Geometry of networks endowed with a causal structure is discussed using the conventional framework of equilibrium statistical mechanics. The popular growing network models appear as particular causal models. We focus on a class of tree graphs, an analytically solvable case. General formulae are derived, describing the degree distribution, the ancestor-descendant correlation and the probability a randomly chosen node lives at a given geodesic distance from the root. It is shown that the Hausdorff dimension $d_H$ of the causal networks is generically infinite, in contrast to the maximally random trees, where it is generically finite.

I. INTRODUCTION

A. Preamble

The network study is an old field of research, which has recently become particularly active (see [1]). This is largely due to the opening of an access to rich data on natural systems: the World-Wide Web, the Internet, the various biological networks (gene transcription, cell metabolism, protein interactions), the sociological networks (citation index, collaborations, phone calls), etc. Interesting empirical regularities have been observed, like the small-world property of networks or the frequently observed scale-free nature of degree distributions. On the theory side, the natural conceptual framework for network research is the graph theory: the nodes and the links of a graph represent the active agents and the interactions, respectively. However, it was soon realized that the classical graph theory [2] is inadequate and has to be generalized, in order to cover the new reality. This observation has triggered, in turn, an intense theoretical activity, that led to the construction of a number of insightful models. It is clear, however, that much remains to be done.

As recalled in ref. [3], in studying complex systems one can adopt one of the two complementary approaches: the diachronic and the synchronic one. In the former, one focuses on the time evolution of the system, which helps discovering the dynamics at work. In the latter, one considers an ensemble of dynamically similar systems at a fixed large time, which helps identifying the generic structural traits.

Most of the recently constructed models adopt the diachronic approach and deal with growing networks [4]-[20]. This led, among others, to the remarkable discovery of the preferential attachment rule and of its crucial role in network evolution [4, 5]. The mathematics of the diachronic approach rests largely on master equations and related manipulations. The synchronic approach has also been advocated and various static statistical ensembles have been constructed and studied [3],[21]-[30]. Here, the mathematics is that of the equilibrium statistical mechanics and probability theory. One of the aims of this paper is to help establishing a bridge between the two sets of results. It will be seen that the widely accepted distinction between growing and equilibrium networks is not really correct. The truly distinctive property of growing networks, their causal structure, can be usefully incorporated in a static model. We limit ourselves to tree graphs, because in this case the use of the methods of analytic combinatorics enables one to get exact solutions.

We shall discuss at length the geometry of connected tree graphs endowed with a causal structure. Our discussion will cover, in particular, some of the recently popular growing network models [4, 6], but we shall proceed considering static statistical ensembles of trees, employing a formalism which proved to be useful in deriving generic results for other random geometries. For example, we shall show that the causal trees have the "small world" property: their Hausdorff dimension is infinite. The advantage of our approach is that is enables one to show at once that this property holds in a wide class of models.

The plan of the paper is as follows: In the next two subsections we recall some basic concepts and we define the observables to be calculated later on. In sect. II we begin by deriving a number of general results that hold for causal trees: The central role is played by a recursion relation satisfied by the partition function (sect. II A). This recursion relation enables one to find closed expressions for the degree distribution (sect. II B), the ancestor-descendant correlation (sect. II C) and the
two-point function measuring the distribution of shortest path lengths between pairs of nodes (sect. IID). In sect. IIE we establish contact between our formalism and the growing network models. This is used in sect. IIF, where we calculate explicitly a set of observables for some simple growing networks. In sect. III we compare the causal model with the maximally random one: In sect. IIIA we collect all general formulae. In sect. IIIB we calculate the observables, assuming the same microstate weights as in sect. IIF, and we find dramatically different results. This illustrates the importance of graph symmetries. In sect. IIE we establish contact between our formalism and the physical interest $z_N$ grows exponentially with $N$, up to a power prefactor:

$$z_N \sim e^{\bar{R} N} \quad \text{for} \quad N \to \infty$$

and $Z(\mu)$ develops a singularity at $\mu = \bar{\mu}$ (see sect. IIA for a more rigorous argument). One is primarily interested in the regime controlled by the singular part of $Z(\mu)$. Indeed, as $\delta \mu \equiv \mu - \bar{\mu}$ tends to zero one becomes increasingly sensitive to the behavior of trees with arbitrarily large $N$.

