Radio-to-TeV γ-ray emission from PSR B1259–63

Abstract We discuss the implications of the recent X-ray and TeV γ-ray observations of the PSR B1259–63 system (a young rotation powered pulsar orbiting a Be star) for the theoretical models of interaction of pulsar and stellar winds. We show that previously considered models have problems to account for the observed behaviour of the system. We develop a model in which the broad band emission from the binary system is produced in result of collisions of GeV-TeV energy protons accelerated by the pulsar wind and interacting with the stellar disk. In this model the high energy γ-rays are produced in the decays of secondary neutral pions, while radio and X-ray emission are synchrotron and inverse Compton emission produced by low-energy (≤ 100 MeV) electrons from the decays of secondary charged π± mesons. This model can explain not only the observed energy spectra, but also the correlations between TeV, X-ray and radio emission components.

1 Introduction

PSR B1259–63 is a ∼48 ms radio pulsar in a highly eccentric (e∼0.87), 3.4 year orbit with a Be star SS 2883 [1]. The pulsar crosses the Be star disc twice per orbit, just prior to and just after periastron. Unpulsed radio, X-ray and γ-ray emission observed from the binary system are produced due to the collision of pulsar wind with the wind of Be star. Observations of the temporal and spectral evolution of the non-thermal emission from the system provide a unique opportunity to probe the physics of the pulsar winds (PW) which is, in spite of the wealth of observational phenomena, and a 40-year old observation history, remains a matter of debate.

The interaction of the PW with the wind from the companion star, is responsible for the formation of a "compactified" pulsar wind nebula (PWN) with the size about the binary separation distance (typically, on AU-scale). Compact size, large matter density and the presence of a strong source (companion star) which illuminates the nebula make the physical properties of the compact PWN significantly different from the ones of their larger scale cousins.

We present the results of the last observation campaign of the PSR B1259–63 system during the 2004 pulsar periastron passage and their applications for the theoretical modelling of the source. We show that most of the observed properties of the system in radio-to-TeV band can be naturally explained within a model of proton-loaded pulsar wind.

2 Multi-wavelength observations of the system during 2004 periastron passage.

The upper panel of Fig. 1 shows the X-ray lightcurve of the system [2] together with the TeV [3] and radio [4] lightcurves. For comparison we show also the data from archival X-ray [5,6] and radio [7,8] observations. Rapid growth of the X-ray flux found in XMM-Newton observations of 2004 is correlated with the rapid growth of the unpulsed radio emission from the system. The growth of radio and X-ray flux at these phases can be attributed to the pulsar entering the Be star disk.

Unfortunately, TeV observations start somewhat later and it is not possible to see whether the TeV flux grows during the pre-periastron disk crossing. However, simple geometrical argument tells that the orbital phase θ at which the pulsar should enter the disk for the second time should be shifted by 180° relative to the first entrance. From Fig. 1 one can infer that the first pre-periastron entrance falls roughly between the phases 70° < θ < 110°. Thus, the pulsar has to enter the disk again between the
Fig. 1 Comparison between the X-ray (top), TeV (middle) and radio (bottom) lightcurves. XMM-Newton observations are marked with triangles, BeppoSAX ones with circles, and ASCA ones with squares. Data for four different periastron passages are shown with different colors: red (1994), green (1997), black (2000) and blue (2004). Bottom X axis shows the orbital phase, $\theta$, top X axis shows days from periastron, $\tau$.

Fig. 2 The X-ray (top) and TeV (bottom) flux as a function of the relative phase $\Delta \theta = \theta - \theta_0$ (see text for the definition of $\theta_0$). The curves show a fit with a gaussian of the half-width $\Delta \theta_0 = 18.5^\circ$.

