We determined prognostic impact of \textit{KRAS}, \textit{BRAF}, \textit{PIK3CA} and \textit{TP53} mutation status and mutation heterogeneity among 164 colorectal cancer (CRC) patients undergoing liver resections for metastatic disease. Mutation status was determined by Sanger sequencing of a total of 422 metastatic deposits. In univariate analysis, \textit{KRAS} (33.5\%), \textit{BRAF} (6.1\%) and \textit{PIK3CA} (13.4\%) mutations each predicted reduced median time to relapse (TTR) (7 vs 22, 3 vs 16 and 4 vs 17 months; \(p<0.001\), 0.002 and 0.023, respectively). \textit{KRAS} and \textit{BRAF} mutations also predicted a reduced median disease-specific survival (DSS) (29 vs 51 and 16 vs. 49 months; \(p<0.001\) and 0.008, respectively). No effect of \textit{TP53} (60.4\%) mutation status was observed. Postoperative, but not preoperative chemotherapy improved both TTR and DSS (\(p<0.001\) for both) with no interaction with gene mutation status. Among 94 patients harboring two or more metastatic deposits, 13 revealed mutation heterogeneity across metastatic deposits for at least one gene. Mutation heterogeneity predicted reduced median DSS compared to homogeneous mutations (18 vs. 37 months; \(p=0.011\) for all genes; 16 vs. 26 months; \(p<0.001\) analyzing \textit{BRAF} or \textit{KRAS} mutations separately). In multivariate analyses, \textit{KRAS} or \textit{BRAF} mutations consistently predicted poor TRR and DSS. Mutation heterogeneity robustly predicted DSS but not TTR, while postoperative chemotherapy improved both TTR and DSS. Our findings indicate that \textit{BRAF} and \textit{KRAS} mutations as well as mutation heterogeneity predict poor outcome in CRC patients subsequent to liver resections and might help guide treatment decisions.

Approximately 40\% of all patients diagnosed with distant metastases from colorectal cancer (CRC) have metastatic deposits confined to the liver.\textsuperscript{1} Partial liver resection has been shown to improve long-term survival for selected CRC patients,\textsuperscript{2–4} with a 10-year disease-free survival approaching 20\% reported even for patients suffering from multiple liver deposits.\textsuperscript{3}

Selection of patients eligible for surgery has traditionally been based on clinicopathological prognostic factors.\textsuperscript{5–7} Recent work, however, has focused on the response to chemotherapy and various molecular alterations in the tumor as more appropriate prognostic factors after liver resections. Response to neoadjuvant chemotherapy has been related to improved survival,\textsuperscript{8} whereas \textit{KRAS} and \textit{BRAF} mutations have been associated with more aggressive disease and a poor prognosis.\textsuperscript{9–12} While liver resection for metastatic CRC (mCRC) has become routine practice,\textsuperscript{13} the fact that the majority of patients undergoing surgery subsequently relapse\textsuperscript{14} underlines the need for better predictive markers guiding treatment decisions.

In addition to individual molecular markers, tumor heterogeneity has become a major issue with respect to tumor evolution and, potentially, therapy outcome. Preliminary
evidence indicates that clonal evolution may cause acquired resistance to EGFR blockade. Moreover, in a parallel study in collaboration with others, we found intraindividual heterogeneity with respect to copy number alterations to predict outcome after liver resections (Sveen et al., manuscript submitted). While several studies have compared genetic alterations between primary tumors and their corresponding metastatic deposits, the biological and clinical implications of intraindividual metastatic heterogeneity remain poorly understood.

Sampling of multiple synchronous metastatic deposits represents a challenge in most solid tumors. However, the fact that liver resections for CRC metastases in general contain multiple lesions makes this a suitable model for studying intermetastatic mutation heterogeneity.

The aim of this study was twofold. First, we aimed to assess the influence of mutations in four major driver genes (KRAS, BRAF, PIK3CA and TP53) considered as potential prognostic factors in CRC in patients treated with liver resections. Second, as genetic heterogeneity may characterize a distinct tumor phenotype, we analyzed gene mutation status across multiple metastatic deposits from each patient in order to determine intraindividual metastatic heterogeneity and the potential prognostic impact of such mutation heterogeneity.

