INTRODUCTION

Chondrosarcoma is a common primary malignant bone tumor, and is the second most common malignancy following osteosarcoma. They are classified into different grades based on tumor cellularity and nuclear changes in chondrocytes. Low-grade chondrosarcomas correspond to grade I tumors. These tumors are usually treated with curettage and wide

KEYWORDS

chondrosarcoma, IDH, isocitrate dehydrogenase, meta-analysis, overall survival, recurrence-free survival
excision and likely have a good prognosis, whereas, high-grade (grade II–III) chondrosarcomas have a high risk of relapse and even metastasis which requires more aggressive treatment. The most aggressive form of chondrosarcoma is dedifferentiated chondrosarcoma, which is associated with a dismal prognosis and rapid development of widespread metastases.

Besides tumor grades, several clinicopathological features have been shown to be of prognostic importance in chondrosarcoma patients including gender, tumor location, diameter, and extent of resection. Recently, emerging data have clarified the genomic landscape of chondrosarcomas. Isocitrate dehydrogenase (IDH) mutation is a common genetic alteration in gliomas and is also found in about 50% of central chondrosarcomas. In gliomas, this mutation is associated with a favorable prognosis. However, published data are equivocal regarding the association of IDH1/2 mutations and outcomes of chondrosarcoma patients. This meta-analysis aims to explore the clinicopathological and prognostic characteristics of IDH1/2 mutations in chondrosarcoma.

2 | METHODS

2.1 | Ethical approval

An ethical approval is not needed for this study because this is a meta-analysis and systematic review based on published studies.

2.2 | Literature search

PubMed and Web of Science databases were searched for relevant articles from inception to November 2020. We used the following term: chondrosarcoma AND (IDH1 OR IDH2 OR IDH1/2 OR IDH OR isocitrate dehydrogenase). This study generally followed the recommendations of the Preferred Reporting Items for Systematic Review and Meta-Analysis (PRISMA) statement.

2.3 | Selection criteria and abstract screening

All search results from two electronic databases were imported into EndNote (Clarivate, PA, US) and duplicates were removed. Two reviewers independently screened the title and abstract of these search results. Studies were included if they provided individual patient data (IPD) of chondrosarcoma patients and IDH1/2 mutation data. We excluded studies without IPD; reviews; case reports, proceeding papers, conference abstracts, or books. If there are any discrepancies among the two reviewers, discussion and consensus were reached.

2.4 | Full-text screening and data extraction

The full-text of suspected studies were independently read by two reviewers and IPD were extracted into a standardized worksheet. The following IPD were extracted: authors, institution, country, year of publication, demographic information, tumor location, tumor diameter, histopathological subtypes, tumor grades, patient outcomes (recurrence, recurrence-free survival [RFS] time, metastasis, metastasis-free survival [MFS] time, overall survival [OS] status, OS time), and status of IDH1/2 mutations.

2.5 | Statistical analyses

Categorical data were presented as frequency (percentage), and comparisons between groups were performed using the chi-square test. Continuous variables are expressed as mean ± standard deviation (SD) for normal distributions and median + interquartile range (IQR) for non-normal distributions. The distribution of continuous variables was assessed using skewness, kurtosis, and visual inspection of the histogram. Continuous variables were compared between two groups by t-test or Mann–Whitney U-test, as appropriate. Univariate and multivariable Cox proportional hazards models were conducted to determine the association of

---

**FIGURE 1** Study flowchart
IDH1/2 mutations with clinical outcomes (recurrence, metastasis, and overall survival). Proportionality assumptions of the Cox regression models were assessed by log-log survival curves and with the use of Schoenfeld residuals. The deviance residuals and the dfbeta values were used to examine influential observations. Hazard ratios (HR) are presented as mean and 95% confidence interval (CI). A two-sided \( p \)-value of \(< 0.05\) was considered statistically significant. The statistical analyses were performed using IBM SPSS Statistics for Windows, version 22.0 (IBM Corp., Armonk, N.Y., USA) and R software, version 3.6.1 (The R Foundation, Vienna, Austria).

2.6 Quality assessment and risk of bias analysis

We evaluated the quality of included studies in our meta-analysis using the Newcastle–Ottawa Scale (NOS).\(^{19}\) Two reviewers independently awarded the number of stars using a standardized checklist. We considered studies moderate to high quality if they have six stars or more.

3 RESULTS

We identified 136 articles for the title and abstract screening; 34 of these were selected for full-text reading. Following this step, we included 14 studies comprising 488 chondrosarcoma patients with available IDH1/2 mutational status for data analyses (Figure 1).\(^{10-12,17,20-29}\) All studies but three had moderate to good quality using the NOS tool assessment. Table 1 and Table S1 present the characteristics of all included studies.