Fig. 3 Evolution of the X-ray photon index $I_{\gamma ph}$ over the orbital phase $\theta$. Radio flux and spectral index evolution from the 1997 periastron passage are shown in black. The graphical representation of the evolution of the X-ray photon index (the spectrum is well fit by an absorbed powerlaw model) along the orbit is given in Figure 3. The most remarkable feature of the spectral evolution of the system is the hardening of the X-ray spectrum close to the moment when pulsar enters the Be star disk at the phase $\theta \simeq \theta_0 - 2\Delta \theta_0 \simeq 70^\circ$. One can see that the decrease of the photon index $I_{\gamma ph}$ is simultaneous with the onset of the rapid growth of the X-ray flux. Similar hardening of the spectrum down to the photon index $I_{\gamma ph} \simeq 1$ (or, equivalently, down to the spectral index $\alpha \simeq 0$) at the moment of disk entrance is observed in the radio data shown in Fig. 3 in black. To the best of our knowledge, neither the hardening of the X-ray spectrum, nor strong correlation between the radio and X-ray flux and spectral index variations was predicted in any of existing models of X-ray emission from the system.
To find the range of possible theoretical models which can explain the data it is useful first to make basic qualitative estimates of different time scales present in the system.

### 3.1 Characteristic cooling times.

**Electrons.** One of the main differences between the synchrotron and IC mechanisms of X-ray emission is the difference in the cooling time scales. The cooling time of the TeV electrons which can produce synchrotron emission at the energies \( \epsilon_S \sim 1 - 10 \ \text{keV} \) in the magnetic field \( B \) is

\[
    t_S \simeq 6 \times 10^2 \left[ B / 0.1 \text{G} \right]^{-3/2} \left[ \epsilon_S / 10 \text{keV} \right]^{-1/2} \text{ s}.
\]

The spectrum of optically thin synchrotron emission from the cooled electron population has the photon index \( \Gamma_{ph} \geq 1.5 \). Any hardening of the X-ray spectrum down to the values \( \Gamma_{ph} < 1.5 \) (e.g. due to the increased injection of electrons at higher energies) would be "washed out" by the synchrotron cooling at the at the \( 10^2 - 10^3 \) s time scale. To the contrary, the typical IC cooling time in X-rays is

\[
    t_{IC\ (T)} \simeq 6 \times 10^5 \left[ R / 10^{13} \text{cm} \right]^2 \left[ \epsilon_{IC} / 10 \text{keV} \right]^{-1/2} \text{ s}.
\]

We have assumed that the seed photons for the IC scattering come from the companion star of luminosity \( L_* \simeq 10^{38} \text{ erg/s} \) and temperature \( T \simeq 2 \times 10^4 \text{ K} \); the subscript "(T)" indicates that the estimate applies for the Thompson regime. Estimating the size of emission region to be about the binary separation distance, \( R \sim 10^{13} \text{ cm} \), one can find that electrons emitting IC radiation at 1 keV cool at the day time scales. Observation of the gradual evolution of the X-ray photon index down to \( \Gamma_{ph} \sim 1.2 \) and then back to \( \Gamma_{ph} \geq 1.5 \) on the time scale of several days during the first entrance to the disk (see Fig. 3) is consistent with the IC, rather than synchrotron model of X-ray emission.

In principle, it is possible that X-ray and TeV \( \gamma \)-ray emission from the system are, respectively, low- and high-energy tails of the IC spectrum. Substituting naively the energy of TeV photons \( \epsilon_{IC} \sim 1 \text{ TeV} \) into Eq. 2 one finds that the time scale of the spectral variability at TeV energies should be very short. However, at TeV energies the IC scattering proceeds in the Klein-Nishina regime and the cooling time in this regime grows with energy,

\[
    t_{IC\ (KN)} \sim 8.5 \times 10^3 \epsilon_{IC}^{0.7} \left[ R / 10^{13} \text{ cm} \right]^2 \text{ s} \quad (3)
\]

The minimum of the IC cooling time, \( \sim 10^9 \) s, is reached at roughly at the energy of transition between Thompson and Klein-Nishina regimes, \( E_c \sim \epsilon_{IC} \sim 10 - 100 \text{ GeV} \).

Pulsar wind electrons are able to escape from the region of the dense photon background along the contact surface of pulsar and stellar wind. If the two winds do not mix, the pulsar wind flows along the contact surface with the speed \( v_{PW} \sim 10^{10} \text{ cm/s} \) and escapes beyond the binary separation distance over the time scale

\[
    t_{esc} \sim R / v_{PW} \simeq 10^5 \left[ R / 10^{13} \text{ cm} \right] \text{ s} \quad (4)
\]