Material and Methods

Patients

Metastatic liver deposits were collected from 164 mCRC patients undergoing partial liver resection between August 2006 and March 2013. The total number of deposits sampled and analyzed was 428, including six primary samples and 36 samples collected at re-resections from 23 of these patients.

Seventy-six patients had synchronous while 88 patients had metachronous liver metastases. Metastases were considered metachronous if diagnosed 3 months or more after diagnosis of the primary tumor.

All patients had a computer tomography (CT) scan performed before surgery. In addition, patients who received preoperative chemotherapy (n = 72) had CT scans performed within 4 weeks before start of chemotherapy and after three and six treatment cycles to evaluate response to therapy.

The treatment regimen administered most often included oxaliplatin and fluorouracil, administered as FOLFOX or Nordic FLOX. Fourteen patients were treated with irinotecan before liver resection, and 13 patients were also exposed to EGFR (seven patients) or VEGF inhibitors (six patients), 12 of these in combination with irinotecan. Fifty-three patients received chemotherapy after liver resection (postoperative chemotherapy).

Response to preoperative chemotherapy was determined according to the Response Evaluation Criteria in Solid Tumors (RECIST 1.1). Clinical data were retrieved from electronic patient's charts. Baseline patient characteristics and treatment are summarized in Table 1 with further details in Supporting Information Table S1. The study was approved by the Regional Ethical Committee, and all patients provided written informed consent.

Sample collection and evaluation

Following removal, the resected liver specimens were subjected to immediate dissection in the operating theater, and tissue samples were snap-frozen in liquid nitrogen. In addition, a small part of each sample was formalin fixed and paraffin embedded to allow for histopathological confirmation of tumor cell content. The amount of tumor cells in the whole section slides was on average 76% (range 10–100%). A total of 14 samples from ten patients were excluded due to poor genomic DNA (gDNA) quality and/or a high degree of normal tissue contamination, leaving samples from 408 metastases and six primaries available for mutation analysis. For 45 of the patients SNP6 data including ASCAT calculations of the aberrant cell fraction for each sample were also available (Sveen et al., manuscript submitted).

DNA isolation

Genomic DNA from all patient samples was extracted from fresh frozen tissue using the QIAamp DNA Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer’s instructions.

RNA isolation

RNA was extracted from fresh frozen tissue using the RNasy Mini Kit (Qiagen), and complimentary DNA (cDNA) was synthesized using qScript cDNA SuperMix (Quanta, Biosciences, Gaithersburg, MD), with 320 ng total RNA as input. Both procedures were performed according to the manufacturer’s instructions.
Table 1. Patient characteristics and treatment for 164 metastatic colorectal cancer patients treated with partial liver resection between August 2006 and March 2013 at Haukeland University Hospital, Bergen, Norway

| Characteristic | Value |
|---------------|-------|
| Age (years) at diagnosis, mean (range) | 63 (22–83) |
| Sex (male, female), n | 91, 73 |
| Months of follow-up, median (range) | 57 (20–98) |
| Primary tumor site (colon, rectum, multiple), n | 110, 48, 6 |
| Nodal status of primary cancer (pN0, pN+), n | 56, 108 |
| Disease-free interval (months) between primary and metastases, mean (range) | 3 (0–54) |
| Synchronous or metachronous liver metastases1, n | 76, 88 |
| CEA before liver surgery (<200, >200, missing), n | 108, 15, 41 |
| WHO performance status at start of treatment (0, I, II, missing), n | 102, 58, 3, 1 |
| Number of sampled and analyzed liver metastases (first liver resection): | |
| -Mean (range) | 2 (1–8) |
| -Patients harboring multiple metastases, n | 102 |
| -Patients harboring single metastasis, n | 62 |
| Chemotherapy exposure: | |
| -Adjuvant chemotherapy (primary setting), n | 26 |
| -Chemotherapy before liver resection2, n | 72 |
| -Chemotherapy after liver resection (post-operative chemotherapy) | 53 |
| Best response on chemotherapy (CR, PR, SD)3, n | 1, 41, 28 |

