(Dated: August 4, 2017)

Based solely on the analytical properties of the single-particle Green’s function of fermions at finite temperatures, we show that the generalized Luttinger theorem inherently possesses topological aspects. The topological interpretation of the generalized Luttinger theorem can be introduced because i) the Luttinger volume is represented as the winding number of the single-particle Green’s function and thus ii) the deviation of the theorem, expressed with a ratio between the interacting and noninteracting single-particle Green’s functions, is also represented as the winding number of this ratio. The formulation based on the winding number naturally leads to two types of the generalized Luttinger theorem. Exploring two examples of single-band translationally invariant interacting electrons, i.e., simple metal and Mott insulator, we show that the first type falls into the original statement for Fermi liquids given by Luttinger, where poles of the single-particle Green’s function appear at the chemical potential, while the second type corresponds to the extended one for non-metallic cases with no Fermi surface such as insulators and superconductors generalized by Dzyaloshinskii, where zeros of the single-particle Green’s function appear at the chemical potential. This formulation also allows us to derive a sufficient condition for the validity of the Luttinger theorem of the first type by applying the Rouche’s theorem in complex analysis as an inequality. Moreover, we can rigorously prove in a non-perturbative manner, without assuming any detail of a microscopic Hamiltonian, that the generalized Luttinger theorem of both types is valid for generic interacting fermions as long as the particle-hole symmetry is preserved. Finally, we show that the winding number of the single-particle Green’s function can also be associated with the distribution function of quasiparticles, and therefore the number of quasiparticles is equal to the Luttinger volume. This implies that the fundamental hypothesis of the Landau’s Fermi-liquid theory, the number of fermions being equal to that of quasiparticles, is guaranteed if the Luttinger theorem is valid since the theorem states that the number of fermions is equal to the Luttinger volume. All these general statements are made possible because of the finding that the Luttinger volume is expressed as the winding number of the single-particle Green’s function at finite temperatures, for which the complex analysis can be readily exploited.

I. INTRODUCTION

The Luttinger theorem states that the particle density of interacting fermions is equal to the volume in the momentum space enclosed by the Fermi surface [1]. The theorem has been proved valid for normal Fermi liquids originally in perturbation expansion of the interacting single-particle Green’s function in 60’s [1, 2] and later in a non-perturbative way [3]. In the Green’s function language, the Luttinger volume is bounded by the surface, named Luttinger surface, in the momentum ($\mathbf{k}$) space on which the single-particle Green’s function $\tilde{G}(\mathbf{k}, \omega = 0)$ at zero frequency ($\omega$), i.e., at the chemical potential, changes its sign [4]. The fact that the single-particle Green’s function changes its sign in going through either poles or zeros [4, 5] allows Luttinger theorem to be extended even to insulating states [5, 6] of interacting fermions, including multi-orbital systems [7] and non-translational-invariant systems [8]. The extended versions of the Luttinger theorem are called the generalized Luttinger theorem, stating that the particle density of interacting fermions is equal to the Luttinger volume. The Luttinger theorem has also been shown valid for the Tomonaga-Luttinger liquid in one spatial dimension [9].

Although the generalization of the Luttinger theorem has significant advantages, e.g., being able to treat metal and insulator on an equal footing [10–14], its validity has been proved only for limited systems. For example, the validity of the generalized Luttinger theorem has been proved for a particle-hole symmetric single-band Hubbard model on the square lattice [11, 15]. The proof is based on the moment expansion of the single-particle Green’s function, which involves the commutation relations of the Hamiltonian and electron creation/annihilation operators. Therefore, the proof depends on the microscopic Hamiltonian and thus it is difficult to generalize to other systems.

In this paper, we show that the Luttinger volume at zero temperature is expressed as the winding number of the determinant of the single-particle Green’s function. Therefore, the winding number of a ratio between the determinants of the interacting and noninteracting single-particle Green’s functions provides the topological interpretation of the generalized Luttinger theorem. We prove rigorously that the generalized Luttinger theorem is valid for generic interacting fermions as long as the particle-hole symmetry is preserved. The formulation based on the winding number of the single-particle Green’s function also allows us to naturally classify the condition for the validity of generalized Luttinger theorem into two types, depending on whether poles or zeros of the single-particle Green’s function exist at the chemical potential. The first type (type I) corresponds to the original statement for Fermi liquids given by Luttinger [1], whereas the second type (type II) corresponds to the extended one for single-particle gapful systems given by Dzyaloshinskii [5]. Moreover, a sufficient condition for the validity of the Luttinger theorem of type I can be derived from the topological interpretation of the the-
orem. Associating the winding number of the single-particle Green’s function with the distribution function of quasiparticles, we can show that the number of quasiparticle is equal to the Luttinger volume. These general results are based solely on analytical properties of the single-particle Green’s function at finite temperatures, for which the complex analysis can be exploited unambiguously, without any detail of a microscopic Hamiltonian, and can be applied in any spatial dimension to metallic and insulating states, independently of the strength of interactions. Several specific examples of interacting electrons are also provided to demonstrate these results.

The rest of the paper is organized as follows. Section II introduces the notation used in this paper and summarizes analytical aspects of the single-particle Green’s function at finite temperatures which are essential for the analysis in the following sections. Giving the definition of the Luttinger volume in Sec. III A, we show in Sec. III B that the Luttinger volume is temperatures which are essential for the analysis in the follow-

tering aspects of the single-particle Green’s function at finite temperatures, for which the complex analysis can be exploited unambiguously, without any detail of a microscopic Hamiltonian, and can be applied in any spatial dimension to metallic and insulating states, independently of the strength of interactions. Several specific examples of interacting electrons are also provided to demonstrate these results.

In Ref. [18], the Lehmann representation [19] of the single-particle Green’s function at temperature T is

\[ G_{np}(z) = \frac{N_c}{\sum_{m=1}^{N_c} Q_{nm} Q_{mn}^*}{z - \omega_m} \]  

with

\[ Q_{nm} = \sqrt{\text{e}^{(z - E_m)/T} + \text{e}^{(z - E_n)/T}}(r)c_{nm} \]  

and \( \omega_m = E_r - E_n \), where \( m = (r, s) = 1, 2, \ldots, N_c \) represents all possible pairs of eigenstates \( |r\rangle \) and \( |s\rangle \) of Hamiltonian \( H \) with their eigenvalues \( E_r \) and \( E_n \), respectively [20]. We adopt the convention that the chemical potential term is included in \( H \) and therefore \( z = 0 \) in \( G_{np}(z) \) corresponds to the chemical potential. \( \Omega = -T \ln \sum_{r} \text{e}^{-E_r/T} \) is the grand potential and \( c_r \) is a fermion-annihilation operator with single-particle state \( \alpha \) \((= 1, 2, \ldots, L_s)\). For example, \( \alpha \) can be a set of spin \( \sigma \), momentum \( k \), and orbital \( \xi \) indices \( \{\alpha = (\sigma, k, \xi)\} \), or simply a site index \( i \) \((= i)\). The Green’s function \( G_{np}(z) \) is analytically complex in the complex plane except for the excitation energies at \( \omega_{nm} \) and thus poles of \( G_{np}(z) \) appear only on the real-frequency axis.

The Green’s function is now written in an \( L_s \times L_s \) matrix form

\[ G(z) = \mathbf{Q}g(z)\mathbf{Q}^\dagger, \]  

where \( \mathbf{Q} = [Q_{nm}] \) is an \( L_s \times N_c \) rectangular matrix and

\[ g(z) = \text{diag}[1/(z - \omega_1), \ldots, 1/(z - \omega_{N_c})] \]  

is an \( N_c \times N_c \) diagonal matrix with \( \omega_1 \leq \omega_2 \leq \cdots \leq \omega_{N_c} \). The anti-commutation relation of the fermionic operators \( [c_{\alpha\dagger}, c_{\beta}] = \delta_{\alpha\beta} \) guarantees the spectral weight sum rule, which is now written as \( \sum_{m=1}^{N_c} Q_{nm} Q_{nm}^* = \delta_{nm} \) or equivalently

\[ \mathbf{Q}^\dagger \mathbf{Q} = \mathbf{I}. \]  

It should be noted that in general \( \mathbf{Q} \) is not a unitary matrix, i.e., \( \mathbf{Q}^\dagger \mathbf{Q} \neq \mathbf{Q}^\dagger \mathbf{Q} \) \((= N_c)\), where the subscripts denote the size of the resulting matrices.

### B. Diagonal elements of single-particle Green’s function

Next, we consider analytical properties of the diagonal element of the single-particle Green’s function \( G_{\alpha\alpha}(z) \) [21–24] because the particle number is evaluated through the trace of the single-particle Green’s function. It is apparent from Eq. (1) that the imaginary part of \( G_{\alpha\alpha}(z) \), \( \text{Im}G_{\alpha\alpha}(z) \), is always finite when frequency \( z \) is away from the real axis. Therefore, zeros of \( G_{\alpha\alpha}(z) \) must lie on the real-frequency axis. The fact that the single-particle Green’s function is a rational function with respect to \( z \) and \( G_{\alpha\alpha}(z) \sim 1/z \) for large \( |z| \) [see Eqs. (1) and (5)] ensures that the diagonal element of the single-particle Green’s function is in the following form:

\[ G_{\alpha\alpha}(z) = \frac{\prod_{l=1}^{Z_{\alpha\alpha}} (z - \omega_{l\alpha})}{\prod_{m=1}^{P_{\alpha\alpha}} (z - \omega_{m\alpha})} \]  

**II. SINGLE-PARTICLE GREEN’S FUNCTION**

In this section, we shall derive useful analytical properties of the single-particle Green’s function at finite temperatures. As shown in Sec. III, the finite-temperature formulation introduced here significantly simplifies the analysis without encountering any ambiguity in treating the singularities of the single-particle Green’s function at the chemical potential, which is often overlooked in the zero-temperature formulation.

### A. Notation

First, we introduce the notation for the single-particle Green’s function used here. We set \( \hbar = k_B = 1 \) and refer to \( z(\omega) \) as complex (real) frequency. Following the notation
with

\[ P_{zz} - Z_{zz} = 1, \]  

(7)

where \( \zeta^{(a)}_m \) is a real frequency (with \( \omega^{(a)}_1 < \zeta^{(a)}_2 < \cdots < \omega^{(a)}_m \)) at which \( G^{(a)}(\omega^{(a)}_m) = 0 \), \( \omega^{(a)}_m \in \{ \omega_1, \omega_2, \cdots, \omega_{N_z} \} \) with \( \omega^{(a)}_1 < \omega^{(a)}_2 < \cdots < \omega^{(a)}_m \), and \( Z_{zz}(P_{zz}) \) is the number of zeros (poles) of \( G_{zz}(z) \) [25]. Here, \( P_{zz} \) is counted only when the corresponding spectral weight is non-zero, i.e., \(|Q_{zz}| > 0 \). Thus, \( P_{zz} \) can be smaller than \( N_{ex} \).

Typical frequency dependence of \( G_{zz}(\omega) \) is shown in Fig. 1. The analytical properties of \( G_{zz}(\omega) \) is understood as follows. Since

\[ G(z)^\dagger = Q g(z)^\dagger Q^\dagger = G(z), \]  

(8)

\( G(\omega) \) is Hermitian and thus \( G_{zz}(\omega) \) is real for real frequency \( \omega \). In the vicinity of a pole at \( \omega^{(a)}_m \), \( G_{zz}(\omega) \) is positive (negative) on the right (left) side of \( \omega^{(a)}_m \) because

\[ G_{zz}(\omega \approx \omega^{(a)}_m) = \frac{|Q_{zz}|^2}{\omega - \omega^{(a)}_m} \]  

(9)

with the positive spectral weight, i.e., \(|Q_{zz}|^2 > 0 \). On the other hand, its derivative

\[ \frac{\partial G_{zz}(\omega)}{\partial \omega} = - \sum_{m=1}^{P_{zz}} \frac{|Q_{zz}|^2}{(\omega - \omega^{(a)}_m)^2} \]  

(10)

is always negative for \( \omega \neq \omega^{(a)}_m \), indicating that \( G_{zz}(\omega) \) is a decreasing function of \( \omega(\neq \omega^{(a)}_m) \). This immediately concludes that there must exist only a single frequency at which \( G_{zz}(\omega) = 0 \) between two distinct successive real frequencies where \( G_{zz}(\omega) \) exhibits poles, i.e.,

\[ \omega^{(a)}_1 < \zeta^{(a)}_1 < \omega^{(a)}_2 < \cdots < \zeta^{(a)}_m < \omega^{(a)}_m, \]  

(11)

with

\[ \begin{cases} G_{zz}(\omega) > 0, & \text{for } \omega^{(a)}_m < \omega < \zeta^{(a)}_m \\ G_{zz}(\omega) = 0, & \text{for } \omega = \zeta^{(a)}_m \\ G_{zz}(\omega) < 0, & \text{for } \zeta^{(a)}_m < \omega < \omega^{(a)}_{m+1} \end{cases} \]  

(12)

as shown in Fig. 1.