### 3.1 Prevalence of IDH mutations in chondrosarcomas

IDH1/2 mutations were detected in 250 patients (51.2%). The prevalence of IDH1 and IDH2 were 38.7% and 12.1%,

| Study | Institution | Country | Study period | Detection methods | No. of cases | NOS stars |
|-------|-------------|---------|--------------|-------------------|--------------|-----------|

Abbreviations: C, comparability; IHC, immunohistochemistry; NA, not available; NGS, next-generation sequencing; NOS, Newcastle-Ottawa Scale; O, outcome; PCR, polymerase chain reaction; S, selection.
respectively. \textit{IDH1} and \textit{IDH2} mutations were mutually exclusive except for one case. Among 488 analyzed cases, \textit{IDH1} and \textit{IDH2} mutation genotypes were reported in 237 cases. The detailed genotypes of \textit{IDH1} and \textit{IDH2} mutations are shown in Table 2. The prevalence of \textit{IDH} mutations was statistically different between tumor locations with the highest prevalence seen in phalanges (100%) and femur (83.0%) and the lowest prevalence found in vertebrae and sternum (0%) (Table 3).

### 3.2 Associations of \textit{IDH} mutations with clinicopathological factors and patient outcomes

Table 3 shows the correlations of \textit{IDH} mutations with clinicopathological features. Compared to \textit{IDH}-wild type (\textit{IDH}-wt) tumors, \textit{IDH}-mut chondrosarcomas were associated with older age and larger tumor diameter ($p = 0.003$). In addition, \textit{IDH} mutations were more likely to occur in long bones chondrosarcomas (e.g., femur, humerus, tibia) and flat bones (e.g., pelvis, cranium) whereas, these mutations were completely absent in irregular bones (e.g., vertebrae, sternum). We also found an association of \textit{IDH} mutations with chondrosarcoma grades; the prevalence of \textit{IDH} mutations was significantly increased with grades with the highest prevalence being identified in dedifferentiated tumors.

The median follow-up duration of chondrosarcomas was 20.5 months. The presence of \textit{IDH1/2} mutations were associated with a decreased recurrence rate but a significantly higher risk of patient death (Table 3). For time-to-event analysis, \textit{IDH1/2} mutations were not associated with tumor RFS (HR = 0.63; 95% CI = 0.30–1.31; $p = 0.21$) and MFS (HR = 1.75; 95% CI = 0.91–3.36; $p = 0.09$), but they were significantly correlated with patient OS (HR = 1.81; 95% CI = 1.15–2.87; $p = 0.01$) (Figure 2). The significant result was retained in the multivariate model adjusted for age, gender, tumor grades, and tumor locations (HR = 1.90; 95% CI = 1.06–3.42; $p = 0.03$).

Stratified by tumor grades, we found an association of \textit{IDH} mutation with longer RFS in the high-grade group (Figure 3) using the log-rank test ($p = 0.049$). Because of the small sample size with available survival data when dividing into different subgroups, we did not found any associations of \textit{IDH1/2} mutations with patient RFS, MFS, and OS using the Cox proportional hazards model in other chondrosarcoma grades (Table 4).

### 3.3 The characteristics of cranial chondrosarcomas

There were 96 cases of cranial chondrosarcoma included in our meta-analysis. The characteristics of these neoplasms are summarized in Table 5. \textit{IDH} mutations were only detected in skull base chondrosarcoma and were not present in craniofacial tumors ($p < 0.001$). Patient outcomes were missing in the majority of cranial chondrosarcomas so we excluded them from the analyses.

### 4 DISCUSSION

\textit{IDH} mutation is a highly recurrent genetic event in glial and hematopoietic tumors.\textsuperscript{13,30} In mice, there is established evidence that mutant \textit{IDH} can trigger enchondromatosis, which could subsequently undergo additional tumorigenesis to become chondrosarcoma.\textsuperscript{31} Our study confirmed the presence of this mutation in over 50% of chondrosarcoma patients and its prevalence is elevated with tumor grade with the highest prevalence seen in dedifferentiated tumors. \textit{IDH} mutations are very specific to cartilaginous tumors but do not exist in other mesenchymal neoplasms such as osteosarcoma or undifferentiated pleomorphic sarcoma.\textsuperscript{11,21,29} Of note, it is crucial to distinguish chondrosarcoma from osteosarcoma because the former is not chemosensitive while the primary treatment of osteosarcoma involves neoadjuvant chemotherapy.\textsuperscript{32} Additionally, about a quarter of conventional osteosarcoma can produce cartilaginous areas, making it challenging to distinguish these two tumor entities in small biopsies. Unlike gliomas where \textit{IDH1 R132H} mutation is predominant and can be diagnosed by immunohistochemistry,\textsuperscript{33} the distribution of \textit{IDH1} mutations is more heterogeneous in chondrosarcoma with \textit{R132C} being the most frequent followed
by R132G and R132L. As there are no antibodies specific for R132C currently available, the best approach to detect this hotspot mutation is to use traditional Sanger sequencing or pyrosequencing. \( \text{IDH2} \) mutations are prevalent in patients with acute myeloid leukemia and occur most frequently at codon 140.\(^{13} \) We did not find any \( \text{IDH2} \) R140 mutations among the included studies. \( \text{IDH2} \) mutation solely occurred at codon 172 in chondrosarcomas with R172S being the most frequent \( \text{IDH2} \) genotype.