1Metastases were considered metachronous if diagnosed ≥3 months after diagnosis of the primary tumor.
2≥3 courses of treatment (except three patients who had to stop treatment after one or two cycles, due to side effects).
3Response Evaluation Criteria in Solid Tumors (RECIST 1.1). Not calculated for the patients receiving only one treatment course.
4Abbreviations: CEA: carcinoembryonic antigen; CR: complete response; PR: partial response; SD: stable disease.

DNA preamplification
Genomic DNA from all samples was globally amplified with a phi29 polymerase using the REPLI-g Midi Kit (Qiagen) according to the manufacturer’s instructions. In brief, gDNA was incubated in denaturation buffer for 3 min before addition of neutralization buffer and a master mix containing phi29 DNA polymerase with exonuclease proofreading activity. The isothermal amplification reaction was carried out for 16 hr at 30°C.

Mutation screening
BRAF V600 status was analyzed for as previously described.23 KRAS exon 2 (harboring codons 12 and 13) and PIK3CA exon 9 and 20 were amplified by PCR (detailed in Supporting Information Methods) and Sanger sequenced. Capillary gel electrophoresis, data collection and sequence analyses were performed on an automated ABI 3700 DNA sequencer (Applied Biosystems, Carlsbad, CA).

Mutation screening was performed on preamplified gDNA in order to save patient material. All alterations detected were verified in an independent amplification using original gDNA as template. For cases with intrindividual heterogeneity samples with wild-type results were also reanalyzed using original gDNA.

TP53 mutation analysis was performed for the whole coding region of the gene on cDNA from all liver metastatic deposits as previously described24 (for further details, see Supporting Information Methods). In short, TP53 was amplified in a nested PCR and the PCR products were purified and sequenced on an automated ABI 3700 DNA sequencer (Applied Biosystems).

All mutations identified were verified by exon-wise sequencing of gDNA. For cases with intrindividual heterogeneity, wild-type results based on cDNA were also reanalyzed using gDNA.

Statistics
For descriptive statistics we used the mean, median, counts and proportions (percents). The time to event or censoring was calculated from the start of treatment for liver metastases (liver resection or start of preoperative chemotherapy).

Patients dying of causes other than CRC with no evidence of relapse were treated as censored observations. As for patients dying subsequent to having a relapse from their CRC, these patients were considered as dying from CRC unless dying for reasons obviously unrelated to their CRC.

Unadjusted survival curves for time to relapse (TTR) and disease-specific survival (DSS) were estimated using the Kaplan–Meier plot25 and compared between subgroups with the log-rank test.26

To adjust for possible confounders the Cox proportional hazards model was applied.27 Due to collinearity multivariate analyses were performed adjusting for different variables in the Cox models. In the Supporting Information Tables results are presented by hazard ratios (HRs) and their 95% confidence intervals (CIs).

All statistical analyses were performed using the SPSS v.22 software. All p-values are given as two-sided.

Results
Mutation frequencies and intrindividual heterogeneity
Overall, the proportions of patients revealing a mutation in KRAS, BRAF, PIK3CA or TP53 were 33.5, 6.1, 13.4 and 60.4%, respectively. Detailed information on individual mutations is listed in Supporting Information Table S2. As expected, most of the KRAS mutations detected were point mutations localized to codons 12 and 13 (104 and 25 samples, respectively). In addition, we found one insertion...
between these two codons in two samples and a point mutation localized at codon 19 in one sample. All but two of the BRAF-mutated samples harbored the V600E mutation. All PIK3CA mutations were point mutations, the most frequent ones being E542K and E545K in exon 9. As for TP53, 226 and 27 samples harbored point mutations and indels, respectively. Notably, in five of the patients more than one TP53 mutation was detected in each mutated sample, and for one patient the second TP53 mutation was found in one out of three metastases only.