This time scale is essentially shorter than the IC cooling time both in X-ray and in the TeV energy bands. Electrons escaping from the innermost region of pulsar wind/stellar wind interaction fill the larger extended region (a "compactified" PWN of the size \( R_{PWN} \) of about several binary separation distances) and can loose their energy via IC emission at longer time scales in the less dense photon background produced by the Be star. The escape time from the compact PWN can be naively estimated assuming diffusion in the weak PWN magnetic field. E.g. taking the diffusion coefficient \( D \) equal to the Bohm diffusion coefficient at \( E_c \sim 1 \text{ TeV} \) and depending on the energy as \( D \sim E^{-\alpha} \) (\( \alpha = 1 \) for the case of Bohm diffusion) one finds

\[
    t_{PWN} \simeq 10^4 \left[ B / 0.1 \text{G} \right] \left[ E_c / 1 \text{ TeV} \right]^{-\alpha} \left[ R_{PWN} / 10^{13} \text{ cm} \right]^2 \text{ s} \quad (5)
\]

During the periods of the pulsar passage through the dense equatorial disk of Be star (typical density of the slow equatorial stellar wind at the location of the pulsar is \( n_{disk} \sim 10^{10} - 10^{11} \text{ cm}^{-3} \)), bremsstrahlung and ionisation energy losses can compete with the IC loss. Indeed, the energy independent bremsstrahlung loss time,
output in electrons with energies below the "Coulomb break"

\[ E_{\text{Coul}} \simeq 30 \left[ n_{\text{disk}} / 10^{11} \text{ cm}^{-3} \right] \text{ MeV} \] (9)

(estimated from the condition that the Coulomb loss time is equal to the escape time, \( t_{\text{Coul}} \sim t_{\text{esc}} \) will be channeled into the heating of the disk, rather than on emission from the system. As a result, only electrons with energies above \( E_{\text{Coul}} \) can be injected into the compactified PWN.

3.2 Protons.

GeV-TeV energy protons can loose their energy only in interactions with the protons from the stellar wind. The enhancement of the \( pp \) interaction rate is expected during the pulsar passage through the dense equatorial disk of Be star. The \( pp \) interaction time

\[ t_{\text{pp}} \simeq 1.6 \times 10^4 \left[ n / 10^{11} \text{ cm}^{-3} \right]^{-1} \text{ s} \] (10)

is comparable to the electron bremsstrahlung loss time \( \mathcal{B} \). Following the same way of reasoning as in the case of bremsstrahlung, one can find that as much as 10% of the power \( L_p \) contained in the PW protons can be channeled in the secondary particles (\( \gamma \)-rays, neutrinos, electrons, positrons) produced in \( pp \) interactions. The \( \pi^0 \) decay \( \gamma \)-rays carry away about 1/3 of the power output in \( pp \) interactions. Thus, the "\( \gamma \)-ray efficiency" of \( pp \) interactions is somewhat lower than the efficiency of bremsstrahlung,

\[ L_\gamma / L_p \simeq 0.3 t_{\text{esc}} / t_{\text{pp}} \sim 3\% \left[ n_{\text{disk}} / 10^{11} \text{ cm}^{-3} \right] \] (11)

However, if the PW is proton-dominated, the luminosity of the \( \gamma \)-ray emission from \( pp \) interactions can exceed the bremsstrahlung luminosity.

4 IC model of X-ray to TeV emission.

Taking into account that the seed photons for the IC scattering have energies of about 10 eV (assuming the temperature of Be star \( T \approx 2 \times 10^4 \) K), one can find that the IC emission from electrons of the energy \( E_e \) peaks at

\[ \epsilon_{IC} \simeq 4 \left( E_e / 10 \text{ MeV} \right)^2 \text{ keV} \] (12)

The energy of the upscattered photons becomes approximately equal to the energy of electrons at

\[ \epsilon_{IC, (\pi^0 \to \text{KN})} \simeq 30 \text{ GeV} \] (13)

(the transition to the Klein-Nishina regime). If the spectrum of electrons is a simple powerlaw with the spectral index \( p_e \) (\( dN_e / dE \sim E^{-p_e} \)), the IC spectrum below and above the Thompson – Klein-Nishina break is, respectively, \( dN_e / dE \sim E^{(p_e+1)/2} \) and \( dN_e / dE \sim E^{-p_e+1} \ln E \).