C. Determinant of single-particle Green’s function

Let us now examine analytical properties of the determinant of the single-particle Green’s function, already analyzed to a certain extent in Refs. [5], [24] and [26]. Here, we shall show that the determinant of the single-particle Green’s function can be expressed as a simple rational polynomial function as in Eq. (23) with the numbers of zeros and poles satisfying Eq. (26) (see also Appendix A of Ref. [23]).

From the Cauchy-Binet theorem, the determinant of the single-particle Green’s function

\[ \det G(z) = \det [Q g(z) Q^\dagger] \]  

(13)

is identically zero if \( N_{ex} < L_z \). However, generally \( N_{ex} \geq L_z \) and thus we can safely assume that \( \det G(z) \) is not identically zero. From Eqs. (4) and (5), the asymptotic behavior of the determinant for large \( |z| \) is \( \det G(z) \sim (1/|z|)^L_z \). This already suggests that \( \det G(z) \) has a form shown in Eqs. (23) and (26). In the following, we shall show that zeros of \( \det G(z) \) are all on the real-frequency axis.

Let us first triangularize \( G(z) \) by a unitary transformation (Schur decomposition),

\[ R(z) = U(z) G(z) U(z)^\dagger, \]  

(14)

where \( R(z) \) is an upper triangle matrix and \( U(z) \) is a unitary matrix. From Eq. (3), \( R(z) \) can be written as

\[ R(z) = \tilde{Q}(z) g(z) \tilde{Q}(z)^\dagger, \]  

(15)

where \( \tilde{Q}(z) = U(z) Q \) is an \( L_z \times N_{ex} \) matrix with its matrix element

\[ \tilde{Q}_{am}(z) = \sqrt{\Omega^{(a)} - E_c} \sqrt{\Omega^{(a)} - E_c} \langle r | \tilde{c}_a(z) | s \rangle \]  

(16)

and \( \tilde{c}_a(z) = \sum_{\beta=1}^{L_z} U_{a\beta}(z) c_\beta \). It is apparent from Eq. (5) and the unitarity of \( U(z) \) that \( \tilde{Q}(z) \) fulfills the sum rule

\[ \tilde{Q}(z) \tilde{Q}(z)^\dagger = I \]  

(17)

as \( [\tilde{c}_a(z), \tilde{c}_\beta(z)] = \delta_{a\beta} \).

The diagonal element of \( R(z) \) is now given as

\[ R_{zz}(z) = \sum_{m=1}^{N_z} \frac{|\tilde{Q}_{am}(z)|^2}{z - \omega_{m}}. \]  

(18)

Since the sum rule \( \sum_{m=1}^{N_z} |\tilde{Q}_{am}(z)|^2 = 1 \) must hold for arbitrary \( z \), \( \tilde{Q}_{am}(z) \) is bounded in the entire complex \( z \) plane, and thus it must be constant, i.e.,

\[ \tilde{Q}_{am}(z) = \tilde{Q}_{am}. \]  

(19)
known as Liouville’s theorem [27]. Therefore, \( R_{oa}(z) \) has the same analytical properties as \( G_{oa}(z) \) and it is written as

\[
R_{oa}(z) = \frac{\prod_{l=1}^{L_a} (z - \tilde{\zeta}^{(a)}_l)}{\prod_{m=1}^{L_a} (z - \tilde{\omega}^{(a)}_m)}
\]  

(20)

with

\[
\tilde{P}_{oa} - \tilde{Z}_{oa} = 1,
\]

(21)

where \( \tilde{\zeta}^{(a)}_1 < \tilde{\zeta}^{(a)}_2 < \cdots < \tilde{\zeta}^{(a)}_{L_a} \) is a real frequency at which \( R_{oa}(z^{(a)}_\zeta) = 0 \), and \( \tilde{\omega}^{(a)}_m = \{\omega_1, \omega_2, \cdots, \omega_{N_a}\} \) with \( \omega_1 < \omega_2 < \cdots < \omega_{P_{oa}} \). \( \tilde{P}_{oa} \) is the number of zeros (poles) of \( R_{oa}(z) \) [25] and \( \tilde{Z}_{oa} \) is counted only when the corresponding spectral weight is non-zero, i.e., \(|\tilde{Q}_{am}| > 0\). Similarly to Eq. (11), we can also show that

\[
\tilde{\omega}^{(a)}_1 < \tilde{\zeta}^{(a)}_1 < \tilde{\omega}^{(a)}_2 < \tilde{\zeta}^{(a)}_2 < \cdots < \tilde{\zeta}^{(a)}_{L_a} < \tilde{\omega}^{(a)}_{P_{oa}}.
\]

(22)

Since \( \det G(z) = \det R(z) \), \( \det G(z) \) is now readily evaluated as

\[
\det G(z) = \prod_{a=1}^{L_a} \left[ \frac{\prod_{l=1}^{L_a} (z - \tilde{\zeta}^{(a)}_l)}{\prod_{m=1}^{L_a} (z - \tilde{\omega}^{(a)}_m)} \right] = \frac{\prod_{l=1}^{L_a} (z - \tilde{\xi}_l)}{\prod_{m=1}^{L_a} (z - \tilde{\omega}_m)}
\]

(23)

with

\[
\tilde{\xi}_l \in \{\tilde{\zeta}^{(a)}_l | a = 1, 2, \ldots, L_a; l = 1, 2, \ldots, \tilde{Z}_{oa}\}
\]

(24)

and

\[
\tilde{\omega}_m \in \{\tilde{\omega}^{(a)}_m | a = 1, 2, \ldots, L_a; m' = 1, 2, \ldots, \tilde{P}_{oa}\},
\]

(25)

where \( Z_{\det} = \sum_{a=1}^{L_a} Z_{oa} \) is the number of zeros of \( \det G(z) \) and \( P_{\det} = \sum_{a=1}^{L_a} \tilde{P}_{oa} \) is the number of poles of \( \det G(z) \). Here, each zero (pole) is counted in \( Z_{\det} \) (\( P_{\det} \)) as many times as its order and thus some of \( \tilde{\xi}_l \) (\( \tilde{\omega}_m \)) in Eq. (24) (Eq. (25)) might be the same. We can now readily show that

\[
P_{\det} - Z_{\det} = L_a.
\]

(26)

It is apparent above that zeros of \( \det G(z) \) are all on the real-frequency axis. Note however that generally there is no relation similar to Eq. (11) (i.e., only one zero between the two successive poles) for zeros and poles of \( \det G(z) \) in Eq. (23). Note also that in \( \det G(z) \) is analytical as long as \( z \) is away from the real-frequency axis because \( \tilde{\xi}_l \) and \( \tilde{\omega}_m \) are both real.

### D. Particle number

Using \( G(z) \), the average particle number \( N \) is evaluated as

\[
N = \sum_{r=-\infty}^{\infty} e^{i\omega_r \nu} \text{tr}[G(i\omega_r)],
\]

(27)

where \( i\omega_r = (2\nu + 1)i\pi T \) with integer \( \nu \) is the fermionic Matsubara frequency [28, 29] and \( 0^+ \) represents infinitesimally small positive real number. The frequency sum in Eq. (27) can be converted to the contour integral,

\[
N = \int_{\Gamma} \frac{dz}{2\pi i} n_f(z) \text{tr}[G(z)]= \sum_{a=1}^{L_a} \sum_{m=1}^{N_a} n_f(\omega_m)|\tilde{Q}_{am}|^2,
\]

(28)

where

\[
n_f(z) = \frac{1}{e^{z/T} + 1}
\]

(29)

is the Fermi-Dirac distribution function and contour \( \Gamma \) encloses the singularities of \( \text{tr}[G(z)] \), not the ones of \( n_f(z) \), in the counter-clockwise direction, as shown in Fig. 2(a).

### III. GENERALIZED LUTTINGER THEOREM

Based on the finite-temperature formulation, we shall now show that (i) the Luttinger volume can be represented as the winding number of the determinant of the single-particle Green’s function in the zero-temperature limit, (ii) the winding number of a ratio between the determinants of the interacting and noninteracting single-particle Green’s functions provides the topological interpretation of the generalized Luttinger theorem, (iii) the topological interpretation can naturally separates two qualitatively different types (types I and

![Fig. 2](image_url)
By substituting this identity in Eq. (28), we can readily show that the single-particle Green’s function $G(z)$ is diagonalized with respect to the particle density. As shown in Appendix A, Eq. (33) can also be derived directly from the derivative of the grand potential $\Omega$ with respect to the chemical potential $\mu$, (see also Ref. [2]).

There are three remarks in order. First, the Luttinger volume $V_L$ in the zero-temperature limit is identical with the volume enclosed by the Fermi surface in metallic systems as originally proposed by Luttinger [1], and the volume enclosed by the Luttinger surface in single-particle gapful systems, as generalized by Dzyaloshinskii [5] (examples for this remark will be given in Sec. IV). Second, the Luttinger volume $V_L$ is an extensive quantity. For example, if the single-particle Green’s function $G(z)$ is diagonalized with respect to a single-particle index $\alpha$ (e.g., band index and momentum), i.e., $G(z) = \delta_{\alpha \alpha} G_{\alpha \alpha}(z)$, then the Luttinger volume is given as

$$V_L = \sum_{\alpha} V_{L,\alpha},$$

where

$$V_{L,\alpha} = \int \frac{dz}{2\pi i} n_{\alpha}(z) \frac{\partial \ln \det G_{\alpha \alpha}^{-1}(z)}{\partial z}$$

is the Luttinger volume labeled with $\alpha$. Therefore, the Luttinger volume $V_L$ defined here is apparently an extensive quantity with respect to the single-particle index $\alpha$. Third, in the noninteracting limit, $V_L = N$ simply because the self-energy $\Sigma(z) = 0$.

From Eq. (23) and the Cauchy’s integral theorem (or the argument principle) [27], we can now show that

$$V_L = \sum_{m=1}^{P_{\text{ex}}} n_{\alpha}(\tilde{\omega}_m) - \sum_{j=1}^{Z_{\text{ex}}} n_{\alpha}(\tilde{\zeta}_j),$$

where $\tilde{\zeta}_j$ and $\tilde{\omega}_m$ are zeros and poles of the determinant of the single-particle Green’s function given in Eqs. (24) and (25), respectively. Note that $V_L$ is a well-defined quantity and is unambiguously evaluated even for insulating states at zero temperature. This is simply because the chemical potential is always uniquely determined in the zero-temperature limit even when it is located in a single-particle gap. It should also be noticed in Eq. (37) that, in the zero-temperature limit, each pole (zero) exactly at the chemical potential contributes a factor of $1/2$ (−1/2) to the Luttinger volume $V_L$ since $n_{\alpha}(0) = 1/2$. This implies that the Luttinger volume can be fractionalized when the zero-energy singularities exist in the determinant of the single-particle Green’s function.

The generalized Luttinger theorem states that

$$\lim_{T \to 0} N = \lim_{T \to 0} V_L,$$

or more explicitly, by equating Eqs. (28) and (37),

$$\sum_{\alpha=1}^{N_{\text{ex}}} \sum_{m=1}^{P_{\text{ex}}} n_{\alpha}(\tilde{\omega}_m) |Q_{\alpha m}|^2 = \sum_{m=1}^{P_{\text{ex}}} n_{\alpha}(\tilde{\omega}_m) - \sum_{j=1}^{Z_{\text{ex}}} n_{\alpha}(\tilde{\zeta}_j),$$

and taking the zero-temperature limit. It is now obvious in Eq. (39) that the generalized Luttinger theorem is represented with the number of zeros and poles of the determinant of the single-particle Green’s function.

We should note that an equation similar to Eq. (39) has been reported by Ortloff et al. [8] for single-band systems directly using the zero-temperature formulation where the Heaviside step function $\Theta(\omega)$ appears, instead of the Fermi-Dirac distribution function $n_F(\omega)$. However, in their zero-temperature formulation, the value of the Heaviside step function at zero energy, $\Theta(0)$, is not specified [8, 14]. Our finite-temperature formulation described here clarifies that the Heaviside step function at zero energy in the zero-temperature formulation should be regarded as $\Theta(0) = n_F(0) = 1/2$. The ambiguity in treating poles and zeros of the single-particle Green’s function (or the determinant of the single-particle Green’s function) at the chemical potential is therefore clearly resolved in the finite-temperature formulation.

B. Luttinger volume and winding number of $\det G(z)$

Here we shall show that, in the zero-temperature limit, the Luttinger volume $V_L$ defined in Eq. (34) is represented exactly as the winding number of the determinant of the single-particle Green’s function. Since the Fermi-Dirac distribution
function \( n_F(\omega) \) in the zero-temperature limit takes three values depending on \( \omega \), i.e.,

\[
\lim_{T \to 0} n_F(\omega) = \begin{cases} 
0 & \text{for } \omega > 0 \\
\frac{1}{2} & \text{for } \omega = 0 \\
1 & \text{for } \omega < 0
\end{cases}, \tag{40}
\]

we divide contour \( \Gamma \) into three pieces, \( \Gamma_\langle, \Gamma_0, \text{and } \Gamma_\rangle \), as shown in Fig. 2(b), where contour \( \Gamma_\langle \text{ and } \Gamma_\rangle \) encloses the negative (positive) real axis and contour \( \Gamma_0 \) encloses the origin.