Among 94 patients from whom two or more metastatic deposits collected at the same resection were examined, 13 patients revealed mutation heterogeneity for at least one of the four genes examined across their metastatic deposits (Fig. 1). For each individual gene, the number of patients revealing heterogeneous mutation results for KRAS, BRAF, PIK3CA and TP53 was 10, 1, 5 and 9, respectively. Notably, in five patients, KRAS or TP53 mutations seemed to evolve over time either between the primary and the metastases or between the first and second liver resection (see details in Supporting Information Table S2).

Mutation frequencies in subgroups of patients with different chemotherapy exposure are listed in Supporting Information Table S3.
Mutation status and prognosis after liver resection

To evaluate the prognostic impact of the mutations described above in patients treated with liver resections, we excluded patients who had undergone a previous liver resection \( (n = 13) \) before inclusion in the present study, leaving a total of 151 patients.

In univariate analyses (Fig. 2), we found \( \text{KRAS} \) and \( \text{BRAF} \) mutations both to be associated with reduced median TTR (7 vs. 22 and 3 vs. 16 months; \( p < 0.001 \) and \( p = 0.002 \), respectively) and reduced median DSS (29 vs. 51 and 16 vs. 49 months; \( p = 0.008 \) and \( p < 0.001 \), respectively). Because \( \text{KRAS} \) and \( \text{BRAF} \) mutations are known to be mutually exclusive,\(^{28,29} \) we performed a combined analysis in addition (Fig. 2). Patients harboring either a \( \text{KRAS} \) or a \( \text{BRAF} \) mutation revealed an inferior median TTR (7 vs. 24 months) as well as DSS (26 vs. 56 months, \( p < 0.001 \) for both comparisons) compared to patients with deposits wild-type for both genes. Mutations in \( \text{PIK3CA} \) were associated with a reduced TTR (4 vs. 17 months; \( p = 0.023 \)), but not with reduced DSS, while \( \text{TP53} \) mutation status revealed no significant relation to either TTR or DSS. Considering the number of metastatic deposits, patients with multiple liver deposits had a somewhat shorter TTR compared to patients with one deposit only (\( p = 0.008 \)) while no significant effect on DSS was recorded (Supporting Information Table S4).

Interestingly, \( \text{KRAS} \) mutations seemed to be associated with a shorter median TTR in patients harboring synchronous (\( p = 0.002 \)) as well as metachronous (\( p = 0.019 \)) disease, but with DSS only in synchronous disease (\( p = 0.001 \); Supporting Information Fig. S1a). Similar findings were observed for \( \text{KRAS} \) and \( \text{BRAF} \) mutations combined (Supporting Information Fig. S1b).

Influence of chemotherapy exposure

Among the 151 patients, 33 patients received preoperative chemotherapy only, 17 patients had chemotherapy after surgery only, 36 patients received both presurgical and postsurgical chemotherapy, while 65 patients received no chemotherapy neither before nor after their liver surgery. Comparing all the four treatment groups together, a significant effect on TTR (\( p < 0.001 \)) as well as DSS (\( p = 0.001 \)) was recorded, with a clear preference for postoperative chemotherapy (Fig. 3). Analyzing separately for preoperative or postoperative therapy as variables in univariate analysis, interestingly postoperative therapy influenced TTR as well as DSS for the total group of patients (\( p < 0.001 \) for both) (Fig. 3), while presurgical chemotherapy improved TTR among patients harboring a \( \text{KRAS} \) mutation only (Supporting Information Figs. S2c and S2d; \( p = 0.018 \)). However, except for a weak interaction between \( \text{KRAS} \) and \( \text{BRAF} \) wild-type status and benefit from preoperative chemotherapy (\( p = 0.02 \)), no statistically significant interaction between mutation status for any of the genes analyzed and benefit from chemotherapy administered in the preoperative or postoperative setting was recorded (Supporting Information Figs. S2 and S3). Notably chemotherapy response (partial response vs. stable disease) \( \text{per se} \) did not influence survival after liver resection in our dataset (Supporting Information Table S4); neither did we observe any difference in TTR or DSS between patients commencing postsurgical chemotherapy within a time frame of 4 weeks vs. patients commencing on chemotherapy later than 4 weeks after surgery (Supporting Information Fig. S4).

