Nuclear matter and chiral phase transition at large-$N_c$

Francesco Giacosa

Two aspects of the QCD phase diagrams are studied in the limit of a large number of colors: at zero temperature and nonzero density the (non)existence of nuclear matter, and at zero density and nonzero temperature the chiral phase transition.

1 Introduction and Summary

The limit in which the number of colors $N_c$ is sent to infinity (large-$N_c$ limit) represents a systematic approach to study properties of QCD. The world for $N_c \gg 3$ is simpler because planar diagrams dominate. However, the basic ingredients ‘survive’ in the large-$N_c$ limit: quark-antiquark mesons exist and become weakly interacting, baryons also exist but are formed of $N_c$ quarks. Recently, a lot of effort has been spent to study the properties of the phase diagram of QCD when $N_c$ is varied.

Along the line of zero temperature and nonzero chemical potential, a natural question is if nuclear matter binds for $N_c > 3$. We shall find that this is not the case: in view of the peculiar nature of the scalar attraction between nuclei we obtain that nuclear matter ceases to form as soon as $N_c > 3$ is considered. Namely, the scaling behavior of the scalar attraction depends on the nature of the exchanged field with a mass of about 0.6 GeV. Present knowledge in low-energy QCD spectroscopy shows that this light scalar field is (predominately) not a quark-antiquark field, the alternative possibilities being tetraquark, pion-pion interpolating field, molecular state, etc. In all these interpretations the scalar attraction diminishes in comparison with the vector repulsion, mediated by the well-known vector meson $\omega$, when $N_c$ is increased. As a result, nuclear matter does not take place: the investigation leading to this result is achieved though a simple effective model of the Walecka type.

When moving along the finite temperature axis while keeping the density to zero, it is interesting to study how different chiral effective models behave at large-$N_c$. It is quite remarkable that two very well-known models, the quark-based Nambu Jona-Lasinio (NJL) model and the hadron-based $\sigma$-model, deliver different result for the critical temperature for chiral restoration $T_c$. While in the NJL model $T_c$ scales as $N_c^0$ and is thus, just as the deconfinement phase transition, large-$N_c$ independent, in the $\sigma$-model one obtains that $T_c \propto \sqrt{N_c}$. This mismatch can be solved by including in the $\sigma$-model one (or more) $T$-dependent parameter(s): a rather simple modification of the mass term is enough to reobtain the expected scaling $T_c \propto N_c^0$.

The paper is organized as follows: in Sec. 2 and Sec. 3 we study nuclear matter and the

*Based on the presentation given at ‘Rencontres de Moriond, QCD and High Energy Interactions’, March 20-27 2011, La Thuile (Italy).
chiral phase transition for $N_c > 3$, respectively. In Sec. 4 we briefly present our conclusions.

2 Nuclear matter at large-$N_c$

Nuclear matter at large-$N_c$ is studied by means of an effective Walecka-Lagrangian\cite{9}

$$\mathcal{L} = \bar{\psi} \gamma^\mu (i \partial_\mu - g_\omega \omega_\mu) - (m_N - g_S S) \psi + \frac{1}{2} \partial^\mu S \partial_\mu S - \frac{1}{2} m_S^2 S^2 + \frac{m_\omega^2}{2} \omega_\mu \omega^\mu + ...$$

(1)

where $S$ represents a scalar field with a mass of about 0.6 GeV and $\omega$ the isoscalar vector meson. The large-$N_c$ scaling properties of the latter are well known: $m_\omega \propto N_c^0$, $g_S \propto \sqrt{N_c}$. We now examine the possibilities\cite{3} for the scalar state $S$:

- $S$ as quark-antiquark field: $m_S \propto N_c^0$ and $g_S \propto \sqrt{N_c}$. This is the only case in which nuclear matter exists in the large-$N_c$ limit. The binding energy increases with $N_c$. However, this scenario is –as previously anticipated– unfavored\cite{4}.

- $S$ as tetraquark field\cite{10} $m_S \propto N_c$ and $g_S \propto N_c^0$. Nuclear matter does not bind for $N_c > 3$. On the contrary, for $N_c = 2$ an increased binding is found. This scenario represents a viable possibility in agreement with phenomenology. It might also play an important role at nonzero temperature and density\cite{11}.

- $S$ as an effective two-pion-exchange effect\cite{12} $m_S \sim 2m_\pi \propto N_c^0$, $g_S \propto \sqrt{N_c}$. Although the scaling laws are the same as in the quark-antiquark case, no binding is obtained in view of numerical details.

- $S$ as a low-mass scalar glueball\cite{13} $m_S \propto N_c^0$ and $g_S \propto N_c^0$. No binding for $N_c > 3$ is obtained. Note: this scenario is unfavored by present lattice data which place the glueball at about 1.6 GeV\cite{14}.