Accordingly, the Luttinger volume can be divided into three parts,

\[
V_L = \left( \oint_{\Gamma_\langle} + \oint_{\Gamma_0} + \oint_{\Gamma_\rangle} \right) \frac{dz}{2\pi i} n_F(z) \frac{\partial \ln \det G(z)^{-1}}{\partial z}. \tag{41}
\]

In the zero-temperature limit, the integral along contour \( \Gamma_\rangle \) vanishes because \( n_F(\omega) = 0 \) for \( \omega > 0 \). Thus, we find that

\[
\lim_{T \to 0} V_L = n_{\det G^{-1}}(\Gamma_\langle) + \frac{1}{2} n_{\det G^{-1}}(\Gamma_0) \tag{42}
\]

where

\[
n_{\det G^{-1}}(C) = \oint_C \frac{dz}{2\pi i} \frac{\partial \ln \det G(z)^{-1}}{\partial z} = \oint_{\det G^{-1}(C)} \frac{d(\det G^{-1})}{2\pi i} \frac{1}{\det G^{-1}}. \tag{43}
\]

Here \( \det G^{-1}(C) \) represents the contour in complex \( \det G^{-1} \) plane which is parametrized by \( z \in C = \Gamma_\langle \text{ and } \Gamma_0 \). Therefore, \( n_{\det G^{-1}}(C) \) is the winding number of \( \det G^{-1} \) around the origin of the complex \( \det G^{-1} \) plane (see Fig. 3) and thus it is necessarily integer. Notice also that

\[
n_{\det G^{-1}}(\Gamma_\langle) = -n_{\det G}(\Gamma_\langle) \tag{44}
\]

by definition.

We should also emphasize here that \( n_{\det G^{-1}}(\Gamma_\langle), n_{\det G^{-1}}(\Gamma_0), \) and \( n_{\det G^{-1}}(\Gamma_\rangle) \) are given simply by counting the number of poles and zeros of the determinant of the single-particle Green’s function below, exactly at, and above the chemical potential, i.e.,

\[
n_{\det G^{-1}}(\Gamma_\langle) = \sum_{m=1}^{p_{\text{ax}}} \Theta_\langle(\bar{\omega}_m) - \sum_{l=1}^{Z_{\text{ax}}} \Theta_\langle(-\bar{\zeta}_l), \tag{45}
\]

\[
n_{\det G^{-1}}(\Gamma_0) = \sum_{m=1}^{p_{\text{ax}}} \delta_{\bar{\omega}_m, 0} - \sum_{l=1}^{Z_{\text{ax}}} \delta_{\bar{\zeta}_l, 0}, \tag{46}
\]

and

\[
n_{\det G^{-1}}(\Gamma_\rangle) = \sum_{m=1}^{p_{\text{ax}}} \Theta_\rangle(\bar{\omega}_m) - \sum_{l=1}^{Z_{\text{ax}}} \Theta_\rangle(-\bar{\zeta}_l) \tag{47}
\]

respectively. Here \( \Theta_\langle(\omega) \) is the Heaviside step function defined as

\[
\Theta_\langle(\omega) = \begin{cases} 
1 & (\omega > 0) \\
c & (\omega = 0) \\
0 & (\omega < 0)
\end{cases}, \tag{48}
\]

and \( \delta_{\alpha, \beta} \) is the Kronecker delta, which is 1 only when \( \alpha = \beta \) and zero otherwise.

C. Topological interpretation of the generalized Luttinger theorem

We shall now examine the condition under which the generalized Luttinger theorem is valid. For this purpose, we analyze the deviation of the Luttinger volume from the noninteracting limit, which can be represented as the winding number of the ratio \( D(z) \) between the determinants of the interacting and noninteracting single-particle Green’s functions defined in Eq. (52).

The Luttinger volume \( V_L \) for the noninteracting system is \( N \). This can be shown directly by comparing Eq. (28) and the definition of \( V_L \) given in Eq. (34).

\[
V_L^0 = \oint_{\Gamma} \frac{dz}{2\pi i} n_F(z) \frac{\partial \ln \det G_0(z)^{-1}}{\partial z} = N, \tag{49}
\]

because

\[
\frac{\partial \ln \det G_0(z)^{-1}}{\partial z} = \text{tr} \left[ G_0(z) \right] \tag{50}
\]

when \( \Sigma(z) = 0 \) in Eq. (31). Therefore, the deviation \( \Delta V_L \) of the Luttinger volume from the noninteracting limit is the second term of the right-hand side in Eq. (33), i.e.,

\[
\Delta V_L = V_L - V_L^0 = -\oint_{\Gamma} \frac{dz}{2\pi i} n_F(z) \text{tr} \left[ G(z) \frac{\partial \Sigma(z)}{\partial z} \right]. \tag{51}
\]

By introducing the ratio between the determinants of the interacting and noninteracting single-particle Green’s functions

\[
D(z) = \frac{\det G_0(z)}{\det G(z)} = \det[I - G_0(z)\Sigma(z)] \tag{52}
\]

directly in Eqs. (34) and (49), we can show that

\[
\Delta V_L = \oint_{\Gamma} \frac{dz}{2\pi i} n_F(z) \frac{\partial \ln D(z)}{\partial z}, \tag{53}
\]
the deviation of the Luttinger volume from the noninteracting
\[ n_i = \frac{\text{det} G_0(z)}{\text{det} G(z)} \]
where contour \( \Gamma \) is defined in Fig. 2(a).

We first notice that, in the zero-temperature limit, contour \( \Gamma \) for the integral of Eq. (53) in complex \( z \) plane is reduced to contours \( \Gamma_c \) and \( \Gamma_0 \) (see Fig. 2) because \( n_{\text{tr}}(\omega) = 0 \) for \( \omega > 0 \), as discussed in Sec. III B. Therefore, at zero temperature, the deviation of the Luttinger volume from the noninteracting one, \( \Delta V_L \), given in Eq. (53) corresponds exactly to the winding number \( n_{D}(C) \) of \( D(z) \) around the origin of complex \( D \) plane, i.e.,

\[
\lim_{\tau \to 0} \Delta V_L = n_{D}(\Gamma_c) + \frac{1}{2} n_{D}(\Gamma_0) \tag{54}
\]

and \( D(C) \) represents the contour in complex \( D \) plane, which is parametrized by \( z \in C = \Gamma_c \text{ and } \Gamma_0 \) (see Fig. 4). It should be emphasized that the quantity \( n_{D}(C) \) evaluated in Eq. (55) must be integer as it is the winding number. Since the Fredholm-type determinant \( D(z) \) can be defined for infinite dimensional matrices, Eq. (55) is valid even in the thermodynamic limit. It should be also noticed that from the definition of \( D(z) \) in Eq. (52)

\[
n_{D}(C) = n_{\text{det} G^{-1}(C)} - n_{\text{det} G_{0}^{-1}(C)}
\]

where \( n_{\text{det} G^{-1}(C)} \) is defined in Eq. (43).

It is now apparent in Eq. (54) that there exists two cases where the generalized Luttinger theorem is valid. The first case (type I) is when \( n_{D}(\Gamma_c) \) and \( n_{D}(\Gamma_0) \) are both zero, i.e.,

\[
n_{D}(\Gamma_c) = n_{D}(\Gamma_0) = 0. \tag{57}
\]

Figure 4 schematically shows contour \( D(C) \) in complex \( D \) plane and explains the relation between the winding number \( n_{D}(C) \) and the generalized Luttinger theorem. Applying the weak version of Rouche’s theorem [27] to Eq. (55), we find that

\[
|D(z) - 1| < 1 \tag{58}
\]

for \( z \in \Gamma_c \) and \( \Gamma_0 \) is a sufficient condition for \( V_L = V_L^0 \) (see Fig. 4). Considering the fact that \( D(z) = 1 \) in the noninteracting limit, the inequality (58) represents the robustness of the theorem against the perturbation of fermion interactions. In fact, the generic inequality (58) can reproduce a particular condition which ensures the convergence of the perturbation expansion of the self-energy for a spin-density-wave state reported in Ref. [30].

Another case (type II) which ensures the validity of the generalized Luttinger theorem is when neither \( n_{D}(\Gamma_0) \) nor \( n_{D}(\Gamma_c) \) is zero but they cancel each other, i.e.,

\[
n_{D}(\Gamma_0) = -2n_{D}(\Gamma_c) \neq 0. \tag{59}
\]

The condition \( n_{D}(\Gamma_0) \neq 0 \) or, equivalently,

\[
n_{\text{det} G^{-1}}(\Gamma_0) \neq n_{\text{det} G^{-1}(\Gamma_0)} \tag{60}
\]

implies that the number of singularities of the determinant of the single-particle Green’s function at the chemical potential is altered by introducing interactions. This happens, for example, if the whole Fermi surface (or a portion of the Fermi surface) is gapped out by introducing interactions. Nevertheless, as long as Eq. (59) is satisfied, the generalized Luttinger theorem is guaranteed to be valid.

D. Validity of the generalized Luttinger theorem for particle-hole symmetric systems

Based on the analytical properties of the single-particle Green’s function derived above, we shall now prove rigorously that the generalized Luttinger theorem is valid for generic interacting fermions as long as the particle-hole symmetry is preserved. For this purpose, it is important to recall that when the particle-hole symmetry is preserved, the Hamiltonian is invariant under a transformation, for example, \( c_\alpha \to c_\beta^\dagger \). It then follows that \( G_{\beta \alpha}(z) = -G_{\beta \alpha}(-z) \) and thus \( \det G(z) = (-1)^l_0 \det G(-z) \), where \( L_0 \) is the dimension of \( G(z) \). Therefore, \( \det G(z) = 0 \) when \( \det G(z) = 0 \). Similarly, it can be shown that \( \det G(-z)^{-1} = 0 \) when \( \det G(z)^{-1} = 0 \).

Thus, for particle-hole symmetric systems, (i) there exist a pair of states \( m = (r, s) \) and \( \bar{m} = (\bar{r}, \bar{s}) \) with excitation energies \( \omega_m \) and \( \omega_{\bar{m}} \), respectively, distributed symmetrically with respect to zero energy, i.e., \( \omega_{\bar{m}} = -\omega_m \), at which \( \det G(z) \) has poles, and similarly (ii) zeros of \( \det G(\omega) \) appear symmetrically with respect to zero energy at \( \xi_l \) and \( \xi_{\bar{l}} \) where \( \xi_l = -\xi_{\bar{l}} \).
Note also that, for particle-hole symmetric systems, the chemical potential is exactly zero, independently of the temperature [31]. Using these properties as well as the identity for the Fermi-Dirac distribution function
\[ n_F(\omega) + n_F(\omega) = 1 \] in Eq. (37), we can readily evaluate the Luttinger volume
\[ V_L = \frac{1}{2} \left( P_{\text{det}} - Z_{\text{det}} \right) = \frac{L_s}{2}. \]
Here Eq. (26) is used in the second equality [32]. Apparently, \[ \Delta \] and \[ N \] are generally given as poles and zeros of \[ G_k(z) \] in Eq. (37), we can readily evaluate the Luttinger volume
\[ V_L = \frac{1}{2} \left( P_{\text{det}} - Z_{\text{det}} \right) = \frac{L_s}{2}. \]
Here Eq. (26) is used in the second equality [32]. Apparently, in the noninteracting limit, \[ V_L^0 = N \], as shown in Eq. (49), and \[ N = L_s/2 \] for the particle-hole symmetric case. Therefore, \[ \Delta V = 0 \], completing the proof that the generalized Luttinger theorem is valid for generic interacting fermions with the particle-hole symmetry. Notice that Eq. (62) is satisfied for all temperatures, including zero temperature.

Finally, we should note that the generalized Luttinger theorem is satisfied with the condition of either type I or type II is satisfied when either condition of type I or type II is satisfied.

IV. EXAMPLES FOR SINGLE-BAND INTERACTING ELECTRONS WITH TRANSLATIONAL SYMMETRY

In this section, we first summarize the analytical properties of the single-particle Green’s function for a single-band, paramagnetic, and translationally symmetric system. We then explore the generalized Luttinger theorem of types I and II by examining a simple metal and a one-dimensional Mott insulator. As an example of multi-orbital systems with translational symmetry, the Hubbard model on the honeycomb lattice is examined within the Hubbard-I approximation in Appendix B.