![Kaplan-Meier survival curves illustrating time to relapse (left panels) and disease-specific survival (right panels) after liver surgery for metastatic colorectal cancer with respect to mutation status for \( \text{KRAS} \), \( \text{BRAF} \), \( \text{KRAS} \) and \( \text{BRAF} \) combined, \( \text{PIK3CA} \) and \( \text{TP53} \) (\( n = 151 \) in each panel). A patient was classified as harboring a gene mutation as long as it was present in at least one lesion. \( p \)-values are from log-rank tests.](image)

**Mutation status and prognosis after liver resection**

To evaluate the prognostic impact of the mutations described above in patients treated with liver resections, we excluded patients who had undergone a previous liver resection \( (n = 13) \) before inclusion in the present study, leaving a total of 151 patients.

In univariate analyses (Fig. 2), we found \( \text{KRAS} \) and \( \text{BRAF} \) mutations both to be associated with reduced median TTR (7 vs. 22 and 3 vs. 16 months; \( p < 0.001 \) and \( p = 0.002 \), respectively) and reduced median DSS (29 vs. 51 and 16 vs. 49 months; \( p = 0.008 \) and \( p < 0.001 \), respectively). Because \( \text{KRAS} \) and \( \text{BRAF} \) mutations are known to be mutually exclusive,\(^{28,29} \) we performed a combined analysis in addition (Fig. 2). Patients harboring either a \( \text{KRAS} \) or a \( \text{BRAF} \) mutation revealed an inferior median TTR (7 vs. 24 months) as well as DSS (26 vs. 56 months, \( p < 0.001 \) for both comparisons) compared to patients with deposits wild-type for both genes. Mutations in \( \text{PIK3CA} \) were associated with a reduced TTR (4 vs. 17 months; \( p = 0.023 \)), but not With reduced DSS, while \( \text{TP53} \) mutation status revealed no significant relation to either TTR or DSS. Considering the number of metastatic deposits, patients with multiple liver deposits had a somewhat shorter TTR compared to patients with one deposit only (\( p = 0.008 \)) while no significant effect on DSS was recorded (Supporting Information Table S4).

Interestingly, \( \text{KRAS} \) mutations seemed to be associated with a shorter median TTR in patients harboring synchronous (\( p = 0.002 \)) as well as metachronous (\( p = 0.019 \)) disease, but with DSS only in synchronous disease (\( p = 0.001 \); Supporting Information Fig. S1a). Similar findings were observed for \( \text{KRAS} \) and \( \text{BRAF} \) mutations combined (Supporting Information Fig. S1b).

Influence of chemotherapy exposure

Among the 151 patients, 33 patients received preoperative chemotherapy only, 17 patients had chemotherapy after surgery only, 36 patients received both presurgical and postsurgical chemotherapy, while 65 patients received no chemotherapy neither before nor after their liver surgery. Comparing all the four treatment groups together, a significant effect on TTR (\( p < 0.001 \)) as well as DSS (\( p = 0.001 \)) was recorded, with a clear preference for postoperative chemotherapy (Fig. 3). Analyzing separately for preoperative or postoperative therapy as variables in univariate analysis, interestingly postoperative therapy influenced TTR as well as DSS for the total group of patients (\( p < 0.001 \) for both) (Fig. 3), while presurgical chemotherapy improved TTR among patients harboring a \( \text{KRAS} \) mutation only (Supporting Information Figs. S2c and S2d; \( p = 0.018 \)). However, except for a weak interaction between \( \text{KRAS} \) and \( \text{BRAF} \) wild-type status and benefit from preoperative chemotherapy (\( p = 0.02 \)), no statistically significant interaction between mutation status for any of the genes analyzed and benefit from chemotherapy administered in the preoperative or postoperative setting was recorded (Supporting Information Figs. S2 and S3). Notably chemotherapy response (partial response vs. stable disease) \( \text{per se} \) did not influence survival after liver resection in our dataset (Supporting Information Table S4); neither did we observe any difference in TTR or DSS between patients commencing postsurgical chemotherapy within a time frame of 4 weeks vs. patients commencing on chemotherapy later than 4 weeks after surgery (Supporting Information Fig. S4).
Figure 3. (a) All four treatment groups presented. (b) All patients receiving preoperative chemotherapy (alone or combined with postoperative chemotherapy) vs. patients receiving no preoperative chemotherapy (with or without postoperative chemotherapy). (c) Patients receiving postoperative chemotherapy (alone or in concert with preoperative therapy) vs. patients receiving no postoperative chemotherapy (with or without preoperative chemotherapy). (d) All patients receiving chemotherapy for liver metastases at any time vs. patients who did not receive any chemotherapy. \( n = 151 \) in each panel.
Mutation heterogeneity and prognosis after liver resection