Of course, eq. (4) can be inverted by Laplace transformation

$$z_N = \frac{e^{\bar{R} N}}{2\pi i} \int_{-i\infty}^{i\infty} d\delta \mu \ Z(\delta \mu) \ e^{\delta \mu N}$$

with the integration contour passing on the right of the singularity at $\delta \mu = 0$. It will often be convenient to work in the grand-canonical ensemble and to Laplace transform the result to the physically more interesting canonical ensemble at the very end. In practice, we shall always assume that $N \to \infty$ and we shall keep the leading term only.

Notice, that there is an analogy between the labelings of graphs and the positions of a system in a (discrete) phase-space. Hence, $\rho(T)$ and $L(T)$ are the analogues of the weight of a microstate and of the corresponding phase-space volume, respectively.

Little is specific to causal trees in the content of this section. One could repeat verbatim the above definitions and keep the same microstate weights in the context of a different tree ensemble. However, in this new ensemble the trees would have different symmetries and, therefore, $L(T)$ would be in general different. Consequently, the physics would be different too. We shall see later, comparing causal and maximally random trees, that introducing a new symmetry can change dramatically the geometry of generic graphs.

B. Basic concepts

Let us recall some definitions: A rooted tree is a tree with one marked node. A planted tree is a rooted one with an extra link attached to the root, so that the degree of the root is increased by unity. The other end of this extra link is not counted as a node, in a sense this end remains "free". The different tree ensembles are simply related and choosing to work with one of them is a matter of convenience. In this paper we deal with planted tree graphs [31].

By assumption, a label is attached to each node and two graphs with identical topology but labeled differently are considered different. We say a tree is endowed with a causal structure when the labels always appear in growing numerical order as one moves along the tree from the root towards an arbitrary node. These are the tree graphs we are interested in.

Introduce a statistical ensemble of these trees. Let us denote by $T$ a given topology and by $L(T)$ the number of distinct causal labelings of $T$. We attach the same weight

$$\rho(T) = w(n_1, n_2, \ldots, n_N)$$

(1)

to each acceptable labeling. Here $N$ is the total number of nodes, $n_i$ denotes the degree of the node $i$ and $w$ is some appropriate positive-definite function. A model is defined by choosing a particular form of $w$.

It will be seen that the presence of a causal structure generates non-trivial observable inter-node correlations. Hence, it is of interest to discuss models where these specific correlations do not interfere with correlations of a different origin. With this motivation, we assume in this paper that $\rho(T)$ factorizes [32]

$$\rho(T) = \prod_{i=1}^{N} q_{n_i}$$

(2)

On the other hand, we keep $q_n$ as general as possible.

The partition functions of canonical and grand-canonical ensembles are defined in the usual way by summing the weights of all possible microstates. Thus by definition:

$$z_N = \frac{1}{N!} \sum_{T} L(T) \rho(T)$$

(3)

and

$$Z(\mu) = \sum_{N} z_N e^{-\mu N}$$

(4)

The prefactor $1/N!$ in eq. (3) is compensated by the number of terms in the summand. Indeed, the number of labeled causal trees with $N$ nodes is $(N - 1)!$ [33]. It is not difficult to convince oneself that in all cases of physical interest $z_N$ grows exponentially with $N$, up to a power prefactor:

$$z_N \sim e^{\bar{R} N} \quad \text{for} \quad N \to \infty$$

and $Z(\mu)$ develops a singularity at $\mu = \bar{\mu}$ (see sect. IIA for a more rigorous argument). One is primarily interested in the regime controlled by the singular part of $Z(\mu)$. Indeed, as $\delta \mu \equiv \mu - \bar{\mu}$ tends to zero one becomes increasingly sensitive to the behavior of trees with arbitrarily large $N$.

