Abstract

Losses from the proton and antiproton beams of the Fermilab Tevatron have been shown to produce a halo which contribute to backgrounds to physics signals in the Collider Detector at Fermilab (CDF). To provide a measure of the beam halo and losses, we have installed arrays of scintillation counters on both sides of the CDF detector. We describe here the physical configuration of these counters, their implementation and performance within the Fermilab Accelerator Control Network (ACNET). We show correlations between these new devices and the accelerator operating conditions. We point out that the use of these monitors is leading to improvement in the accelerator operations and reduced backgrounds in CDF.

Key words: Radiation detectors, radiation monitoring, beam monitors, beam halo and losses, Tevatron, CDF

1 Introduction

The Run II program for the Tevatron started in 2001 and the CDF experiment has been taking data with recent luminosities comparable with the peak luminosity obtained at the end of Run I [1]. However, the CDF detector has encountered operational problems and observed high backgrounds which have been correlated with proton and antiproton losses from the Tevatron.
For example, high loss rates have caused high anode currents and consequent chamber trips in most muon detectors, especially in central muon upgrade and extension (CMP, CMX) chambers [2]. A number of low voltage switching power supply failures were also observed in periods of high beam loss rates associated with Tevatron injection and aborts. In addition, backgrounds in the CDF detector have been associated with a halo of particles accompanying the beam. Figure 1 shows an event display of an off-axis muon producing a hard bremsstrahlung in the central calorimeter. The muon “track” is identified by the set of contiguous towers in $\eta = - \log (\tan \frac{\theta}{2})$ at constant azimuth ($\phi$). The vertical scale is the energy in the calorimeter transverse to the beam. These events form backgrounds to physics signals involving photons and missing transverse energy.

CDF measures beam losses using the beam shower counters located closest to the CDF detector (BSC-1). The BSC-1 are small scintillation counters at a radius between 4–7 cm relative to the center of the beam pipe and located approximately 5 m on either side of the CDF interaction point (IP). Losses are calculated as the coincidence between the counter signal and beam particles passing the plane of the BSC-1. A detailed description of the BSC-1 and the loss calculation may be found elsewhere [3]. Because the BSC-1 are small, located near the beam line and near to the CDF IP, they are ideal for monitoring the small angle beam losses which affect various components in the tracking volume. However, these counters do a poor job of measuring the beam halo affecting the outer regions of the detector. Further, the raw BSC-1 photomultiplier tube (PMT) signals are unavailable due to the electronics requirements for the system. These PMTs have also shown strong afterpulsing [4]. Both of these issues make additional timing coincidences problematic.

We address these concerns by installing a set of counters (halo monitors) in the CDF collision hall. In this article, we describe the physical configuration of the halo monitors and their readout. These monitors detect the halo particles at a radial distance of about 50 cm around the beam line in full azimuthal coverage and at maximum available distance from the CDF detector. The monitors are capable of detecting particles at larger angles from the beam line and are complementary to the beam shower counters.

2 Setup

The CDF detector is located in the B0 section of the Tevatron at Fermilab. Two halo monitors are located in the west and east alcoves in the CDF collision

---

1 These power supply failures were traced to a catastrophic, single event failure (single event burn out) in a radiation soft, power MOSFET used in the supplies.
hall, at positions $z = -1809$ cm and $z = 1664$ cm with respect to the IP. Both monitors consist of an array of four scintillator counters arranged in a non-overlapping rectangle surrounding the final focus, low $\beta$ quadrupoles. Figures 2–4 illustrate the layout of the monitors.

The counters used for these monitors come from a set of spares originally manufactured for the KTeV muon identification and veto systems [7]. These counters are made of Bicron BC-412 scintillator [5] and have an active volume of $1.3 \times 15 \times 150$ cm$^3$. The scintillator is glued to a wedge shaped, lucite light guide which is in turn glued to an EMI-9954KB PMT [6]. Bicron, BC-600, optical cement is used for all glue joints. The end of the scintillator opposite the PMT was painted black to avoid signals from light reflected off the far end. The counter assemblies are then wrapped in aluminum foil and 76.2 $\mu$m thick black plastic. The wrapping materials are held in place using black vinyl tape. Figure 5 is a diagram of a single counter.