The potential impact of mutation heterogeneity (defined as different mutation status between metastases harvested from the same patient at the same surgical procedure) on outcome was evaluated in the subgroup of patients harboring two or more liver deposits (n = 94).

First, we confirmed the prognostic impact of KRAS, BRAF and PI3K mutation status revealed in the total patient cohort in the subgroup of patients harboring multiple deposits (Supporting Information Table S5). Next, we compared outcome between (i) patients with mutation heterogeneity affecting either KRAS, BRAF, TP53 or PI3K and patients revealing at least one homogenous but no heterogeneous mutation in either gene (a). Similar analyses comparing patients harboring no mutations, heterogeneous or homogenous mutations in either KRAS or BRAF without attention to TP53 or PI3K status (b). p-values are from log-rank tests. p-values relate to comparison between all three groups. p* values relate to the difference between patients harboring heterogeneous vs. homogenous mutations.

Multivariate analyses

As KRAS and BRAF mutations were mutually exclusive, these parameters (BRAF or KRAS mutation vs. wild-type status for
both) were combined into one parameter for the multivariate analyses. In addition, as the use of different treatment regimens depended on stage of disease (meta- vs synchronous metastases, nodal status of the primary) as well as previous therapy, repeated multivariate analyses were performed entering different variables into the models.

The detailed results of these analyses are summarized in Table 2 and Supporting Information Table S6. For the total cohort (n = 151) as well as for the subcohort harboring multiple metastatic deposits (n = 94), mutations affecting KRAS or BRAF in a homogeneous or heterogeneous manner consistently predicted a poor TTR as well as a poor DSS across all models. In addition, postoperative chemotherapy (with or without prior preoperative therapy) improved TTR as well as DSS. Notably, in the subgroup of patients with multiple deposits (n = 94), mutation heterogeneity independently predicted DSS but not TTR across models (Supporting Information Table S6).

Discussion

Liver resections improve outcome in CRC patients harboring liver metastases, and some patients become long-term survivors. It represents a major surgical intervention however, and the fact that many patients only gain limited benefit calls for identification of improved prognostic and predictive factors.

The aim of this study was twofold; first, we assessed the influence of mutations in four key driver genes (KRAS, BRAF, PIK3CA and TP53) determined on metastatic deposits on outcome after liver resections for CRC. Second, we analyzed gene mutation status across multiple deposits from each patient in order to determine intraindividual mutation heterogeneity and its potential impact on prognosis.

The frequencies of KRAS, PIK3CA and TP53 mutations resemble what has been detected by others in metastatic liver deposits, but for BRAF the incidence was slightly higher than in most other series analyzing liver metastases. While previous studies have revealed BRAF mutations to be associated with a poor outcome following liver resection for CRC, the results for KRAS mutation have been at variance.

Here, BRAF as well as KRAS mutation status (each one individually as well as combined) was associated with a poor prognosis in univariate analysis in the total patient cohort as well as in the subgroup of patients harboring multiple liver deposits. Moreover, both mutations consistently predicted a poor outcome across different multivariate models. Considering PIK3CA and TP53 mutation status, conflicting results have linked mutations in these genes to outcome in CRC patients. Here, we found PIK3CA mutations to be associated only with a reduced TTR but not DSS in univariate analysis; in contrast, no association between TP53 mutation status and outcome (either TTR or DSS) was recorded.