Of course, eq. (4) can be inverted by Laplace transformation

$$z_N = \frac{e^{\bar{R} N}}{2\pi i} \int_{-i\infty}^{i\infty} d\delta \mu \ Z(\delta \mu) \ e^{\delta \mu N}$$

(6)

with the integration contour passing on the right of the singularity at $\delta \mu = 0$. It will often be convenient to work in the grand-canonical ensemble and to Laplace transform the result to the physically more interesting canonical ensemble at the very end. In practice, we shall always assume that $N \to \infty$ and we shall keep the leading term only.
C. Observables

Let us define the observables we shall calculate in this paper:

The most popular observable is the degree distribution. When the weight of a microstate has the factorized form, as in (2), the degree distribution \( \pi_n \) is given by the simple and obvious formula

\[
\pi_n = N^{-1} q_n \frac{\partial \ln z_N}{\partial q_n} \quad (7)
\]

The factor \( N^{-1} \) above is included to have the distribution normalized to unity.

In the thermodynamic limit \( N \to \infty \)

\[
\pi_n = q_n \frac{\partial \bar{\mu}}{\partial q_n} \quad (8)
\]

The next observable is the correlation between node degrees, say the probability that a node has degree \( k \) when its neighbor’s degree is \( l \). In a causal tree, one of these nodes is an ancestor and the other a descendant.

A very interesting observable is the Hausdorff dimension \( d_H \) controlling the scaling with \( N \) of the linear size of a typical tree:

\[
\langle r \rangle_N \sim N^{1/d_H} \quad (9)
\]

One usually takes for \( r \) the distance between an arbitrary pair of nodes. In rooted trees it is more natural to consider the distance separating a randomly chosen node from the root. One first calculates a specific two-point function \( C(r, \mu) \), the grand-canonical weight of all trees with a node separated from the root by \( r \) steps. Using \( C(r, \mu) \) one finds

\[
\langle r \rangle_\mu = \int_0^\infty dr \frac{C(r, \mu)}{r} \quad (10)
\]

This quantity usually diverges when \( \delta \mu \to 0 \). The behavior on the r.h.s. (right-hand side) of (9) is determined by observing that \( \delta \mu \) scales like \( N^{-1} \) (see (6)).

II. GEOMETRY OF TREES ENDOWED WITH A CAUSAL STRUCTURE

A. Recursion relation

We start by deriving a recursion relation for the partition function \( z_N \). To this end we construct a new planted tree by attaching the \( k \) "free link-ends" of the planted trees \( T_1, \ldots, T_k \) to a new root. We denote the resulting compound tree by \( T = T_1 \oplus \cdots \oplus T_k \) (this is illustrated in FIG. 1 for \( k = 3 \)).

The number of ordered labelings of the compound tree is

\[
L(T_1 \oplus \cdots \oplus T_k) = \frac{N!}{N_1! \cdots N_k!} \frac{1}{k!} L(T_1) \cdots L(T_k) \quad (11)
\]

Here \( N_i \) denotes the total number of nodes in the tree \( T_i \) and \( N = \sum_i N_i \). One has to give \( N + 1 \) labels to the nodes of the compound tree. However, the smallest label must be attached to the root. The remaining \( N \) labels are arbitrarily distributed among the trees. This is the origin of the the multinomial factor. Permuting the trees \( T_i \) does not change the compound tree [35]. This explains the presence of the factor \( 1/k! \). It will be seen that the composition rule (11) is a very basic property of the model.

Obviously the weight of the new tree factorizes

\[
\rho(T_1 \oplus \cdots \oplus T_k) = q_{k+1} \rho(T_1) \cdots \rho(T_k) \quad (12)
\]

The partition function \( z_{N+1} \) can be constructed by summing the trees of size smaller or equal to \( N \):

\[
z_{N+1} = \frac{1}{(N + 1)!} \sum_{k=1}^\infty \sum_{T_1, \ldots, T_k} \delta_{N_1 + \cdots + N_k, N} \times L(T_1 \oplus \cdots \oplus T_k) \rho(T_1 \oplus \cdots \oplus T_k) \quad (13)
\]

Inserting (11) into (13) and rearranging terms in the sum we obtain after trivial algebra:

\[
z_{N+1} = \frac{1}{N + 1} \sum_{k=1}^\infty \frac{q_{k+1}}{k!} \sum_{N_1, \ldots, N_k} \delta_{N_1 + \cdots + N_k, N} \prod_{i=1}^k z_{N_i} \quad (14)
\]