Each counter is characterized, after assembly, using three cosmic ray telescopes. The three telescopes identify cosmic rays passing through each end and the middle of the counters. Operating characteristics including the relative gain, dark rate and counter efficiency are recorded for each telescope as a function of PMT bias voltage with a discriminator threshold of 30 mV. The operating voltage for each counter is chosen to be 100 V above the “knee” of the efficiency vs PMT voltage (plateau) curve. The knee is defined to be the 90% efficiency point on the plateau curve as measured with the telescope farthest from the PMT. The light attenuation length of each counter is measured at the operating voltage.

A high voltage power supply (Power Designs model HV-1547) provides bias voltages for all the counter PMTs. The individual values are set by a Berkeley high voltage zener divider box. After installation, the ungated single rate (dark current) for each counter is measured at the same discriminator settings and PMT bias voltages used during the counter production tests described above. Table 1 summarizes the operating parameters for these counters.

Beam halo is measured by forming a coincidence between the counter signals and a beam bunch signal as the bunch passes through the plane of the counter array on its way to the CDF IP. To mark the beam crossings, we use the 38 ns wide Bunch Crossing (CDF\_BC) signal. The CDF\_BC signal defines the CDF collision times with a repetition period of 396 ns. CDF\_BC is derived from the 53 MHz Tevatron RF and is received from a “TRigger And Clock + Event Readout” (TRACER) module [8]. The TRACER module also distributes the timing signals which mark the first bunch in a revolution (CDF\_B0) and CDF\_ABORT which mark the “abort gaps” where there are no bunch crossings. All such accelerator timing signals are fanned out to TRACER modules. Figure 6 shows the relevant clock signals.
The counter PMT signals are brought up to a NIM crate in a CDF counting room where they are discriminated using a LeCroy 4413 discriminator (threshold 30 mV, width 20 ns). The discriminator width is set to allow for light propagation delays (8 ns) and slewing for the counters. The discriminated counter signals are carried to a Programmable Logic Unit (PLU) (LeCroy model 4516) to form the coincidence with the CDF\_BC. The CDF\_BC signal, originally of TTL-standards, is first converted to NIM standard and then its width is decreased to 20 ns by a discriminator (LeCroy model 621L). The resulting signal is time-aligned with the counter signals using a delay line. The time-alignment accounts for the beam particle time-of-flight (TOF) difference between the plane of the arrays and the interaction time. A Fan Input/Output Unit is utilized to obtain four copies of this signal for the proton monitor counters. Before making another four copies for the antiproton counters, an additional 5 ns delay is applied to account for TOF difference between the proton and the antiproton side. All CDF\_BC duplicates are further passed through a NIM-ECL converter to be sent to the PLU. The eight outputs from the PLU are counted by CAMAC scalers. Figure 7 shows the logic diagram for the readout. The time alignment of the discriminated signals at the AND gate is shown in Figure 8.

The delay setting for halo coincidences is determined using a delay (coincidence) curve technique. Given a fixed counter signal propagation time, coincidence rates are measured as a function of the delay applied to the CDF\_BC signal. We estimate the CDF\_BC delay necessary for the coincidence by measuring the cable lengths, module propagation delays and calculating the flight delays. We then installed a delay cable approximately 40 ns shorter than this expected length and measured the coincidence rates incrementing the delay by 8 ns between measurements. The coincidence data is read out by visual scalers and rates are calculated by sampling for 10 seconds and dividing the counts by 10. Effects due to beam intensity variations in time are taken into account by simultaneously reading from a separate, ungated counter. The decrease observed in the rates read by the ungated counter at the end of the data taking is 6%. The coincidence rates from the counters are normalized to the rate measured with the ungated counter and delay curves are obtained using these normalized rates. The halo CDF\_BC delay is chosen to correspond to the mid-points of the coincidence plateaus for all of the eight counters. Figure 9 shows the delay curves for all counters. The figure exhibits a collision peak as well as a halo peak. The collisions follow the halo signals at twice the particle TOF between the monitors and the IP. The difference of about 10 ns between the collisions for protons and antiprotons is due to the different \( z \) positions of the counter arrays. The ratio of proton to antiproton beam currents of approximately 10:1 is clearly reflected in the halo peaks. Figure 10 details the halo coincidence curves for each counter. The full width at half maximum of the coincidences is \( \sim 35 \) ns as expected.
The halo coincidence signals are read out through two CAMAC scalers (Fermilab “Beams Division” model 333 [9]). These scalers are a part of the Fermilab Accelerator Controls Network (ACNET). ACNET is a system to monitor and control the Fermilab accelerator complex. A graphical interface gives one access to accelerator data in real time and previous data from archives. The rates for the individual counters are calculated using the expression:

\[
\text{Rate} = \frac{N_{2,i} - N_{1,i}}{N_{2,0} - N_{1,0}} \times (\text{Rate of channel 0}),
\]

where \(N_{1,i}\) and \(N_{2,i}\) are the two consecutive readings of scaler channel \(i\) which corresponds to an ACNET device. Channel 0 of both CAMAC scalers counts the Tevatron beam revolutions (period of 20.7 \(\mu\)s).

We also calculate the total rate of each counter array within ACNET. These summed rates, Proton Halo SuM (C:B0PHSM) and Antiproton Halo SuM (C:B0AHSM), are calculated as:

\[
\text{Rate} = \frac{\sum (N_{2,i} - N_{1,i})}{N_{2,0} - N_{1,0}} \times (\text{Rate of channel 0})
\]

where the sum is over channels, \(i\).

The halo monitor counters are also used to measure the “DC beam” (component of the beam not captured in bunches) by measuring the halo in the abort gaps of one Tevatron cycle. We follow the same logic and use the exact halo measurement setup except for two details: in addition to the bunch crossing signal from the TRACER module as described above, we carry an abort gap signal (CDF_ABORT) to the PLU and form the coincidence with the counters. In order to avoid contamination from the collision of the last bunch before the abort gap, 116 ns is removed from the leading edge of the duplicate CDF_ABORT gate. The abort gap coincidence signals correspond to eight scaler channels and their rates are calculated using formulae 1 and 2.

The rates calculated as in Equations 1 and 2 have been available on ACNET since April, 2002. The ACNET data for the proton and antiproton monitor total rates (C:B0*SM) are archived with a minimum update frequency of 1 Hz. The minimum data logging rate for individual counters is 1 minute in the CDF logger.

We verify the rate calculations by measuring the singles rates from ACNET and comparing these rates with those expected from previous measurements. We first measured the beam off coincidence rates using ACNET data and

---

2 This calculation is implemented within the ACNET software framework.
calculated the expected values given the singles rates from Table 1 as a cross-check. For the calculation, we assumed a uniform, 35 ns resolving time for halo coincidences and approximately 2.4 $\mu$s for abort gap coincidences. Table 2 shows a comparison between the calculated and measured rates. The quoted uncertainties include only the statistical errors. The measured and calculated values are in good agreement.

The choice of discriminator widths for the counters, CDF$_{BC}$ and CDF$_{ABORT}$ gates imposes an upper limit on the rates these devices can effectively measure. The maximum (saturation) rate for the beam halo measurements is 1.7 MHz (maximum CDF$_{BC}$ rate). The summed rates saturate at 4 times the above rate (6.8 MHz). The abort gap rates saturate at 4.6 MHz, limited by the discriminator width (20 ns), the retriggering time of the discriminator (2 ns) and duty factor of the CDF$_{ABORT}$ signal after adjustment. The maximum rate of the summed signals is 18.4 MHz.

### 3 Performance of the Monitors

A first look at the performance of the monitors shows that they are indeed sensitive to the proton and antiproton losses. Figures 11 and 12 compare halo monitor rates with the beam losses measured at CDF. These data are taken during Tevatron store 1243. Note the clear features in the antiproton halo rates that are just visible in the antiproton loss rates (Figure 12). These features exist only in the antiproton monitors and are to be examined in more detail.