Our results established a strikingly heterogeneous distribution of \( \text{IDH1/2} \) mutations in specific anatomical locations. The distribution of \( \text{IDH1-positive} \) tumors in the bones of extremities was significantly higher than other types, suggesting different pathways of tumorigenesis among these neoplasms. Besides \( \text{IDH} \) mutation, other common genetic alterations in chondrosarcoma include \( \text{COL2A1}, \text{CDKN2A/B}, \text{TP53} \) mutations with a prevalence of 20–30%.\(^{12,27} \) \( \text{TERT} \) promoter mutation/amplification was found in a subset of high-grade chondrosarcomas and likely to concurrently occur with \( \text{IDH} \) mutations, \( \text{CDKN2A/B} \) deletions, or \( \text{TP53} \) mutations.\(^{12} \) That the effect of the \( \text{TERT} \) promoter mutation on patient survival can be modulated by \( \text{IDH} \) mutation and other genetic events in glioma patients has been suggested in prior studies.\(^{34–36} \)

| Variables | Groups | \( \text{IDH1/2-mut} \) | \( \text{IDH1/2-wt} \) | \( p \)-value |

**Abbreviations:** HG-CCS, high-grade chondrosarcoma; IQR, interquartile range; LG-CCS, low-grade chondrosarcoma; SD, standard deviation.

Bold values indicate a statistically significant result.
In cranial chondrosarcomas, we demonstrated different patterns of IDH1/2 mutations by the anatomical site of neoplasms. These mutations were found in 60% of skull base tumors but did not exist in craniofacial chondrosarcomas. These discrepancies might stem from the distinct modes of ossification where skull base bones are structured by endochondral ossification and facial bones originate from intramembranous ossification. The latter mode involves direct differentiation of progenitor cells into osteoblasts and the cartilaginous phase does not take place. The high frequency of IDH1/2 mutations in skull base chondrosarcoma makes it a useful diagnostic tool to differentiate from chordoma, particularly in small biopsy specimens. The effect of IDH mutations on patient outcome in this group is limited and most of the included studies did not provide survival data. Kanamori et al. reported an insignificant correlation of IDH1 mutation with tumor relapse but only seven patients were enrolled in their study. Additional studies are necessary to elucidate the prognostication of IDH1/2 mutations in chondrosarcomas of the head and neck.

The impact of IDH1/2 mutations on chondrosarcoma patient survival is unclear. Lugowska et al. indicated an association of IDH mutation with a shorter OS while other studies failed to establish this relationship. This study concluded a negative impact of IDH mutation on patient OS, emphasizing the independent role of IDH mutation as a
In this study, we found that IDH mutation is more commonly seen in dedifferentiated tumors which could explain the link between IDH mutation and mortality rate. It can help clinicians better predict the clinical course and tailor appropriate treatment decisions. The association of IDH mutation and tumor relapse remains investigational.

IDH mutation was found to be associated with longer RFS in grade II-III chondrosarcomas. We also observed the same trend of correlation of IDH mutation and patient RFS in chondrosarcomas and a decreased risk of tumor relapse in patients harboring IDH1/2 mutations. Although the Cox regression model does not reach statistical significance, it should be noted that the length of follow-up in the Zhu et al. study was quite long compared to other studies (over 21 years), increasing the power of their statistical adjustment. Raw patient survival data was not provided in this study so we could not include them in our survival analyses.

**TABLE 4** Subgroup analyses of impacts of IDH mutations on patient outcomes in different chondrosarcoma grades

| Tumor grades | Hazard Ratio (95% CI) | p-value |
|--------------|----------------------|---------|
| Low-grade    |                      |         |
| RFS          | NA                   | NA      |
| MFS          | NA                   | NA      |
| OS           | NA                   | NA      |
| High-grade   |                      |         |
| RFS          | 0.41 (95% CI = 0.17–1.03) | 0.06    |
| MFS          | 1.55 (95% CI = 0.57–4.24) | 0.39    |

**4.1 Strengths and limitations**

Our study is the first meta-analysis investigating the clinical and prognostic significance of IDH mutations in chondrosarcomas. Our meta-analyses were solely based on individual participant data which significantly increases the statistical power compared to meta-analyses using aggregate data. Given the rarity of chondrosarcomas, it was difficult to reach statistical significance when examining the prognosis of this tumor. Most of the published data failed to demonstrate the prognostic impact of IDH mutations in chondrosarcomas. We incorporated nearly 500 cases of chondrosarcoma and highlighted that IDH1/2 mutations are prevalent in some specific types of chondrosarcoma and assessment of these mutations in challenging cases could help distinguish from chordoma or osteosarcoma. These mutations could be used as an independent prognostic marker to better predict patient outcomes.