Adding \( z_1 = q_1 \) and summing both sides of equation (14) we get

\[
\sum_N N z_N e^{-N \mu} = e^{-\mu} \left( \sum_{k=0}^\infty \frac{q_{k+1}}{k!} Z(\mu)^k \right) \quad (15)
\]

or finally

\[
Z'(\mu) = -e^{-\mu} F(Z) \quad (16)
\]

where

\[
F(Z) = \sum_{k=1}^\infty \frac{q_k}{(k-1)!} Z^{k-1} \quad (17)
\]

Equation (16) can be integrated to give

\[
e^{-\mu} = G(Z) = \int_0^Z \frac{dx}{F(x)} \quad (18)
\]
The function $G(Z)$ is a positive monotonically growing function of $Z$, bounded from above (one can ignore the trivial case where all $q_n$ except $q_1$ and $q_2$ are zero). Hence $\mu$ is bounded from below: $Z(\mu)$ has a singularity at some $\mu = \bar{\mu}$. Denote by $\bar{x}$ the radius of convergence of the series $F(Z)$. The critical value of $\mu$ is given by

$$\bar{\mu} = -\log G(\bar{x})$$

(19)

This formula holds also when the radius of convergence $\bar{x}$ is infinite, since all terms in the series (17) are positive and the integral in (19) is convergent in all cases of interest: $G(\infty) < \infty$.

**B. Degree distribution**

The degree distribution calculated using (8) is

$$\pi_n = \frac{1}{G(\bar{x})} \frac{q_n}{(n-1)!} \int_{0}^{\bar{x}} \frac{dx}{F(x)^2} x^{n-1}$$

(20)

Again, this formula is also valid when $\bar{x} = \infty$.

Summing over $n$ using the definitions of $F$ and $G$ one easily checks that $\pi_n$ is normalized to unity, as it should. One further finds

$$\sum_n n \pi_n = 2 - \frac{\bar{x}}{F(\bar{x})G(\bar{x})}$$

(21)

On a tree, the r.h.s. should equal 2. This is the case when $F(x)$ diverges at $x = \bar{x}$. Otherwise one encounters a pathology, which looks similar to that appearing in some maximally random tree models (and in the so-called balls-in-boxes model, see [3, 34]), where working in the large $N$ limit one misses singular node(s) contributing term(s) of the type $N^{-1}\delta(n-cN)$. In the limit such nonuniformly behaving terms do not contribute to the normalization but do contribute to the r.h.s. of (21). It will be shown later that when $F(\bar{x}) < \infty$ the average distance between nodes is finite. This means that singular nodes (s) - with unbounded connectivity - are indeed expected to show up. In deriving (20) the large $N$ limit has been implicitly used and it is an educated guess that one again misses the singular node(s).

**C. Ancestor-descendant correlation**

Now, we turn to the calculation of the ancestor-descendant degree correlation. It is obvious that an ancestor plays the role of the root of the subgraph involving all its descendants. One can read from (14) the degree distribution of the root:

$$z_l(N) = \frac{1}{N} \frac{q_l}{(l-1)!} \sum_{N_1,\ldots,N_{l-1}} \delta_{N_1+\cdots+N_{l-1},N-1} \prod_{i=1}^{l-1} Z_{N_i}$$

(22)

Going over to the grand-canonical ensemble one finds:

$$\frac{dZ_l(\mu)}{d\mu} = -e^{-\mu} \frac{q_l}{(l-1)!} Z_l^{l-1}(\mu)$$

(23)

which, taking (16) into account and after integration yields

$$Z_l(\mu(Z)) = \frac{q_l}{(l-1)!} \int_{0}^{Z} d\bar{x} \frac{\bar{x}^{l-1}}{F(\bar{x})}$$

(24)