A. Summary of analytical properties

When a system is paramagnetic and translationally symmetric, the single-particle Green’s function \( G_k(z) \) is diagonal with its elements \( G_k(z) \) for each momentum \( k \) and therefore
\[ \det G(z) = \left[ \prod_k G_k(z) \right]^2, \]
where an exponent 2 is due to the spin degeneracy. Applying the argument in Sec. II B, the single-particle Green’s function \( G_k(z) \) for momentum \( k \) with spin \( \sigma \) is generally given as
\[ G_k(z) = \prod_{l=1}^{Z_k} \frac{(z - \zeta_l^{(k)})}{(z - \zeta_l^{(k)})}, \]
where real frequencies \( \zeta_l^{(k)} \) (\( l = 1, 2, \ldots, Z_k \)) and \( \omega_m^{(k)} \) (\( m = 1, 2, \ldots, P_k \)) are poles and zeros of \( G_k(\omega) \) for momentum \( k \), respectively, with
\[ \omega_1^{(k)} < \zeta_1^{(k)} < \omega_2^{(k)} < \zeta_2^{(k)} < \cdots < \zeta_{Z_k}^{(k)} < \omega_{P_k}^{(k)} \]
and
\[ P_k - Z_k = 1. \]
This is a simple example of Eqs. (6) and (7) for the single band system. The number \( P_{\text{det}} \) of poles and the number \( Z_{\text{det}} \) of zeros in \( \det G(z) \) is \( P_{\text{det}} = 2 \sum_k P_k \) and \( Z_{\text{det}} = 2 \sum_k Z_k \), respectively, and hence \( P_{\text{det}} - Z_{\text{det}} = 2 \sum_k 1 \), which corresponds to Eq. (26).

Therefore, for example, Eq. (43) is now simply given as
\[ n_{\text{det}G^{-1}(C)} = 2 \sum_k n_{G_k^{-1}(C)} \]
and the Luttinger volume in Eq. (42) is
\[ \lim_{\rho \to 0} V_L = 2 \sum_k \left[ n_{G_k^{-1}(\Gamma_c)} + \frac{1}{2} n_{G_k^{-1}(\Gamma_0)} \right], \]
where the factor 2 is due to the spin degeneracy. We have also introduced that
\[ n_{G_k^{-1}(C)} = \int_C \frac{dz}{2\pi i} \frac{\partial \ln G_k^{-1}(z)}{\partial z} = \oint_{G_k^{-1}(C)} \frac{1}{2\pi i} G_k^{-1}, \]
where \( G_k^{-1}(C) \) represents the contour in complex \( G_k^{-1} \) plane parametrized by \( z \in C \). Thus, \( n_{G_k^{-1}(C)} \) is the winding number of \( G_k^{-1} \) around the origin of the complex \( G_k^{-1} \) plane (for example, see Fig. 3) and it must be integer. Notice also that \( n_{G_k^{-1}(\Gamma_0)} = \frac{Z_k}{2} \) by definition. As shown in Eqs. (45)–(47), \( n_{G_k^{-1}(\Gamma_0)} \) can also be given by counting the number of poles and zero of the single-particle Green’s function \( G_k(z) \), i.e.,
\[ n_{G_k^{-1}(\Gamma_0)} = \sum_{m=1}^{P_k} \Theta_0(\omega_m^{(k)}) - \sum_{l=1}^{Z_k} \Theta_0(-\zeta_l^{(k)}), \]
and
\[ n_{G_k^{-1}(\Gamma_0)} = \sum_{m=1}^{P_k} \delta_{\omega_m^{(k)}}, \]
where \( \Theta_0(\omega_m^{(k)}) \) is the noninteracting limit and \( \Sigma_k(z) \) is the self-energy, the Fredholm-type determinant of the single-particle Green’s function in Eq. (52) is now simply
\[ D(z) = \left[ \prod_k D_k(z) \right]^2. \]
including the spin degree of freedom. Therefore, the deviation of the Luttinger volume from the noninteracting one in the zero-temperature limit is

$$\lim_{\tau \to 0} \Delta V_L = 2 \sum_k \left[ n_{D_k}(\Gamma_c) + \frac{1}{2} n_{D_k}(\Gamma_0) \right],$$

where

$$n_{D_k}(C) = \oint_C \frac{d\zeta}{2\pi i} \frac{\partial}{\partial \zeta} \ln D_k(z) = \oint_{D_k(C)} \frac{dD_k}{2\pi i} \frac{1}{D_k}$$

and $D_k(C)$ represents the contour of $D_k(z)$, parametrized by $z \in C(= \Gamma_c$ and $\Gamma_0)$, in the complex $D_k$ plane. Thus, $n_D(C)$ in Eq. (55) is now simply

$$n_D(C) = 2 \sum_k n_{D_k}(C).$$

Notice also that by comparing Eqs. (69) and (76),

$$n_{D_k}(C) = n_{G_k^1}(C) - n_{G_k}(C).$$

### B. Type I: Simple metal

Let us first consider the noninteracting limit. The single-particle Green’s function $G_{0k}(z)$ in the noninteracting limit is given as $G_{0k}(z) = 1/(z - \omega(k))$, where $\omega(k) = \varepsilon_k$ and $\varepsilon_k$ is the single-particle energy dispersion in the noninteracting limit. Therefore, we find that $n_{G_k}(\Gamma_c) = 0$ for $k$ inside the Fermi surface, $n_{G_k}(\Gamma_0) = 1$ for $k$ on the Fermi surface, and $n_{G_k}(\Gamma_0) = 0$ for $k$ in the noninteracting limit. Thus, $n_{G_k}(\Gamma_0)$ gives the number of occupied (unoccupied) single-particle states inside (outside) the Fermi surface, and a set of momenta where $n_{G_k}(\Gamma_0) = 1$ forms the Fermi surface and the number of these $k$ points corresponds to the area of the Fermi surface. The analytical properties of $G_{0k}(z)$, including the sign of $G_{0k}(0)$, are summarized in Table I.

Once the interactions are considered, $G_k(\omega)$ can have many poles as well as many zeros for each momentum $k$. However, according to Eq. (66), the number of poles is larger than the number of zeros exactly by one and thus

$$n_{G_k^1}(\Gamma_c) + n_{G_k}(\Gamma_0) + n_{G_k^1}(\Gamma_0) = 1.$$
for a paramagnetic single-band system, where $\Theta_\Omega(\omega)$ is defined in Eq. (48). Equation. (84) clearly shows that the Luttinger volume, defined as the winding number of the single-particle Green’s function in Eq. (68), indeed corresponds to the momentum volume surrounded by the Fermi surface, as expected for a simple metal.

If we assume that the shape of the Fermi surface does not change with and without introducing electron interactions, then obviously the analysis given above shows that $n_D^0(\Gamma_\omega) = 0$ and $n_D^0(\Gamma_\theta) = 0$, thus satisfying the condition of type I for the Luttinger theorem in Eq. (57). However, in general, the condition of type I can be satisfied even if electron interactions alter the shape of the Fermi surface. Thus, we now simply assume that the type-I condition in Eq. (57) is satisfied. Then, it follows immediately that in the zero-temperature limit

$$N = 2 \sum_k \Theta_k \left( G_k^{-1}(0) \right).$$

This is the well known expression of the Luttinger theorem [1, 4], originally proved by the many-body perturbation theory in which the second-term of the right-hand side in Eq. (33) vanishes under the assumption that the self-energy is regular at the chemical potential and thus the perturbation expansion is converged [2] (see also Ref. [24]).

Let us now discuss how the condition in Eq. (57), obtained independently of the many-body perturbation theory, is related to Luttinger’s original statement [1]. The first condition $n_D(\Gamma_\omega) = 0$ in Eq. (57) implies that the number of $k$ points inside the Fermi surface remains the same with and without introducing electron interactions. This is exactly the original statement of the Luttinger theorem, “The interaction may deform the FS (Fermi surface), but it cannot change its volume” [1]. The second condition $n_D(\Gamma_\theta) = 0$ in Eq. (57) implies that the number of zero-energy quasiparticle excitation, i.e., the number of $k$ points on the Fermi surface, is unchanged by introducing electron interactions.

The implication of the second condition is seemingly stronger than the original statement of the Luttinger theorem. However, the essential point of the second condition is to prohibit the appearance of the zeros of the single-particle Green’s function, or equivalently the emergence of the poles of the self-energy, at the chemical potential by introducing electron interactions in order to ensure the convergence of the many-body perturbation theory. Therefore, the Luttinger theorem with the type-I condition in Eq. (57) falls into the original statement of the theorem by Luttinger [1].

We also note that, from Table II, it is plausible to regard the quantity in the parentheses of Eq. (68), i.e.,

$$n_k^{00} = n_{G_k^{-1}(\Gamma_\omega)} + \frac{1}{2} n_{G_k^{-1}(\Gamma_\theta)},$$

as the distribution function of quasiparticles labeled by momenta $k$ in the Fermi-liquid theory at zero temperature (see for example Eq. (1.1) of Ref. [35]). Thus, the winding number $n_{G_k^{-1}(C)}$ of the interacting single-particle Green’s function $G_k(z)$ embodies the concept of the quasiparticle distribution

### TABLE II. Analytical properties of the single-particle Green’s function $G_k(\omega)$ for a simple metal. FS stands for Fermi surface. $n_k^{00}$ is defined in Eq. (86).

| location of $k$ | inside FS | on FS | outside FS |
|-----------------|-----------|-------|------------|
| position of singularities | Eq. (82) | Eq. (81) | Eq. (83) |
| sign of $G_k(0)$ | $G_k^{-1}(0) > 0$ | $G_k^{-1}(0) = 0$ | $G_k^{-1}(0) < 0$ |
| $n_{G_k^{-1}(\Gamma_\omega)}$ | 1 | 0 | 0 |
| $n_{G_k^{-1}(\Gamma_\theta)}$ | 0 | 1 | 0 |
| $n_k^{00}$ | 0 | 0 | 1 |
| $n_k^{00}$ | 1 | 1/2 | 0 |
function (not the bare particle one). Therefore, the Luttinger volume in the zero temperature limit, $\lim_{T \to 0} V_L = 2 \sum h_0$, represents nothing but the number of quasiparticles. Recall now that in the Landau’s Fermi-liquid theory the number $N$ of particles is $a$ priori assumed to be equal to the number of quasiparticles at zero temperature [33, 35]. Hence, the argument here guarantees this fundamental assumption of the Landau’s Fermi-liquid theory if the Luttinger theorem is valid since the theorem equates $N$ with the Luttinger volume. In Appendix C, we generalize $n_0$ for finite (but still low) temperatures and discuss the physical meaning.

C. type II: Mott insulator

As an example of type II for the generalized Luttinger theorem with $n_{2p}(\Gamma_0) \neq 0$ in Eq. (59), let us consider a system where a metal-insulator transition is induced by introducing fermion interactions. In the noninteracting limit, there should exist zero-energy poles in $\det G_0$ at the Fermi energy since the system is metallic. However, once the interactions are introduced and the metal-insulator transition occurs, these zero-energy poles are moved away from the chemical potential and replaced with the zeros of $\det G(0)$ due to the appearance of poles in the self energy (for example, see Fig. 6). This immediately implies that $n_{2p}(\Gamma_0) \neq 0$ because $n_{\text{det} G_0}(\Gamma_0) > n_{\text{det} G_0}(\Gamma_0)$, and thus the case where the metal-insulator transition is induced by introducing fermion interactions should in general corresponds to type II for the generalized Luttinger theorem when the theorem is valid.

To demonstrate this, here we calculate the single-particle Green’s function of the one-dimensional single-band Hubbard model at half-filling by using the CPT [16, 17]. The Hamiltonian is described as

$$H = -t \sum_{\langle i,j \rangle, \sigma} (c_{i\sigma}^\dagger c_{j\sigma} + \text{H.c.}) + U \sum_i n_{i\uparrow} n_{i\downarrow} - \mu \sum_{i,\sigma} n_{i\sigma},$$

where the sum in the first term of the right-hand side, indicated by $\langle i,j \rangle$, runs over all pairs of nearest neighbor sites $i$ and $j$ with the hopping integral $-t$. The on-site interaction (chemical potential) is represented by $U (\mu)$ and $n_{i\sigma} = c_{i\sigma}^\dagger c_{i\sigma}$. We set $\mu = U/2$ at half-filling for which the particle-hole symmetry is preserved.

The CPT allows to approximately evaluate the single-particle Green’s function $G_k(z)$ at any momentum $k$ with arbitrary fine resolution from the numerically exact single-particle Green’s function of a small cluster [16, 17]. In the CPT, the infinitely large cluster on which $H$ is defined is divided into a set of identical clusters, each of which is described by the cluster Hamiltonian $H_c$, the same Hamiltonian $H$ in Eq. (87) but with open-boundary conditions, and the single-particle Green’s function for $H$ is approximated as

$$G_k(z) = \frac{1}{L_c} \sum_{i,j} e^{-ik(r_i-r_j)} \left[ G'_{0\sigma}^{-1}(z) - V_{kj} \right]^{-1},$$

where $L_c$ is the number of sites in the cluster and $r_i$ denotes the spatial location of site $i = 1, 2, \cdots, L_c$ in the cluster. $G_{0\sigma}(z)$ is the exact single-particle Green’s function of the cluster, i.e.,

$$\begin{align*}
\left[ G_{0\sigma}^{-1}(z) \right]_{ij} &= (0|c_{i\sigma}^\dagger [z - H_c + E_{0\sigma}^{-1}]^{-1} c_{j\sigma}|0) \\
&+ (0|c_{i\sigma}^\dagger [z + H_c - E_{0\sigma}^{-1}]^{-1} c_{j\sigma}|0).
\end{align*}$$

where $|0\rangle$ is the ground state of $H_c$ with the eigenvalue $E_{0\sigma}$. $[V_{kj}]_{ij}$ is the matrix element between sites $i$ and $j$ for the inter-cluster hopping term represented in momentum space.