The result that no nuclear matter exists for large-$N_c$ is stable and does not depend on numerical details. In the framework of the so-called strong anthropic principle it is then natural that we live in a world in which $N_c$ is not large.

3 Chiral phase transition at large-$N_c$

The $\sigma$-model has been widely used to study the thermodynamics of QCD\cite{15}. In one of its simplest forms it reads (as function of $N_c$):

$$\mathcal{L}_\sigma(N_c) = \frac{1}{2} (\partial_\mu \Phi)^2 + \frac{1}{2} \mu^2 \Phi^2 - \frac{\lambda}{4 N_c} \Phi^4,$$

(2)

where $\Phi^t = (\sigma, \pi)$ describes the scalar field $\sigma$ and the pseudoscalar pion triplet $\pi$. The quark-antiquark field $\sigma$ represents the chiral partner of the pion: as mentioned in the previous section, it does not correspond to the resonance $f_0(600)$ with a mass of about 0.6 GeV but to the resonance $f_0(1370)$ with a mass of about 1.3 GeV\cite{18}. The scaling law $\lambda \rightarrow 3\lambda/N_c$ takes into account that the meson-meson scattering amplitude scales as $N_c^{-1}$. On the contrary, $\mu^2$ contains no dependence on $N_c$: in this way the quark-antiquark meson masses scales –as desired– as $N_c^0$.

The critical temperature $T_c$ for the chiral phase restoration is calculated by using the so-called CJT formalism\cite{16}, which is a self-consistent resummation scheme for field theoretical calculations at nonzero temperature. In the Hartree and in the double-bubble approximation $T_c$ is given by the expression

$$T_c(N_c) = f_\pi \sqrt{\frac{2 N_c}{3}} \propto \sqrt{N_c},$$

(3)

where $f_\pi = 92.4$ MeV is the pion decay constant. The scaling of $T_c$ is thus in disagreement with the NJL model\cite{8} where $T_c \propto N_c^0$ and with basic expectations\cite{2}. This result is due to the
fact that for $N_c \gg 3$ a gas of free mesons is realized and thus no transition takes place. In fact, the mechanism responsible for the restoration of chiral symmetry in hadronic models is given by mesonic loops, whose effect vanishes for $N_c \gg 3$. On the contrary, in the NJL model the restoration of chiral symmetry is generated by the quark loops, which do not vanish in the large-$N_c$ limit.

The inconsistency between the NJL model and the $\sigma$-model can be easily solved by replacing

$$\mu^2 \to \mu(T)^2 = \mu^2 \left(1 - \frac{T^2}{T_0^2}\right)$$

(i.e., making it $T$-dependent) where the parameter $T_0 \simeq \Lambda_{QCD} \propto N^0_c$ introduces a new temperature scale. This is in line with the fact that the $\sigma$-model can be obtained by hadronization of the NJL model. In this scheme the parameters of the $\sigma$-model turn out to be temperature-dependent. Note also that the here considered $T^2$-behavior –although naive at the first sight– has been also obtained in Ref. 17. In this way the critical temperature is modified to

$$T_c(N_c) = T_0 \left(1 + \frac{1}{2} \frac{T_0^2}{f^2} \frac{3}{N_c}\right)^{-1/2} \propto N^0_c,$$

which is now large-$N_c$ independent, just as in the NJL case. For $N_c = 3$, using $T_0 = \Lambda_{QCD} \simeq 225$ MeV, the critical temperature $T_c$ is lowered to $T_c \simeq 113$ MeV. Interestingly, in the framework of $\sigma$-models with (axial-)vector mesons one has to make the replacement $f_\pi \to Z f_\pi$ with $Z = 1.67 \pm 0.2$. In this way the critical temperature reads $T_c \simeq 157$ MeV, which is remarkably close to the lattice results.

Beyond the phenomenologically motivated modification presented here, one can go further and couple the present $\sigma$-model (and generalizations thereof) to the Polyakov loop. Also in this case the critical temperature turns out to be, as desired, independent on $N_c$. The reason for this behavior can be traced back to the fact that the transition of the Polyakov loop (which describes the confinement-deconfinement phase transition) triggers also the restoration of chiral symmetry.

4 Conclusions

In this work we have investigated the properties of nuclear matter and chiral phase transition in the large-$N_c$ limit.

We have found that present knowledge on the spectroscopy of scalar mesons indicates that nuclear matter does not bind for $N_c > 3$. Namely, the nucleon-nucleon attraction in the scalar-isoscalar channel turns out not to be strong enough to bind nuclei when $N_c$ is increased. Therefore, nuclear matter seems to be a peculiar property of our $N_c = 3$ world.

For what concerns the chiral phase transition at nonzero temperature and zero density, we have found that care is needed when using effective hadronic models of the $\sigma$-type. The critical temperature $T_c$ does not scale as expected in the large-$N_c$ limit. It is however possible to introduce simple modifications of chiral hadronic models in such a way that the expected result $T_c \propto N^0_c$ is recovered.
