enhance B. pseudomallei uptake into THP-1 cells compared with those from nonsurvivors. Conversely, we did not find a difference in ADCP activity in U937 cells between survivors and nonsurvivors. When using U937 cells, comparable phagocytic activities of serum samples between survivors and nonsurvivors might be due to the comparable levels of IgG1 or IgG3 that can effectively interact with FcγRIIa-R131. The phagocytic activities of IgG1 and IgG3 imply that higher IgG2 levels can enhance ADCP activity in effector innate immune cells carrying the FcγRIIa-H131 allele and that this ADCP activity was associated with protection against death in acute melioidosis patients.

Elevated ADCP activity of serum samples from patients without bacteremia almost reached statistical significance (p = 0.07) compared with those from patients with bacteremia when we used THP-1 cells but not when we used U937 cells. The ADCP activity results imply that the immune complex in circulating blood can be removed more effectively in persons with the FcγRIIa-H131 phenotype.

One limitation of this study is that we used different cell types, which might have different genetic and phenotypic backgrounds resulting in different outcomes of ADCP activity in serum from survivors and nonsurvivors. This finding should be confirmed in U937 cells transfected with the FcγRIIa-H131 receptor. In addition, IgG2 serum samples from patients also contain the other 3 IgG subclasses, IgG1, IgG3, and IgG4, and IgM and IgA that might influence outcomes. In addition, the antibody-dependent phagocytosis activity of serum in this study was tested solely in human mononcytic cells, U937 and THP-1, whereas FcγRIIa also is constitutively expressed on the surface of other effective immune cells including dendritic cells, neutrophils, and B cells.

We did not find a statistically significant association between FcγRIIa-H131 phenotype and ADCP activity in either THP-1 or U937 cells when adjusting for death, diabetes status, and pre-existing renal disease. This result might be due to a low number of patients with the FcγRIIa-R131 phenotype (7.3%) in our cohort; therefore, we did not have the statistical power to detect a difference in outcome.

In conclusion, the data in this study emphasize the role of IgG subclasses in clinical outcomes of infectious diseases. The relationship between elevated IgG2 levels and protection against death in melioidosis is comparable with those in other encapsulated bacterial infections. The relationship between elevated IgG2 levels and protection against death in melioidosis constitutes critical information for selecting the appropriate antibody subclasses for therapeutic antibody and vaccine development, in particular for patients with the FcγRIIa-H131 phenotype.

Acknowledgments

etymologia

Falciparum [fal-ˈsɪ-pə-rəm]
Aparna Tiwari, Abhinav Sinha

From the Latin falx or falc (sickle or scythe-shaped) and parum (like or equal to another) or parere (to bring forth or bear). The species falciparum in the genus Plasmodium is the parasite that causes malignant tertian malaria in humans.

There were many terms suggested for this parasite, such as Enatozoon falciforme by Antolisei and Angelini in 1890 and Haemotozoon falci-forme by Thayer and Hewetson in 1895, because of its sickle-shaped gametocytes, the sexual stage of falciparum parasites. However, the term falciparum, suggested by William Henry Welch in 1897, was eventually accepted. In 1954, Plasmodium falciparum (previously Laverania malariae) was approved by the International Commission on Zoological Nomenclature.