We evaluate $G'_{0\sigma}(z)$ for a one-dimensional 12-site cluster, i.e., $L_c = 12$, with the Lanczos exact-diagonalization method [37, 38]. Note that the single-particle Green’s function $G_k(z)$ obtained by the CPT can be represented in the Lehmann representation [17, 18] and satisfies the spectral-weight sum rule in Eq. (5) with positive-definite spectral weight. Therefore, the CPT is an appropriate method to demonstrate the formalism derived in Sec. III.

To examine the analytical properties of the single-particle Green’s function $G_k(z)$, here we calculate the single-particle spectral function $A_k(\omega)$ defined in Eq. (80) and the imaginary part of the self-energy

$$S_k(\omega) = -\frac{1}{\pi} \text{Im} G_k(\omega + i\delta^+),$$

where $\Sigma_k(\omega) = z - 2t \cos k - G_k^{-1}(z)$. Since the singularities (i.e., poles and zeros) of the single-particle Green’s function $G_k(z)$ in complex $z$ plane occur only in the real frequency $\omega$ axis, these two quantities $A_k(\omega)$ and $S_k(\omega)$ can capture the structure of poles and zeros of $G_k(z)$: a divergence of $A_k(\omega)$ [$S_k(\omega)$] corresponds to a pole (zero) of $G_k(\omega + \delta^+)$ in the limit of $\delta^+ \to 0$. The CPT has been employed to study intensively the single-particle excitation spectra $A_k(\omega)$ of the one-dimensional Hubbard model [16], and therefore we shall focus only on the analytical properties of $G_k(\omega)$ in the following.

The results of $A_k(\omega)$ and $S_k(\omega)$ for $U = 0$ and $U/t = 6$ at zero temperature are shown in Figs. 6(a) and 6(b), respectively. Here, we set that $\delta^+ / t = 0.05$ and thus the diverging behavior of $A_k(\omega)$ and $S_k(\omega)$ is replaced by sharp peak structures. The value of $U/t = 6$ is chosen merely for better visibility of the spectra, although the one-dimensional Hubbard model at half-filling is insulating for any $U (> 0)$ [39], which can be correctly reproduced by the CPT [17].

For the noninteracting case, the Fermi points locate at $k = \pm \pi/2$ and the self-energy is zero by definition [see Fig. 6(a)]. On the other hand, for $U/t = 6$, $A_k(\omega)$ exhibits the single-particle excitation gap, as shown in Fig. 6(b). More interestingly, we find in Figs. 6(b) and 6(c) that a peak of $S_k(\omega)$ intersects the zero energy, i.e., $\omega = 0$, exactly at $k = \pm \pi/2$. Since the peak of $S_k(\omega)$ corresponds to the zero of $G_k(\omega)$, the result indicates that $G_{k=\pm \pi/2}(0) = 0$. The momenta $k = \pi/2$ and $-\pi/2$ thereby form the Luttinger surface [5], which is defined as a set of momenta $k$ such that $G_k(0) = 0$. A typical behavior
of $A_k(\omega)$ and $G_k(\omega)$ on the Luttinger surface is schematically shown in Fig. 7(b).

Because of $G_k(0) = 0$ on the Luttinger surface by definition, the order of singularities in $G_k(\omega)$ for momentum $k$ on the Luttinger surface must be

$$\omega_1^{(k)} < \xi_1^{(k)} < \cdots < \omega_m^{(k)} < \xi_m^{(k)} = 0 < \omega_{m+1}^{(k)} < \cdots, \quad (92)$$

where $\xi_m^{(k)}$ is the $m_{LS}$-th zero of $G_k(\omega)$, i.e., $G_k(\omega = \xi_m^{(k)}) = 0$, and exactly zero [40]. Therefore, the number of poles $\{\omega_1^{(k)}, \omega_2^{(k)}, \ldots\}$ below (above) the chemical potential is larger than the number of zeros $\{\xi_1^{(k)}, \xi_2^{(k)}, \ldots\}$ below (above) the chemical potential by one. From Eqs. (70)–(72), we can now easily find that $n_{G_k}(\Gamma_\omega) = n_{G_k}(\Gamma_\omega) = 1$ and $n_{G_k}(\Gamma_\omega) = -1$, i.e., $n_{G_k}(\Gamma_\omega) = 1$ and $n_{G_k}(\Gamma_\omega) = -2$, where $n_{D_k}(C)$ is given in Eq. (78). Thus, this momentum contributes to the Luttinger volume $V_L$ by one, including the spin degree of freedom [see Eq. (68)].

FIG. 6. $A_k(\omega) = -\text{Im}G_k(\omega + i\delta^+)/\pi$ (blue solid lines) and $S_k(\omega) = -\text{Im}\Sigma_k(\omega + i\delta^+)/\pi$ (red dashed lines) of the one-dimensional single-band Hubbard model at half-filling for (a) $U = \mu = 0$, (b) $U = 2\mu = 6\delta$, and (c) same as (b) but only for $k = \pi/2$, $\delta^+/t = 0.05$ is set for all calculations. Note that different figures use different intensity scales. For visibility, $S_k(\omega)$ is divided by $(U/t)^2$ in (b) and (c). The results for $k = \pi/2$ in (a) and (b) are indicated by thick lines.

FIG. 7. Schematic figures of $A_k(\omega) = -\text{Im}G_k(\omega + i\delta^+)/\pi$ (blue shaded region) and $G_k(\omega)$ (red solid lines) with momentum $k$ (a) inside, (b) on, and (c) outside the Luttinger surface for a Mott insulator. Here $\omega = 0$ corresponds to the chemical potential in the zero-temperature limit. The poles of $G_k(\omega)$ are indicated by dots along with dashed vertical lines.
TABLE III. Analytical properties of the single-particle Green’s function $G_k(ω)$ for a Mott insulator. LS stands for Luttinger surface. $n^{(0)}_k$ is defined in Eq. (86).

| Location of $k$ | Inside LS | On LS | Outside LS |
|-----------------|-----------|-------|------------|
| Position of singularities | Eq. (93) | Eq. (92) | Eq. (94) |
| Sign of $G_k(0)$ | $G_k(0) > 0$ | $G_k(0) = 0$ | $G_k(0) < 0$ |
| $n_{G_k^{-1}(Γ_0)}$ | 1 | 1 | 0 |
| $n_{G_k^{-1}(Γ_0)}$ | 0 | -1 | 0 |
| $n_{G_k^{-1}(Γ_0)}$ | 0 | 1 | 1 |
| $n^{(0)}_k$ | 1 | 1/2 | 0 |

We also find in Fig. 6(b) that the topmost (bottommost) singularity below (above) the chemical potential for $|k| < π/2$ is a pole of $A_k(ω) [S_k(ω)]$, implying that

$$\omega_1^{(k)} < ζ_1^{(k)} < \cdots < ω^{(k)}_{n<_{LS}} < 0 < ζ^{(k)}_{n<_{LS}+1} < \cdots$$ (93)

and thus $G_k(0) > 0$ [see also Fig. 7(a)]. From Eqs. (70)–(72), we find that $n_{G^{-1}_k(Γ_0)} = 1$ and $n_{G^{-1}_k(Γ_0)} = n_{G^{-1}_k(Γ_0)} = 0$, which contributes two to the Luttinger volume $V_L$ in the zero-temperature limit, including the spin degree of freedom. It is also apparent that $n_{D_k(Γ_0)} = n_{D_k(Γ_0)} = 0$ for momentum below the Luttinger surface.

On the other hand, as shown in Fig. 6(b), the topmost (bottommost) singularity below (above) the chemical potential for $|k| > π/2$ is a pole of $S_k(ω) [A_k(ω)]$. This implies that

$$\omega_1^{(k)} < ζ_1^{(k)} < \cdots < ω^{(k)}_{n<_{LS}} < 0 < ζ^{(k)}_{n<_{LS}+1} < \cdots$$ (94)

and thus $G_k(0) < 0$ [see also Fig. 7(c)]. From Eqs. (70)–(72), we find that $n_{G^{-1}_k(Γ_0)} = n_{G^{-1}_k(Γ_0)} = 0$ and $n_{G^{-1}_k(Γ_0)} = 1$, which contributes zero to the Luttinger volume $V_L$ in the zero-temperature limit. These analytical properties of $G_k(ω)$ are summarized in Table III.

Counting the momentum volume surrounded by the Luttinger surface in Fig. 6, we can find that the Luttinger volume $V_L$ is exactly $N$, the number of total electrons, therefore satisfying the generalized Luttinger theorem. Indeed, as discussed above, we also find from zeros and poles of the single-particle Green’s function that the type II condition is fulfilled, i.e., $n_{D_k(Γ_0)} = -2n_{D_k(Γ_0)} \neq 0$, where $n_{D_k(Γ_0)}$ is given in Eq. (77). Since the system studied here is particle-hole symmetric, these results simply demonstrate the general statement in Sec. III D.

Finally, it is instructive to directly count how many times $G_k^{-1}(z)$ and $D_k(z)$ wind around the origin in the complex $G_k^{-1}$ and $D_k$ planes, respectively, when $z$ moves along contour $C$ shown in Fig. 2 (b). Recall that $n_{G^{-1}_k}(C)$ and $n_{D_k}(C)$ can be evaluated either by counting the number of zeros and poles of $G_k(z)$, as shown above, or by directly counting the winding numbers of $G_k^{-1}(z)$ and $D_k(z)$ [see Eq. (69) and (76)]. For this purpose, it should be noted that as long as the poles and zeros are properly included, contour $C (= Γ_0, Γ_0, and Γ_0)$ can be chosen rather freely. Therefore, as shown in Fig. 8, we consider the following contours

$$z = \begin{cases} 
 r_0 e^{iφ} & \text{for } Γ_0 \\
 r_ε e^{iφ} - a & \text{for } Γ_0 \\
 r_ε e^{iφ} + a & \text{for } Γ_0 
\end{cases}$$ (95)

parametrized by angle $φ (−π < φ ≤ π)$. Here, we set $r_0 = t$, $r_ε = r_ε = 2t$, and $a = 3t$.

Figure 9 summarizes the results for the trajectory of $G_k^{-1}(z)$ in the complex $G_k^{-1}$ plane at three representative momenta, i.e., below, and on, and above the Luttinger surface. Directly counting how many times and which direction the trajectory winds around the origin in the complex $G_k^{-1}$ plane, we find in Fig. 9 that i) $n_{G^{-1}_k}(Γ_0) = 1$ and $G_k^{-1}(Γ_0) = G_k^{-1}(Γ_0) = 0$ for $k$ below the Luttinger surface, ii) $n_{G^{-1}_k}(Γ_0) = G_k^{-1}(Γ_0) = 1$ and $G_k^{-1}(Γ_0) = −1$ for $k$ on the Luttinger surface, and iii) $n_{G^{-1}_k}(Γ_0) = G_k^{-1}(Γ_0) = 0$ and $G_k^{-1}(Γ_0) = 1$ for $k$ above the Luttinger surface. These results are indeed exactly the same as those obtained above in Table III by counting the number of zeros and poles of $G_k(ω)$ in Eqs. (92)–(94).

Figure 10 shows the results for the trajectory of $D_k(z)$ in the complex $D_k$ plane at the three representative momenta. Counting how many times and which direction the trajectory winds around the origin in the complex $D_k$ plane, we find in Fig. 10 that i) $n_{D_k}(Γ_0) = n_{D_k}(Γ_0) = n_{D_k}(Γ_0) = 0$ for $k$ below and above the Luttinger surface, and ii) $n_{D_k}(Γ_0) = n_{D_k}(Γ_0) = 1$ and $n_{D_k}(Γ_0) = 2$ for $k$ on the Luttinger surface. Therefore, we can show that $n_{D_k}(Γ_0) + 1/2 n_{D_k}(Γ_0) = 0$ for each momentum $k$ and hence the generalized Luttinger theorem is valid since $lim_{\tau → 0} ΔV_L = 0$ [see Eq. (75)], the same conclusion reached above by counting the number of poles and zeros of $G_k(ω)$.
FIG. 9. Trajectory of $G_k^{-1}(z)$ in the complex $G_k^{-1}$ plane when $z$ moves along contour $C = (\Gamma_0, \Gamma_x, \Gamma_y)$ given in Eq. (95) and also in Fig. 8 for three representative momenta, i.e., $k = 0$ (inside the Luttinger surface), $k = \pi/2$ (on the Luttinger surface), and $k = \pi$ (outside the Luttinger surface). The CPT is employed for the one-dimensional one-band Hubbard model defined in Eq. (87) with $U/t = 6$ at half-filling. By directly counting how many times and which direction (indicated by arrows) the trajectory winds around the origin in the complex $G_k^{-1}$ plane, we find that (a) $n_{G_k^{-1}}(\Gamma_0) = 1$, (b) $n_{G_k^{-1}}(\Gamma_x) = 0$, (c) $n_{G_k^{-1}}(\Gamma_y) = 0$, (d) $n_{G_k^{-1}}(\Gamma_z) = 1$, (e) $n_{G_k^{-1}}(\Gamma_0) = -1$, (f) $n_{G_k^{-1}}(\Gamma_x) = 1$, (g) $n_{G_k^{-1}}(\Gamma_z) = 0$, (h) $n_{G_k^{-1}}(\Gamma_0) = 0$, and (i) $n_{G_k^{-1}}(\Gamma_x) = 1$. These are exactly the same as those obtained by counting the number of poles and zeros of the single-particle Green’s function $G_k(z)$ given in Eqs. (92)–(94) (see also Table III).