Using similar arguments one writes the weight of graphs where the root has the degree $l$ and its daughter the degree $k$ as

$$z_{kl}(N) = \frac{q_l}{N(l-2)!} \sum_{N_1,\ldots,N_{l-1}} \delta_{N_1+\cdots+N_{l-1},N-1} \times$$

$$\prod_{i=1}^{l-2} Z_{N_i}, z_k(N_{l-1})$$

(25)

Hence

$$\frac{dZ_{kl}(\mu)}{d\mu} = -e^{-\mu} \frac{q_l}{(l-2)!} \frac{q_k}{(k-1)!} Z_l^{l-2}(\mu) Z_k(\mu)$$

(26)

Integrating the above equation one finally obtains

$$Z_{kl}(\mu(Z)) = \frac{q_l}{(l-2)!} \frac{q_k}{(k-1)!} Z_l^{l-2}(\mu) Z_k(\mu)$$

(27)

which is the conditional probability, up to normalization, that a descendant has the degree $k$ when the ancestor’s degree is $l$. The normalization is determined summing over $k$ on the r.h.s. above, with the result $(l-1)Z_l(\mu)$. It is a slightly different measure of neighbor correlation than that proposed in ref. [6], but it carries similar information. Because of the integration the dependence on $k$ and $l$ does not factorize, in general.

Eq. (27) holds in the grand-canonical ensemble. One would like to have an expression valid in the canonical ensemble, where the graph has a well defined number of nodes. This requires Laplace transforming the r.h.s. of eq. (27) (one should transform first and normalize next). One can argue that in the thermodynamical limit and in the regime $\delta \mu \to 0$ this often amounts to just replace $Z \to \bar{x}$ in (27). Indeed, let $Z - \bar{x} \sim \delta \mu^\alpha$. Then

$$\int d\delta \mu e^{\delta \mu N} Z_{kl}(\mu) \approx Z_{kl}(\bar{\mu}) \int d\delta \mu e^{\delta \mu N - \delta \mu^\alpha}$$

(28)

Evaluating the integral by the saddle-point method one gets an exponential of a quantity scaling like $N^{\alpha/(\alpha-1)}$. This gives a factor of unity in the limit $N \to \infty$, provided $0 < \alpha < 1$, a condition often met in applications.
D. Fractal dimension

Repeating over and over the iteration process leading to eq. (27) one gets

$$Z_{k_1, k_2, \ldots, k_r}(\mu(Z)) = \prod_{j=2}^{r} \frac{q_{k_j}}{(k_j - 2)!} \frac{q_{k_1}}{(k_1 - 1)!} \int_{0}^{Z} dx_r \frac{x_r^{k_r - 2}}{F(x_r)} \times \int_{0}^{x_r} dx_{r-1} \frac{x_{r-1}^{k_{r-1} - 2}}{F(x_{r-1})} \cdots \int_{0}^{x_2} dx_1 \frac{x_1^{k_1 - 1}}{F(x_1)}$$

(29)

Summing over node degrees $k_1, k_2, \ldots, k_r$ one obtains the weight of all graphs with a point separated by $r$ links from the root, i.e. the two-point correlation function $C(r, \mu)$ introduced in sect. 1.2:

$$C(r, \mu(Z)) = \int_{0}^{Z} dx_r \frac{F'(x_r)}{F(x_r)} \int_{0}^{x_r} dx_{r-1} \frac{F'(x_{r-1})}{F(x_{r-1})} \cdots \times \int_{0}^{x_2} dx_2 \frac{F'(x_2)}{F(x_2)} \int_{0}^{x_2} dx_1$$

(30)

For finite $\bar{x}$, replacing the upper limit of integration over $x_1$ by $\bar{x}$ and performing all integrations, one gets

$$C(r, \mu(Z)) \leq \bar{x} \left( \frac{\ln F(Z)}{r - 1} \right)^{r - 1}$$

(31)

Hence, the tail of $C(r, \mu)$ falls at least as fast as a Poissonian. Consequently $\langle r \rangle_{\mu}$ grows at most like $\ln F(Z)$. Assuming that $F(z)$ has at most a power singularity at $z = \bar{x}$ one concludes that

$$\langle r \rangle_{\mu} \leq \text{const} \ln \frac{1}{\delta \mu}$$

(32)

and therefore

$$\langle r \rangle_N \leq \text{const} \ln N$$

(33)

since $\delta \mu$ scales like $N^{-1}$. The argument is rather heuristic, but suggestive (see also the examples in the next section). It appears that generically the causal trees have the small-world property $d_{\mu} = \infty$, contrary to the maximum entropy trees whose generic fractal dimension is finite [3, 39, 41]. This phenomenon is easy to understand intuitively: the causal structure suppresses long branches. This can be seen by noting that along a branch from the root to the leaf no label permutations are possible, hence a tree with a few long branches admits much less causal labelings then a “short fat” one.