The IC emission in the 10-100 GeV energy band is characterized by one more spectral feature. Namely, the IC cooling time of the 10-100 GeV electrons is comparable to the escape time from the compact region with a dense photon background. Estimating the energy of the cooling break in the IC emission spectrum from the condition \( t_{\text{esc}} \simeq t_{IC, (\pi^0)} \) one finds \( \epsilon_{IC, \text{ cool}} \simeq 4 \left[ R / 10^{13} \text{ cm} \right] \) GeV. Taking into account the coincidence of the cooling break energy with the energy of transition to the Klein-Nishina regime one can not expect to detect the conventional steepening of the IC spectrum above the cooling break because of the reduced efficiency of the IC scattering in the Klein-Nishina regime. One more complication of the detailed calculation of the IC emission spectrum in the GeV-TeV energy band is that in order to explain the observed behaviour of the TeV lightcurve during the periastron passage within the IC model one has to assume that either additional non-radiative cooling mechanism dominates electron energy loss close to the periastron, or a cut-off in the electron spectrum at sub-TeV energies is present \[ \mathcal{K} \]. The combined effect of the above mentioned difficulties makes the detailed predictions for the IC spectrum in the GeV-TeV band quite uncertain and we do not attempt the detailed fit of the observed spectrum in this band. Instead we concentrate of the attempt to fit the general shape of the spectral energy distribution in the X-ray to TeV \( \gamma \)-rayband within the IC model.

Fig. 4 shows an example of the fit the the spectrum of PSR B1259–63 in IC model for X-ray to TeV emission. One can see that EGRET upper limit on the flux from the system requires the presence of a break in the IC spectrum at the energies \( E \sim 1 \) MeV. In the model fit shown in the Figure, the electron spectrum below the break at \( E_e = 100 \) MeV has the spectral index \( p_e = 2 \), while above the break the spectrum steepens to \( p_e + 1 = 3 \). It is clear that the overall shape of the IC spectrum in the keV to TeV energy band agrees well with the data.

The energy of the break in the electron spectrum (~ 100 MeV) is close to the energy of the Coulomb break given by Eq. (9). As it was discussed above, electrons with energies below \( E_{\text{Coul}} \) loose all their energy via the severe Coulomb loss before they are able to escape from
the dense equatorial disk of Be star to the less dense PWN. As a result, regardless of the initial injection spectrum of electrons from the PW, the spectrum of electrons injected in the compact PWN has a low-energy cut-off at the energy \( E_{\text{Coul}} \). The IC cooling of electrons in the PWN leads to the formation of the characteristic power-law tail of electron distribution below \( E_{\text{Coul}} \) with \( p_e = 2 \).

The electron spectrum above the energy \( E_{\text{Coul}} \) (assumed to be a powerlaw with the spectral index \( p_e = 3 \) in the model fit of Fig. 4) is determined by the balance of acceleration and energy losses in the pulsar/stellar wind shock region.

Electrons responsible for the X-ray IC emission produce synchrotron radiation in radio band at the characteristic frequency
\[
\epsilon_S \simeq 1.5 [B/0.1 \, \text{G}] [E_e/30 \, \text{MeV}]^2 \, \text{GHz}
\] (14)
The ratio of the synchrotron to IC luminosity is given by the ratio of the energy densities of the magnetic field and radiation,
\[
L_S/L_{\text{IC}} = 2 \times 10^{-4} [B/0.1 \, \text{G}]^2 [R_{\text{PWN}}/10^{13} \, \text{cm}]^2
\] (15)
The radio luminosity of the system is some 4 orders of magnitude lower than the X-ray luminosity. This imposes a restriction on the possible strength of magnetic field in the X-ray emission region,
\[
B \leq 0.1 [R_{\text{PWN}}/10^{13} \, \text{cm}]^{-1} \, \text{G}
\] (16)
In the model fit of Fig. 4 we have chosen the magnetic field strength \( B = 0.03 \, \text{G} \) and assumed the size of X-ray / radio emission region \( R_{\text{PWN}} \sim 3 \times 10^{13} \, \text{cm} \).

5 Alternative mechanisms of TeV γ-ray emission.

5.1 Bremsstrahlung.

The IC model for the keV-to-TeV spectrum has a difficulty to explain the observed correlation of the radio, X-ray and TeV emission because the cooling and escape times of electrons emitting IC radiation in X-ray and TeV bands are different. Since the non-pulsed radio emission from the system is most probably related to the passage of the pulsar through the disk of Be star, an explanation of the observed correlation requires a physical mechanism which would explain the increase of the TeV flux during the disk passage. At least two mechanisms of interaction of the pulsar wind with the Be star disk can lead to the increase of TeV emission: bremsstrahlung and proton-proton interactions.