V. REMARKS

First, the sign of $G_k(0)$ has been originally utilized to quantify interior and exterior of the Fermi or Luttinger surface [1, 5]. However, as summarized in Tables I, II, and III, $n_k^{(0)}$ defined in Eq. (86) can also quantify the location of momentum $k$ which may be inside, outside, or on the Fermi or Luttinger surface. Indeed, as already discussed in Sec. IV B (also see Appendix C), $n_k^{(0)}$ can be interpreted as the quasiparticle distribution function in the Fermi-liquid theory. It should be emphasized that $n_k^{(0)}$ itself has the topological nature since it is associated with the winding number of the single-particle Green’s function $G_k(z)$.

Second, it is interesting to notice that the phase shift discussed in impurity scattering problems can be described with the similar form of Eqs. (52) and (55), where the scattering potential or $T$-matrix replaces the many body self-energy $\Sigma(z)$. In the impurity scattering problems, the integer winding number $n_H(C)$ corresponds to the number of bound states (Levinson’s theorem) [41–44] or the number of external charges (Friedel sum rule) [45–47]. Furthermore, according to the Levinson’s theorem, a fractional factor of $1/2$ should be added in the phase shift when a bound state exists at zero energy [43, 44], which is again analogous to the fractional contribution to $\Delta V_A$ in Eq. (54) when the determinant of the single-particle Green’s function exhibits singularities at the chemical potential.

Third, the topological aspect of the Luttinger theorem found here clearly differs from the topological approach to the Luttinger theorem reported in Ref. [3]. The main difference is twofold: (i) the topological nature examined and (ii) the resulting topological quantity. We have derived here the topological nature of the single-particle Green’s function for general systems, whereas in Ref. [3] the topological nature of the ground-state wave function is studied for Fermi liquids. We have shown that the winding number $n_H(C)$ is the topological quantity which quantifies whether the generalized Luttinger theorem is valid. In Ref. [3], the difference of the Fermi surface volume and the filling factor of a partially filled band is the topological quantity $n$, which is nothing but the number of completely filled bands. Therefore, $n = 0$ corresponds to the case where no filling band exists and Luttinger theorem is always satisfied regardless of values of $n$. Note also that the topological approach in Ref. [3] is formulated for periodic systems with a particular set of system sizes, while our approach can be applied to general systems.
FIG. 10. Trajectory of $D_k(z) = G_{\alpha\beta}(z)/G_k(z)$ in the complex $D_k$ plane when $z$ moves along contour $C (= \Gamma_0, \Gamma_-, \text{and } \Gamma_\pi$ given in Eq. (95) and also in Fig. 8 for three representative momenta, i.e., $k = 0$ (inside the Luttinger surface), $k = \pi/2$ (on the Luttinger surface), and $k = \pi$ (outside the Luttinger surface). The CPT is employed for the one-dimensional one-band Hubbard model defined in Eq. (87) with $U/t = 6$ at half-filling. By directly counting how many times and which direction (indicated by arrows) the trajectory winds around the origin in the complex $D_k$ plane, we find that (a) $n_{D_{\alpha\beta}}(\Gamma_\pi) = 0$, (b) $n_{D_{\alpha\beta}}(\Gamma_-) = 0$, (c) $n_{D_{\alpha\beta}}(\Gamma_0) = 0$, (d) $n_{D_{\alpha\beta}}(\Gamma_-) = 1$, (e) $n_{D_{\alpha\beta}}(\Gamma_\pi) = -2$, (f) $n_{D_{\alpha\beta}}(\Gamma_-) = 1$, (g) $n_{D_{\alpha\beta}}(\Gamma_\pi) = 0$, (h) $n_{D_{\alpha\beta}}(\Gamma_-) = 0$, and (i) $n_{D_{\alpha\beta}}(\Gamma_\pi) = 0$. Notice that the trajectory winds twice around the origin in (e). Therefore, we find that $n_{\alpha}(\Gamma_\pi) = -2n_{\beta}(\Gamma_\pi) = -4$, satisfying the condition of type II for the generalized Luttinger theorem in Eq. (59).

VI. SUMMARY AND DISCUSSION

Based solely on analytical properties of the single-particle Green’s function of fermions at finite temperatures, we have shown that the Luttinger volume is represented as the winding number of (the determinant of) the single-particle Green’s functions. Therefore, this inherently introduces the topological interpretation of the generalized Luttinger theorem, and naturally leads to two types of conditions (types I and II) for the validity of the generalized Luttinger theorem. Type I falls into the Fermi-liquid case originally discussed by Luttinger in the 1960’s, where the Fermi surface is well defined at momenta where $G_k(\omega = 0)$ exhibits a pole. Type II includes the non-metallic case such as the Mott insulator to which Dzyaloshinskii has extended the Luttinger’s argument in the 2000’s by introducing the new concept of the Luttinger surface defined as a set of momenta where the sign of $G_k(\omega = 0)$ changes. We have also derived the sufficient condition for the validity of the Luttinger theorem of type I, representing the robustness of the theorem against the perturbation. We have also shown rigorously that the generalized Luttinger theorem of both types is valid for generic interacting fermions as long as the particle-hole symmetry is preserved. Moreover, we have shown that the winding number of the single-particle Green’s function can be considered as the distribution function of quasiparticles.

We should emphasize that these general statements can be made by noticing that the generalized Luttinger volume is expressed as the winding number of the single-particle Green’s function at finite temperatures, for which the complex analysis can be exploited readily and successfully without any ambiguity. This allows us to explore the intrinsic features of interacting fermions, independently of details of a microscopic Hamiltonian.

To be more specific in terms of these general analysis of interacting fermions, first we have examined the single-band simple metallic system with translational symmetry and discussed how the original statement of the theorem by Luttinger is understood with respect to our present analysis. We have also demonstrated our general analysis for a Mott insulator by examining the one-dimensional single-band Hubbard model at half-filling. Furthermore, using the Hubbard-I approximation, we have analyzed the half-filled Hubbard model on the honeycomb lattice where no apparent Fermi surface exists in the noninteracting limit.

It should be emphasized that the fermionic anticommutation relation $\{c_{\alpha}, c_{\beta}\} = \delta_{\alpha\beta}$ plays a central role to determine the analytical properties of the single-particle Green’s
function, including the asymptotic behavior for large $|z|$ and the number of zeros and poles of the single-particle Green’s function. Therefore, our analysis can also be extend to any fermionic systems with spin larger than 1/2. However, it is not straightforward to extend the present formalism to the $t$-$J$ model, which is a prototypical model of the strongly correlated electron systems studied extensively for cuprates [37]. In the $t$-$J$ model, an electron moves between sites via the correlated hopping, represented in terms of the projected electron creation and annihilation operators to exclude the double occupancy. For example, the correlated hopping of an electron with spin $\sigma$ from site $j$ to site $i$ with hopping amplitude $t$ is expressed as

$$t_{ij}^\sigma \bar{c}_{ij}^\sigma = t(1 - n_{ij})c_{ij}^\sigma \bar{c}_{ij}^\sigma (1 - n_{ij}),$$

(96)

where $\bar{c}_{ij}^\sigma = (1 - n_{ij})c_{ij}^\sigma$ and $\bar{c}_{ij}^\sigma = c_{ij}^\sigma (1 - n_{ij})$ exclude the double occupancy on each site. Here, $\bar{\sigma}$ represents the opposite spin of $\sigma$. Since the projected electron creation and annihilation operators do not satisfy the anti-commutation relation, $[\bar{c}_{ij}^\sigma, \bar{c}_{ij}^{\bar{\sigma}}] \neq \delta_{ij\bar{\sigma}}$, we can no longer directly apply the same analytical argument of the single-particle Green’s function in Sec. II and Sec. III. Nonetheless, it is interesting to note that the violation of the Luttinger theorem in the two-dimensional $t$-$J$ model has been reported, based on the high-temperature expansion analysis of the momentum distribution function [48] and the exact-diagonalization analysis of the single-particle Green’s function for finite-size clusters [49], although the opposite had been concluded in the earlier study [50].

The numerical computations have been performed with the RIKEN supercomputer system (HOKUSAI Great-Wave). This work has been supported in part by RIKEN iTHERS Project and Molecular Systems.

**Appendix A: Another derivation of Eq. (33)**

Here, we derive Eq. (33) from the derivative of the grand potential $\Omega$ with respect to the chemical potential $\mu$. As shown in the following, this alternative analysis reveals how the Legendre transform of the Luttinger-Ward functional, $\mathcal{F}$, is related to the deviation $\Delta V_L$ of the Luttinger volume from the noninteracting one.

In the main text, we set the chemical potential $\mu$ as the origin of $z$ in the single-particle Green’s function $G_{\alpha\beta}(z)$ [Eq. (1)] by including $\mu$ in Hamiltonian $H$ (see Sec. II A), and thus $z = 0$ in $G_{\alpha\beta}(z)$ corresponding to the chemical potential. However, it is more useful to express $\mu$ explicitly in the formulae for the present purpose, and this can be done simply by replacing the Matsubara frequency $i\omega_n$ with $\mu + i\omega_n$:

$$i\omega_n \rightarrow z = \mu + i\omega_n.$$  

(A1)

The formulae return to those given in the main text by setting $\mu = 0$ after the derivative with respect to $\mu$ is taken.

According to the self-energy-functional theory [51–53], the grand potential $\Omega$ is given as

$$\Omega = T \sum_{\nu = -\infty}^{\infty} \ln \det G(z_\nu) + \mathcal{F},$$  

(A2)

where $\mathcal{F}[\Sigma]$ is the Legendre transform of Luttinger-Ward functional $\Phi[G]$ defined as

$$\mathcal{F}[\Sigma] = \Phi[G] - T \sum_{\nu = -\infty}^{\infty} e^{i\omega_\nu \nu} \text{tr}[G(i\omega_\nu)\Sigma(i\omega_\nu)],$$  

(A3)

and all the quantities in Eq. (A2) are given as $\Omega = \Omega[\Sigma^*], \ G = G[\Sigma^*], \text{ and } \mathcal{F} = \mathcal{F}[\Sigma^*]$ with the self-energy $\Sigma^*$ which satisfies the stationary condition $\delta \Omega/\delta \Sigma_{\nu\nu} = 0$. Note that, because $\Phi[G]$ is the generating function of $\Sigma [1, 2], \mathcal{F}[\Sigma]$ is the generating function of $G$,

$$\frac{\delta \mathcal{F}[\Sigma]}{\delta \Sigma_{\alpha\beta}(z)} = -TG_{\beta\alpha}(z),$$  

(A4)

Thus we can show that

$$\frac{\delta \mathcal{F}[\Sigma]}{\delta z} = \sum_{\alpha, \beta = 1} T \frac{\delta \mathcal{F}[\Sigma]}{\delta \Sigma_{\alpha\beta}} \frac{\delta \Sigma_{\alpha\beta}(z)}{\delta z} = -T \text{tr} \left[ G(z) \frac{\partial \Sigma(z)}{\partial z} \right].$$  

(A5)

Applying $-\delta / \partial \mu$ in both sides of Eq. (A2), we immediately find that the left-hand side gives the average particle number $N$, i.e.,

$$- \frac{\partial \Omega}{\partial \mu} = N,$$  

(A6)

whereas the first term of the right-hand side in Eq. (A2) reads

$$- T \frac{\partial}{\partial \mu} \sum_{\nu = -\infty}^{\infty} \ln \det G(z_\nu)$$

$$= T \sum_{\nu = -\infty}^{\infty} \frac{\partial z_\nu}{\partial \mu} \ln \det G(z_\nu)^{-1}$$

$$= \oint_{\Gamma} \frac{dz}{2\pi i} n_T(z - \mu) \ln \det G(z)^{-1} = V_L.$$  

(A7)

Here, contour $\Gamma$ is indicated in Fig. 2(a) with trivial modification due to non zero $\mu$ and Eq. (34) is used in the last equality.