E. Synchronic view of growing networks

So far, our discussion was very general. Let us now establish a bridge to the popular growing network models.

Of course, here we consider only those models, where one constructs tree graphs. Successive nodes are attached, one at a time, the attachment probability being a function of the degree of the target node:

$$\text{Prob}(k \mid t) = \frac{A_k}{A(t)} \quad \text{with} \quad A(t) = \sum_k N_k(t) A_k$$

(34)

where $N_k(t)$ is the number of vertices with degree $k$ in the tree at time $t$. It is obvious that the tree constructed that way has a causal structure: nodes are labeled by the attachment time.

Notice, that from the perspective of a model builder, the concepts of causal and growing networks are complementary rather than equivalent. A causal network is defined by specifying the microstate weights. Every growing network is causal, of course, but the weights corresponding to a given growth process can have a very complicated, non-local structure. And conversely, given a set of weights it is, in general, not evident what is the corresponding growth process. Only for a class of models there exists a stationary attachment kernel $A_k$.

For linear or shifted linear attachment kernels $A_k$ the normalization factor $1/A(t)$ depends only on the size of the previous configuration and is therefore the same for all trees of the same size [37]. Hence, the preferential attachment recipe is compatible with the factorization of $\rho(T)$. Working in the canonical ensemble, at fixed time, we can drop the normalization factor altogether without any loss of generality and set [38]

$$q_n = q_1 \prod_{k=1}^{n-1} A_k, \quad n > 1$$

(35)

where $q_1$ is some positive constant (eventually set to 1 in explicit calculations). It is instructive to check by inspection that the graph weights produced by the recursion relation (14), coincide with those generated by the growing network model recipe.

F. Examples

1. Barabasi-Albert model [4]

In this model $A_k = k$. Therefore $q_n = (n-1)!$, $F(x) = (1 - x)^{-1}$ and $\bar{x} = 1$. Thus $G(x) = x - \frac{1}{2} x^2$ and the solution to the equation (18) is

$$Z(\mu) = 1 - \sqrt{1 - 2e^{-\mu}} \approx 1 - \sqrt{\delta \mu}$$

(36)

The degree distribution is found from (20):

$$\pi_n = 2 \int_{0}^{1} dx \left( 1 - x \right)^2 x^{n-1} = \frac{4}{n(n+1)(n+2)}$$

(37)

which coincides with the solution given in refs. [6, 36].
The near-neighbor correlation is readily found from (27): 
\[ Z_{kl} = (l - 1) \int_0^1 dx_2 (1 - x_2) x_2^{l-2} \int_0^{x_2} dx_1 (1 - x_1) x_1^{k-1} \]
\[ = \frac{l - 1}{k(k + 1)(k + l - 1)(k + l)} \] (38)
This is very similar to the result of ref. [6], where a slightly different quantity has been calculated. The physical content is the same: the causal structure has induced correlations between the node degrees.

Since in this example 
\[ \int_0^{x_2} dx_2 \frac{F'(x_2)}{F(x_2)} \int_0^{x_2} dx_1 \left( \frac{F'(x_2)}{F(x_2)} - 1 \right) \] (39)
one has 
\[ C(r, \mu(Z)) = \frac{(\ln F(Z))^{r-1}}{(r-1)!} - C(r - 1, \mu(Z)) \] (40)
Hence 
\[ \langle r \rangle_{\mu} \sim \ln F(Z) \sim \ln \frac{1}{\sqrt{\delta \mu}} \] (41)
which implies the following scaling law:
\[ \langle r \rangle_N \sim \frac{1}{2} \ln N \] (42)