While commissioning the abort gap halo monitors, we found that the wide gate allows a significant accidental contamination from beam induced radioactivity. This is best illustrated in Figure 13 where the beam was aborted and the abort gap rates did not immediately go to their cosmic ray value. Performing a lifetime analysis of the above incident, one finds that three, short lived isotopes of potassium are responsible for the increase of the abort gap halo rate. This increased rate is removed by requiring a 2/4 majority in each abort gap halo measurement. The majority coincidence rates form two ACNET devices which are C:B0PAGC (proton) and C:B0AAGC (antiproton). The data logging and saturation characteristics of these devices are the same as the previously listed abort gap halo monitor devices.

The halo monitors have also been observed to correlate well with features in the Tevatron accelerator. Listed here, are the sensitivity to changes in the beam tune, beam vacuum, RF power, Tevatron electron lens (TEL) [10] failures and DØ Roman Pot [11] positions with respect to the beam line. Figures 14–17 illustrate these correlations. Figure 14 shows the rates for the abort gap monitors taken during store 1229. The halo in the abort gap monitors have a
clear response to the TEL operational changes. The rates show high frequency features following the lens being turned off (0.0 mA). As the TEL is turned back on, the rates increase abruptly with a subsequent decrease [12].

Figure 15 illustrates the correlation between the changes in the beam vacuum (T:F1IP1A) and proton halo (C:B0PHSM) rates during store 1207. The former variable is the vacuum ion gauge for the F11 sector of the Tevatron. The vacuum problems, identified here, were subsequently addressed. The vacuum pressure improved from values just under $2 \times 10^{-6}$ Torr to well below $2 \times 10^{-8}$ Torr yielding about 30–40% halo reduction in CDF Collision Hall.

The monitors are also capable of detecting changes along the beam lines. Figure 16 shows an abrupt increase in the antiproton halo monitor rates (C:B0AHSM) as a response to the DØ Roman Pot insertion during store 1229. The DØ detector is located at the DØ section of Tevatron, upstream of CDF in the antiproton direction. As of the writing of this article, we anticipate a controlled test with the pots to be performed.

The abort gap halo rates correlate well with sudden losses within the RF structure in Tevatron. In such cases, more particles escape from the bunches and fill the abort gaps. Figure 17 includes that portion of Tevatron store 1750 at which the power to an RF cavity is lost. Typically, the rates also continuously rise near the end of a store due to time dependent deterioration of the beam tune. This is reflected in the abort gap halo monitor (C:B0PAGC) rates.

The halo monitors are in the regular monitoring list of the CDF experiment as the halo has an impact on silicon and muon detectors. Alarms are currently notifying experimenters on shift when beam conditions move out of tolerances.

4 Conclusion

We installed two counter arrays in the CDF collision hall to improve the monitoring of beam quality. These counters are set up to monitor Tevatron halo and beam in the abort gaps with the proper choice of signal coincidences. The coincidences behave as expected under controlled conditions and new variables are installed in the Fermilab accelerator controls network (ACNET). Such monitors did not exist for Tevatron experiments during Run I. Data from these devices are shown to reproduce losses qualitatively and the devices are observed to be sensitive to effects not previously seen by existing monitors. The data also show that some beam effects are visible with an enhanced sensitivity when compared with existing detectors. The monitors are being used by the Fermilab accelerator experts in order to investigate the properties of the Tevatron beam halo as measured in the CDF collision hall. We
believe these type of monitors also serve as examples for the next generation
of hadron colliders for which the background and radiation conditions will be
more severe.

Acknowledgements

We are very grateful to Dennis Nicklaus from the Fermilab Beams Division
for software support and to Ron Moore (Fermilab, Beams Division) and Rick
Vidal (Fermilab, Particle Physics Division-CDF) for pointing out various cor-
relations. We would also like to thank Dervin Allen, Lew Morris, George Wy-
att, Roberto Davila and Jamie Grado for their help during the installation of
the monitors. M.K.U. acknowledges support under US Department of Energy
grant DE-FG02-91ER40684.