Because the Luttinger volume of the noninteracting system $V_L^0$ is $N$, we find form Eq. (A2) that the deviation of the Luttinger volume from the noninteracting one, $\Delta V_L$, is given as the derivative of the Legendre transform of the Luttinger-Ward functional, $\mathcal{F}$, with respect to $\mu$, i.e.,

$$\frac{\partial \mathcal{F}}{\partial \mu} = V_L - N = \Delta V_L.$$  

(A8)

Finally, $\partial \mathcal{F} / \partial \mu$ can also be directly evaluated as

$$\frac{\partial \mathcal{F}}{\partial \mu} = \sum_{\nu = -\infty}^{\infty} \frac{\partial \mathcal{F}}{\partial \nu} = -T \sum_{\nu = -\infty}^{\infty} \text{tr} [G(z) \frac{\partial \Sigma(z)}{\partial z}](z = z_\nu)$$

$$= - \oint_{\Gamma} \frac{dz}{2\pi i} n_T(z - \mu) \text{tr} \left[ G(z) \frac{\partial \Sigma(z)}{\partial z} \right].$$  

(A9)
where Eq. (A5) is used in the second equality. Therefore, the first equality of Eq. (A8) is nothing but Eq. (33) and thus we have proved that Eq. (33) can also be derived by the derivative of Ω with respect to µ.

Appendix B: Hubbard model on the honeycomb lattice: Hubbard-I approximation

The half-filled Hubbard model on the honeycomb lattice [54–57] is a very instructive and yet non-trivial system to apply the analytical results in Sec. III because only the Fermi points exist in the two-dimensional Brillouin zone and hence the concept of “Fermi surface volume” is absent in the noninteracting limit.

1. Hubbard model on the honeycomb lattice

The Hubbard model on the honeycomb lattice is described by the following Hamiltonian:

$$H_h = H^0_h + U \sum_i \sum_{\alpha=A,B} n_{i\alpha \uparrow} n_{i\alpha \downarrow},$$

(B1)

where $H^0_h$ is the noninteracting tight-binding Hamiltonian on the honeycomb lattice,

$$H^0_h = \sum_{\mathbf{k},\sigma} \left( c_{\mathbf{k}\sigma \uparrow}^\dagger c_{\mathbf{k}\sigma \uparrow} - \frac{\mu}{\gamma_{\mathbf{k}\sigma \uparrow}} \right) c_{\mathbf{k}\sigma \uparrow} c_{\mathbf{k}\sigma \downarrow},$$

(B2)

Here, $c_{\mathbf{k}\sigma \uparrow}^\dagger$ is the Fourier transform of an electron creation operator $c_{\mathbf{i}\sigma \uparrow}$ at the $i$-th unit cell, the location being denoted as $\mathbf{r}_i$ in real space, on sublattice $\xi = (A, B)$ with spin $\sigma = (\uparrow, \downarrow)$, and $\gamma_{\mathbf{k}\sigma \uparrow} = -t(1 + e^{i\mathbf{k}\cdot\mathbf{a}_t} + e^{-i\mathbf{k}\cdot\mathbf{a}_t})$, where the hopping between the nearest neighbor sites is denoted as $-t$ and the primitive translational vectors are given as $\mathbf{a}_t = (1/2, \sqrt{3}/2)$ and $\mathbf{a}_s = (-1/2, \sqrt{3}/2)$, assuming that the lattice constant between the nearest neighbor sites is $1/\sqrt{3}$. The number of unit cells is $L$ and the chemical potential $\mu$ is explicitly included in $H^0_h$. $U$ is the on-site interaction and $n_{i\sigma \uparrow} = c_{i\sigma \uparrow}^\dagger c_{i\sigma \uparrow}$.

Note that the particle-hole symmetry is preserved when $\mu = U/2$ at half-filling. The number $L_n$ of the single-particle states labeled by $\alpha = (\mathbf{k}, \sigma, \xi)$ (see Sec. II A) is

$$L_n = \sum_{\mathbf{k}} \sum_{\sigma = \uparrow, \downarrow} \sum_{\xi = A, B} = 4L.$$

(B3)

In the following of this Appendix, we only consider zero temperature.

2. Noninteracting limit

Let us first consider the noninteracting limit with $U = 0$. As shown in Eq. (B2), the noninteracting Hamiltonian $H^0_h$ is already diagonal with respect to momentum $\mathbf{k}$ and spin $\sigma$. Accordingly, the single-particle Green’s function $G_{0}(z)$ is block diagonalized with respect to $\mathbf{k}$ and $\sigma$, and each element is denoted here as $G_{0,\mathbf{k}\sigma}(z)$. Since

$$G_{0,\mathbf{k}\sigma}(z) = \left( \begin{array}{cc} z + \mu & -\gamma_{\mathbf{k}\sigma} \\ -\gamma_{\mathbf{k}\sigma} & z + \mu \end{array} \right)^{-1},$$

(B4)

we can readily show that

$$\det G_{0,\mathbf{k}\sigma}(z) = \left( \begin{array}{c} 1/(z + \mu - |\gamma_{\mathbf{k}\sigma}|) \\ 1/(z + \mu + |\gamma_{\mathbf{k}\sigma}|) \end{array} \right).$$

(B5)

for given $\mathbf{k}$ and $\sigma$. Notice that, because the single-particle energy dispersion $\pm |\gamma_{\mathbf{k}\sigma}|$ is 0 at the $K$ and $K'$ points (Dirac points), i.e., $\mathbf{k} = \pm \frac{\pi}{3}\left( \frac{1}{2}, \frac{\sqrt{3}}{2} \right)$ and $\pm \frac{\pi}{3}\left( -\frac{1}{2}, \frac{\sqrt{3}}{2} \right)$, respectively, $\det G_{0,\mathbf{k}\sigma}(z)$ has zero-energy poles at these momenta when $\mu = 0$ at half-filling.

The determinant of the single-particle Green’s function is now evaluated as

$$\det G_{0}(z) = \prod_k \prod_{\sigma} \det G_{0,\mathbf{k}\sigma}(z)$$

$$= \left( \begin{array}{c} 1/(z + \mu - |\gamma_{\mathbf{k}\sigma}|) \\ 1/(z + \mu + |\gamma_{\mathbf{k}\sigma}|) \end{array} \right)^8 \prod_{(\mathbf{k}, \mathbf{k'} \neq K, K')} \left( \begin{array}{c} 1/(z + \mu - |\gamma_{\mathbf{k}\sigma}|) \\ 1/(z + \mu + |\gamma_{\mathbf{k}\sigma}|) \end{array} \right)^2.$$  

(B6)

By counting the singularities as many times as its order, we find that at half-filling ($\mu = 0$) the number of poles in $\det G_{0}(z)$ at the chemical potential, corresponding to $z = 0$, is 8 and the number of poles below the chemical potential is $2L - 4$. Since $\det G_{0}(z)$ has no zeros, i.e., $\det G_{0}(z) \neq 0$ for any $z$,

$$\begin{align*}
\frac{1}{n_{\det G_{0}}(\Gamma_0)} &= 8 \\
\frac{1}{n_{\det G_{0}}(\Gamma_c)} &= 2L - 4
\end{align*}$$

(B7)

at half-filling [see Eqs. (45) and (46)]. Therefore, using Eq. (42), we find that $\lim_{\mu \to 0} V_{\mathbf{i}}^0 = 2L$. This is indeed expected for the noninteracting particle-hole symmetric systems since the number of electrons is $L/2 = 2L$. However, we should note that this result is perhaps less obvious when we consider the Fermi surface volume because the Fermi surface here is composed of the Dirac points in the noninteracting limit at half-filling.

3. Hubbard-I approximation

Let us employ the Hubbard-I approximation [58] to treat the on-site interaction at half-filling. In this approximation, the on-site interaction is approximated in the atomic limit with the self-energy $\Sigma_{\mathbf{k}\sigma}(z)$ given as

$$\Sigma_{\mathbf{k}\sigma}(z) = U n_{\mathbf{k}\sigma} + \frac{U^0 n_{\bar{\mathbf{k}}\bar{\sigma}} (1 - n_{\mathbf{k}\sigma})}{z + U n_{\mathbf{k}\sigma}} + \frac{U^0 n_{\bar{\mathbf{k}}\bar{\sigma}} (1 - n_{\mathbf{k}\sigma})}{z + U n_{\mathbf{k}\sigma}},$$

(B8)

where $n_{\mathbf{i}\sigma}$ is the average electron density on sublattice $\xi$ with spin $\sigma$, and $\bar{\sigma}$ indicates the opposite spin of $\sigma$. Noticing that $n_{\mathbf{k}\sigma} = n_{\bar{\mathbf{k}}\bar{\sigma}} = 1/2$ at half-filling with the chemical potential $\mu = U/2$, the interacting single-particle Green’s function
$G_{k\sigma}(z)$ for given $k$ and $\sigma$ is now simply evaluated as

$$G_{k\sigma}(z) = \left[ G_{0k\sigma}(z) - \Sigma_{k\sigma}(z) \right]^{-1}$$

$$= \begin{pmatrix} z - \frac{\gamma_k^2}{2} & -y_k \\ -y_k^* & z - \frac{\gamma_k^2}{2} \end{pmatrix}^{-1}$$

(B9)

and hence

$$\det G_{k\sigma}(z) = \frac{z^2}{(z - \omega_k^+)(z - \omega_k^-)(z + \omega_k^+)(z + \omega_k^-)}$$

(B10)

with

$$\omega_k^\pm = \frac{1}{2} \left( |y_k| \pm \sqrt{|y_k|^2 + U^2} \right).$$

(B11)

Therefore, the determinant of the interacting single-particle Green’s function $G(z)$ is

$$\det G(z) = \prod_k \prod_{\sigma} \det G_{k\sigma}(z)$$

$$= z^{4L} \prod_k \left( \frac{1}{z - \omega_k^+} \right)^2 \left( \frac{1}{z - \omega_k^-} \right)^2 \times \left( \frac{1}{z + \omega_k^+} \right)^2 \left( \frac{1}{z + \omega_k^-} \right)^2$$

(B12)

Since $\omega_k^+ > 0$ and $\omega_k^- < 0$ for non-zero $U$, we find that the number of zeros of $\det G(z)$ at (below) the chemical potential, corresponding to $z = 0$, is $4L$ (0) and the number of poles of $\det G(z)$ at (below) the chemical potential is 0 (4L). Thus, from Eqs. (45) and (46), we find that

\[
\begin{align*}
& n_{\det G^{-1}(\Gamma_0)} = -4L \\
& n_{\det G^{-1}(\Gamma_c)} = 4L
\end{align*}
\]

(B13)

at half-filling. Using Eq. (42), we obtain that $\lim_{z \to 0} V_L = 2L$, thus satisfying the generalized Luttinger theorem.

Knowing the number of zeros and poles of $\det G(z)$, the winding number $n_D(C)$ [see Eq. (56)] of the Fredholm determinant $D(z)$ defined in Eq. (52) is now evaluated as

\[
\begin{align*}
& n_D(\Gamma_0) = -4L - 8 \\
& n_D(\Gamma_c) = 2L + 4
\end{align*}
\]

(B14)

which indeed fulfills the condition of type II for the validity of the generalized Luttinger theorem in Eq. (59) [59]. Note that in the Hubbard-I approximation the metal-insulator transition occurs as soon as a finite $U (> 0)$ is introduced. Therefore, this example studied here also suggests that the (portion of) Fermi surface should disappear with the introduction of electron interactions when the condition of type II is satisfied.

4. Direct counting of winding numbers

As indicated in Fig. 3, the winding numbers, $n_{\det G^{-1}}(C)$ and $n_{\det G^0}(C)$, can be evaluated directly by counting how many times and which direction $\det G^{-1}_0(z)$ and $\det G^{-1}(z)$ wind around the origin in the complex $\det G^{-1}_0$ and $\det G^{-1}$ planes, respectively, when $z$ moves along contour $C$ shown in Fig. 2(b). Since it is instructive, here we shall evaluate directly the winding numbers within the Hubbard-I approximation by considering $3 \times 3$ unit cells (i.e., $L = 9$) with periodic boundary conditions. The smallest system size which contains both $K$ and $K'$ points in the Brillouin zone, as shown in Fig. 11(a). The single-particle energy-dispersion relations for the noninteracting limit and for $U = 5t$ are shown in Figs. 11(b) and 11(c), respectively. Since contour $C$ can be chosen rather freely, as long as the poles and zeros are properly included, here we consider the contours given in Eq. (95) and in Fig. 8.

Figures 12(a)–12(d) show the results of $\arg[\det G^{-1}_0(z)]$ in the noninteracting limit and $\arg[\det G^0(z)]$ with $U = 5t$ for $z$ along contours $\Gamma_0$ and $\Gamma_c$. Here, we have used $\det G_0(z)$ and $\det G(z)$ obtained analytically in Eqs. (B6) and (B12), respectively. Notice in these figures that the arguments of $\det G^{-1}_0(z)$ and $\det G^0(z)$ are divided by 2 [Figs. 12(a) and 12(b)] and 9 [Figs. 12(c) and 12(d)], respectively, for clarity. By directly counting how many times and which direction these quantities wind around the origin we find that $n_{\det G^{-1}_0}(\Gamma_0)/2 = 4$, $n_{\det G^{-1}_0}(\Gamma_c)/2 = 7$, $n_{\det G^0}(\Gamma_0)/9 = -4$, and $n_{\det G^0}(\Gamma_c)/9 = 4$. These results are indeed the same as those obtained above in Eqs. (B7) and (B13) with $L = 9$ by counting the number of zeros and poles of the determinant of the single-particle Green’s functions.