Chemotherapy administered in relation to liver resections has been reported to improve TTR but not DSS. Patients included in this study were selected for chemotherapy based on demographic and medical conditions including age, general health condition and previously chemotherapy exposure. The fact that chemotherapy was not administered in a randomized setting means that the results need to be interpreted carefully. Our finding that postoperative but not preoperative chemotherapy seems to be of significant benefit however is of interest. If confirmed in independent studies, this will have clinical implications. This observation contrasts results obtained with use of primary medical therapy (neoadjuvant chemotherapy) in other cancer forms like breast cancer. However, liver resection normally is followed by a rapid liver tissue regeneration, to be accompanied by secretion of multiple growth factors. This setting may have detrimental effects on subclinical metastatic deposits, offering a potential explanation for a particular benefit of chemotherapy treatment during this time period. The finding of no

Abbreviations: HR: hazard ratio; CI: confidence interval; wt: wild type; mets: metastases; muts: mutations.
interaction (except for a weak association between KRAS and BRAF wild-type status and benefit from preoperative therapy) between gene mutation status and mutation heterogeneity on the one hand and benefit from chemotherapy on the other hand further supports a prognostic role of these mutations, suggesting mechanisms related to tumor cell growth, invasion, metastatic propensity and others and not resistance to chemotherapy to explain our observations.

Heterogeneity within primary tumors is well recognized as an important challenge to personalized medicine. Recent studies have revealed clonal heterogeneity for KRAS mutations within primary CRCs, and several studies have examined concordance in mutation status between primary tumors and metastatic deposits. Mutation heterogeneity across synchronous deposits, however, is not well described.

We observed heterogeneous mutation results in respect to the four driver genes analyzed in 13 of 94 patients (12.2%) harboring multiple liver deposits. Comparing DSS between tumors revealing a heterogeneous mutation affecting any of the four genes analyzed and tumors harboring a homozygous mutation for one (or more) of these genes revealed an inferior DSS for tumors harboring heterogeneous mutations. Notably, mutation heterogeneity was found to be an independent prognostic factor in multivariate analysis.

Ten patients harbored a heterogeneous KRAS mutation, and one revealed a heterogeneous BRAF mutation. Similar to what was recorded in respect to mutation heterogeneity across all four genes analyzed, mutation heterogeneity for BRAF or KRAS revealed an inferior prognosis as compared to homozygous mutations across the two genes. While we may not exclude the possibility that heterogeneity for BRAF and KRAS mutations could explain the findings obtained in respect to heterogeneity across all four genes, our findings in metastatic CRC are consistent with observations by others revealing tumor heterogeneity to predict a poor prognosis across different forms of primary solid tumors.

In conclusion, we confirmed KRAS and BRAF mutations to be a robust prognostic parameter in patients treated with partial liver resections for metastatic CRC. These findings indicate that KRAS/BRAF mutation status should be taken into account together with other prognostic parameters when selecting patients for surgery. Second, our results point to an important role of postsurgical but probably not presurgical chemotherapy in relation to liver resections; confirmation in independent studies is warranted. Finally, our data support the hypothesis that mutation heterogeneity could be a marker associated with an aggressive clinical behavior. If confirmed by others, these findings may be of importance to patient treatment and also improve our understanding of the clinical and biological importance of mutation heterogeneity in metastatic disease.

Acknowledgments
This work was performed in the Mohn Cancer Research Laboratory, Haukeland University Hospital/University of Bergen. The authors appreciate the skilled technical assistance from Dagfinn Ekse, Nhat Kim Duong, Christine Eriksen and Silje Bjørneklett. They thank Geir Egil Eide at Centre for Clinical Research, Western Norway Regional Health Authority and the Department of Global Public Health and Primary Care, University of Bergen, Norway for excellent advice and statistical review.