As it is discussed above, the bremsstrahlung cooling time in the dense Be star disk (13) can be comparable to the IC cooling time both for the highest energy electrons above 1 GeV (see Eqs. 2, 3). The bremsstrahlung cooling time can be comparable to the escape time from the compact equatorial disk so that up to 10% of the power of the pulsar wind can be emitted in the form of bremsstrahlung radiation. Fig. 5 shows the fit for the γ-ray spectrum of the system with a combination of IC and bremsstrahlung emission. The electron spectrum is supposed to be a cut-off powerlaw with the spectral index \( p_e = 2.5 \) and cut-off energy \( E_{\text{cut}} = 20 \, \text{TeV} \). Note that the EGRET upper limit imposes a restriction on the spectrum of electrons because the bremsstrahlung spectrum has the photon index \( \Gamma_{\text{ph}} \simeq p_e \). Assuming that the electron spectrum continues to lower energies without a break would violate the EGRET bound on the flux. A break at the energy \( E \simeq 350 \, \text{MeV} \) was assumed in the electron spectrum in the model fit of Fig. 5. The break at this particular energy is naturally expected in the bremsstrahlung scenario, because below this energy the ionization loss dominates over the bremsstrahlung loss, which leads to the hardening of the electron spectrum by \( \Delta p_e \simeq 1 \) at low energies.

5.2 \( pp \) interactions.

If the pulsar wind is proton-loaded, interactions of the pulsar wind protons with the protons from the dense Be star disk provide an additional source the TeV γ-ray emission. As is is discussed above, the "γ-ray efficiency" of \( pp \) interactions is a factor of several lower than that of bremsstrahlung, but the relative contributions of bremsstrahlung and \( pp \) interactions into the γ-ray emission depend on the proton-to-electron ratio of the PW. If the pulsar wind is mostly proton loaded, the π^0 decay emission can dominate over the γ-ray emission from the pulsar wind electrons. An example of the fit to the TeV γ-rayspectrum within the \( pp \) model is shown in Fig. 6. We have assumed a powerlaw spectrum of protons with the spectral index \( p_p = 2.6 \) for the model fit. Similarly to the case of bremsstrahlung, the EGRET upper limit on the flux imposes a restriction on the spectrum of the protons at several GeV energies. However, contrary to
Since the emission in radio, X-ray and TeV bands is produced via one and the same process (pp interactions), the observed correlation of the radio, X-ray and TeV flux is naturally explained. Besides, the observed hardening of the X-ray spectrum during a several-day period following the moment of the entrance of the pulsar to the disk of Be star is explained by the low energy cut-off at \( \sim 100 \text{ MeV} \) in the spectrum of secondary electrons. Such a cut off arises (a) because of the kinematics of the pion decays and (b) because of the efficient Coulomb cooling of electrons with energies below 100 MeV during the escape from the Be star disk.

The pp interaction scenario is attractive because of one more reason: in this model the overall energy balance of the system is evident. Indeed, in the "purely electronic" models it is not clear why the system is "radiatively inefficient": the spin-down luminosity of the pulsar is \( \sim 10^{36} \text{ erg/s} \), but the bolometric luminosity is just \( L < 10^{34} \text{ erg/s} \), which accounts for no more than one percent of the spin-down luminosity. To the contrary, within "protonic" model one has to assume that proton-loaded PW carries a significant fraction of the spin-down power. As it is explained above, in the pp model the efficiency of conversion of the power contained in the protons into the \( \gamma \)-ray emission is several percents, (see Eq. (11)) which explains the \( \gamma \)-ray luminosity \( L_{\gamma} \sim 10^{34} \text{ erg/s} \).

The pp model can be readily tested with the future observations of the system in the 10 GeV energy band with GLAST. Indeed, from Fig. 6 one can see that in the pp model the EGRET upper limit on the flux at 10 GeV should be close to the actual level of the \( \gamma \)-ray flux from the system. This means that the detection of the system during the periastron passage with a more sensitive instrument, like GLAST should not be a problem.