Similarly, $n_D(C)$ in Eq. (55) can also be evaluated directly by counting how many times and which direction $D(z)$ winds around the origin in the complex $D$ plane, when $z$ moves along contour $C$ shown in Fig. 8. The results of $\arg[D(z)]$ for $z$ along contours $\Gamma_0$ and $\Gamma_c$ with $U = 5t$ are shown in Figs. 12(e) and 12(f), respectively. It is clearly observed in these figures that the winding numbers are $n_D(\Gamma_0)/11 = -4$ and $n_D(\Gamma_c)/11 = 2$. These results are again comparable with those evaluated above in Eq. (B14) with $L = 9$ by counting the number of zeros and poles of the determinant of the single-particle Green’s functions. Indeed, we again find that $n_D(\Gamma_c) + \frac{1}{2} n_D(\Gamma_0) = 0$, confirming the validity of the generalized Luttinger theorem with the condition of type II.

The analysis in this Appendix have clearly demonstrated that the formalism developed in Sec. III can apply without any ambiguity even to systems with point-like Fermi surfaces, where the concept of Fermi surface volume is obscure. We also note that the formalism developed in Sec. III can apply equally to, for example, particle-hole symmetric flat-band systems [60, 61] where the entire Brillouin zone is covered with zero-energy poles of the single-particle Green’s function and thus the well-defined Fermi surface volume is absent in the noninteracting limit, and where the ground state might be ferromagnetic when electron interactions are introduced.
Let us consider momentum $\mathbf{k}$ at which the singularities of $G_{\mathbf{k}}(\omega)$ are given as Eq. (82), i.e., $\mathbf{k}$ below the Fermi surface in the zero-temperature limit. Then we can write that

$$ n_{\mathbf{k}} = n_{F}(\omega_{m_{\text{top}}}) - \sum_{m=1}^{m_{\text{top}}-1} n_{F}(\xi_{m}^{(k)}) + \sum_{m=m_{\text{top}}}^{P_{k}-1} n_{F}(\omega_{m}^{(k)}) - n_{F}(\omega_{m_{\text{top}}^{(k)})}, \quad (C4) $$

where the first term represents the contribution from the quasiparticle excitation, i.e., the topmost excitation below the chemical potential for which $G_{\mathbf{k}}(\omega)$ exhibits a pole, and the second (third) term from the incoherent part below (above) the chemical potential. In the following, we shall show that the contributions to $n_{\mathbf{k}}$ from the incoherent parts are exponentially small at low temperatures.

The second term on the right-hand side of Eq. (C4) can be approximated as

$$ m_{\text{top}} \approx \sum_{m=1}^{m_{\text{top}}-1} \frac{\epsilon_{m}^{(k)} - \epsilon_{m_{\text{top}}}^{(k)}}{\epsilon_{m}^{(k)} - \epsilon_{m_{\text{top}}}^{(k)}} n_{F}(\xi_{m}^{(k)}) - n_{F}(\omega_{m}^{(k)}), \quad (C5) $$

Here, in the second line, we have assumed that each energy interval between the successive pole and zero, $\epsilon_{m}^{(k)} - \epsilon_{m_{\text{top}}}^{(k)}$, in the incoherent part is small enough as compared with the whole energy width of the incoherent part itself, i.e., $\epsilon_{m_{\text{top}}}^{(k)} - \epsilon_{1}^{(k)}$. Similarly, the third term on the right-hand side of Eq. (C4) can be approximated as

$$ \sum_{m=m_{\text{top}}}^{P_{k}-1} \frac{\epsilon_{m}^{(k)} - \epsilon_{m_{\text{top}}}^{(k)}}{\epsilon_{m}^{(k)} - \epsilon_{m_{\text{top}}}^{(k)}} n_{F}(\omega_{m}^{(k)}) - n_{F}(\omega_{m_{\text{top}}^{(k)}}) \approx n_{F}(\epsilon_{P_{k}-1}^{(k)}) - n_{F}(\epsilon_{m_{\text{top}}}^{(k)}). \quad (C6) $$

FIG. 11. (a) The available $\mathbf{k}$ points (red solid circles) for the $3 \times 3$ unit cell cluster of the honeycomb lattice with periodic boundary conditions. The black solid lines represent the boundaries of the Brillouin zone and the blue solid lines indicate the momentum path along which the single-particle energy-dispersion relations are shown in (b) and (c). Four high symmetric momenta are denoted as $\Gamma$: (0, 0), $K$: $(2\pi/3, 2\pi/\sqrt{3})$, $M$: $(0, 2\pi/\sqrt{3})$, and $K'$: $(-2\pi/3, 2\pi/\sqrt{3})$. (b) The single-particle energy-dispersion relation for $U = 0$. (c) Same as (b) but for $U = 5t$ obtained within the Hubbard-I approximation at half-filling. The red vertical lines in (b) and (c) represent the available $\mathbf{k}$ points for the $3 \times 3$ unit cell cluster shown in (a).
Since we assume that $T \ll \zeta_{m_{20}}^{(k)} - \zeta_{m_{20}-1}^{(k)}$, we can set that $n_{\uparrow}(\zeta_{m_{20}}^{(k)}) = 1$ and $n_{\uparrow}(\zeta_{m_{20}-1}^{(k)}) = 0$ in Eqs. (C5) and (C6), respectively. Using $1 - n_{\uparrow}(z) = n_{\uparrow}(-z)$, we thus find that

$$n_k \approx n_{\uparrow}(\omega_{m_{20}}) + n_{\uparrow}(\omega_{m_{20}-1} - \omega_{m_{20}})$$

$$= n_{\uparrow}(\omega_{m_{20}}) + O(e^{\omega_{m_{20}}/T}) - O(e^{-\omega_{m_{20}}/T}).$$

(C7)

Note that the second and the third term in Eq. (C7) are exponentially small because $T \ll -\zeta_{m_{20}}^{(k)}$ and $T \ll \zeta_{m_{20}}^{(k)}$ [see Eq. (C3)].

Similarly, for momenta $k$ at which singularities of $G_k(\omega)$ are given as Eq. (81) (i.e., at the Fermi surface in the zero-temperature limit) and Eq. (83) (i.e., above the Fermi surface in the zero-temperature limit), we find that

$$n_k \approx n_{\uparrow}(\omega_{m_{20}}) + O(e^{\omega_{m_{20}}/T}) - O(e^{-\omega_{m_{20}}/T})$$

(C8)

and

$$n_k \approx n_{\uparrow}(\omega_{m_{20}}) + O(e^{\omega_{m_{20}}/T}) - O(e^{-\omega_{m_{20}}/T}),$$

(C9)
respectively. Here, the subscript \( m_{FS} \) should be read as a label for an excitation on the chemical potential because the Fermi surface is not well defined at finite temperatures. Equations (C7)–(C9) clearly show that \( n_k \) defined in Eq. (C2) is expressed as the Fermi-Dirac distribution function \( n_F(\omega) \) of the quasiparticle excitation energy at momentum \( k \). Therefore, we can conclude that \( n_k \) is considered as the distribution function of quasiparticles at low temperatures.

Let us now consider \( n_k \) from the analytical aspects of the single-particle Green’s function \( G_k(z) \). As shown in Eq. (34), \( n_k \) in Eq. (C2) is also expressed in the contour integral as

\[
n_k = \oint \frac{dz}{2\pi i} n_F(z) \frac{\partial \ln G_k^{-1}(z)}{\partial z}. \tag{C10}\]

Explicitly considering the quasiparticle contribution in the single-particle Green’s function \( G_k(z) \), the Lehmann representation of \( G_k(z) \) [see Eq. (11)] is given as

\[
G_k(z) = \frac{\omega_k}{z - \omega_{m_{_qp}}(k)} + \sum_{m_{m_{qp}}} \frac{|Q_{k m_{qp}}|^2}{z - \omega_{m_{qp}}(k)}, \tag{C11}\]

where \( \omega_{m_{qp}}(k) = \omega_{m_{qp}}(k), \omega_{m_{pq}}(k), \) or \( \omega_{m_{pq}}(k) \) is the quasiparticle excitation energy for momentum \( k \) with the corresponding quasiparticle weight \( a_k = |Q_{k m_{qp}}|^2 > 0 \), and the second term in the right-hand side represents the incoherent part of \( G_k(z) \).

When \( z \) is in the vicinity of the quasiparticle excitation energy, i.e., \( z \approx \omega_{m_{qp}} \), the single-particle Green’s function is approximated as \( G_k(z) \approx \omega_k/(z - \omega_{m_{qp}}(k)) \) and thus we find that

\[
\frac{\partial \ln G_k^{-1}(z)}{\partial z} = G_k(z) \frac{\partial G_k^{-1}(z)}{\partial z} \approx \frac{1}{z - \omega_{m_{qp}}(k)}. \tag{C12}\]

This implies that the logarithmic derivative of \( G_k^{-1}(z) \) behaves like a free fermionic single-particle Green’s function with the excitation energy \( \omega_{m_{ qp}} \), when \( z \approx \omega_{m_{ qp}} \). Therefore, the pole of the single-particle Green’s function at \( \omega_{m_{ qp}} \) contributes to \( n_k \) in Eq. (C10) by \( n_F(\omega_{m_{ qp}}) \).

The same argument as in Eq. (C12) can be applied to each of the remaining \( P_k - 1 \) poles of \( G_k(z) \), which are given in the second term of the right-hand side of Eq. (C11). However, the positive contributions \( n(\omega_{m_{ pq}}) \) from these poles are mostly canceled by the negative contributions \( -n(\omega_{m_{ pq}}) \) from the same number of zeros of \( G_k(z) \) at low temperatures, and thereby the net contribution to \( n_k \) from the remaining incoherent part is exponentially small. We thus again reach the same conclusion that

\[
n_k \approx \oint \frac{dz}{2\pi i} n_F(z) \frac{1}{z - \omega_{m_{ qp}}} = n_F(\omega_{m_{ qp}}), \tag{C13}\]

showing that \( n_k \) is dominated by the lowest-energy single-particle excitation \( \omega_{m_{ qp}} \), and the excitation indeed obeys the Fermi-Dirac statistics, as in Eqs. (C7)–(C9).

The important consequence of this is that the Luttinger volume \( V_L \) in Eq. (C1) provides the average number of quasiparticles. The Landau’s Fermi-liquid theory hypothesizes that the \( V_L = \text{Tr} \left[ G_0 \Gamma_0 \right] \) and \( V_L = \text{Tr} \left[ G \Gamma \right] \) number of particles, \( N \), is equal to that of quasiparticles [35]. Therefore, the argument given here immediately implies that this fundamental hypothesis of the Landau’s Fermi-liquid theory is guaranteed when \( V_L \approx N \). This is the case when the Luttinger theorem is valid at zero temperature or when the particle-hole symmetry is preserved at finite temperatures, as shown in Eq. (62).

Finally, we note that for general complex frequency \( z \),

\[
\frac{\partial \ln G_k^{-1}(z)}{\partial z} = G_k(z) \Gamma_k(z), \tag{C14}\]

where \( \Gamma_k(z) = \frac{\partial G_k^{-1}(z)}{\partial z} = 1 - \frac{\omega_k}{z} \) is the scalar vertex function. The comparison with Eq. (C12) suggests that \( \Gamma_k(z) \) enhances the renormalized quasiparticle spectral weight \( a_k(\leq 1) \) up to 1 in the interacting single-particle Green’s function for \( z \) near the quasiparticle excitation energy \( \omega_{m_{ qp}} \). Notice also that Eq. (C14) allows us for a diagramatic representation of the Luttinger volume and the Luttinger theorem, as shown in Fig. 13.

[59] Here, we have implicitly assumed in Eqs. (B6) and (B7) that the Dirac points are among the allowed momenta for the honeycomb lattice composed of finite 2L sites. However, this assumption is not essential for the conclusion. If the Dirac points are not among the allowed momenta, poles of det $G_0(z)$ in the noninteracting limit appears only above and below the chemical potential but not on the chemical potential, and thus we find that

\[
\begin{align*}
    n_{\text{det}G_0^{-1}(\Gamma_0)} &= 0 \\
    n_{\text{det}G_0^{-1}(\Gamma_>)} &= 2L
\end{align*}
\]

at half-filling [for which the Luttinger volume $V_L^0$ in Eq. (42) is still 2L], while the analytic properties of det $G(z)$ remains the same as in Eqs. (B12) and (B13). Therefore, we find that

\[
\begin{align*}
    n_{\text{det}G^{-1}(\Gamma_0)} &= -4L \\
    n_{\text{det}G^{-1}(\Gamma_>)} &= 2L
\end{align*}
\]

and thus the condition of type II for the validity of the generalized Luttinger theorem is satisfied.