2. Krapivsky-Redner model [6]

Now \( A_k = k + w, q_n = \Gamma(n + w) \) and \( F(x) = \Gamma(w + 1)(1 - x)^{-w-1}. \) (43)

Of course \( \bar{x} = 1 \) and 
\[ G(1) = \frac{1}{(2 + w)\Gamma(w + 1)} \] (44)

Using the above and evaluating the Euler integral that appears in the present case on the r.h.s. of (20) one obtains 
\[ \pi_n = \frac{(2 + w)\Gamma(3 + 2w)}{\Gamma(1+ w) \Gamma(3 + 3 + 2w)} \frac{\Gamma(n + w)}{\Gamma(3 + n + 2w)} \] (45)

Again this reproduces exactly the result of ref. [6]. The reader can easily calculate the correlation \( Z_{kl}. \) We skip this calculation here, because the result is not particularly instructive: the remarkable fact is the very existence of the correlation, not its particular form, which in this particular case is rather cumbersome.

The calculation of \( C(r, \mu) \) is identical to that carried out for the Barabasi-Albert model, except that 
\[ Z = 1 - \delta \mu = 2, \delta \mu \to 0 \] (46)
which implies 
\[ \langle r \rangle_N \sim \frac{w + 1}{w + 2} \ln N \] (47)

3. Constant attachment kernel

For \( A_k = 1 \)
\[ F(x) = \sum_{k=1}^{\infty} \frac{1}{\Gamma(k)} x^{k-1} = e^x, \] (48)

The interest of this example is in the infinite radius of convergence of the above series: \( x = \infty. \) The degree distribution is
\[ \pi_n = \frac{1}{\Gamma(n)} \int_0^{\infty} dx e^{-2x} x^{n-1} = 2^{-n} \] (49)
a result found by several people, including the authors of ref. [6]. We again skip the calculation of \( Z_{kl}. \)

Since \( d \ln F(x) = dx \) one finds 
\[ C(r, \mu(Z)) = \frac{Z^r}{r!} \] (50)
and using
\[ Z = \ln \frac{1}{\delta \mu}, \delta \mu \to 0 \] (51)
one derives
\[ \langle r \rangle_N \sim \ln N \] (52)

III. CAUSAL VERSUS MAXIMALLY RANDOM TREES

A. An important tiny difference

It is instructive to consider for also the well known case of maximum entropy trees (cf. ref. [3, 39–41]). This will help putting the results of the preceding section in proper perspective. As in the preceding section we start with the composition rule for trees, which in the present case, when the causality constraint is lifted, reads:
\[ L(T_1 \oplus \cdots \oplus T_k) = \frac{(N + 1)!}{N! \cdots N_k! k!} L(T_1) \cdots L(T_k) \] (53)

Compared to (11) the difference may seem tiny: one just has \( (N + 1)! \) instead of \( N! \) in the numerator on the r.h.s.. It is so because there is no causality constraint and therefore all \( N + 1 \) labels can be arbitrarily distributed among the trees. However, this tiny difference has rather dramatic consequences. Indeed, repeating the steps which led from (11) to (16) one obtains
\[ Z(\mu) = e^{-\mu} F(Z) \] (54)

No derivative appears on the left-hand side! Instead of eq. (18) one has
\[ e^{-\mu} = H(Z) = \frac{Z}{F(Z)} \] (55)
where the function $H(Z)$ plays the role analogous to that of $G(Z)$ in the preceding section. Eq. (55) implies that the vertex degree distribution is

$$\pi_n = \frac{1}{F(x_*)} \frac{q_n x_n^{n-1}}{(n-1)!}$$  \hspace{1cm} (56)$$

Here $x_* = \min(x_{\text{max}}, \bar{x})$ and $x_{\text{max}}$ is the position of the maximum of the function $H(x) : H'(x_{\text{max}}) = 0, H''(x_{\text{max}}) < 0$.

Since no derivatives appear as one goes over to the grand-canonical ensemble, one does not integrate either. Therefore, iterating the recursion relation one finds that $Z_{kl}(\mu)$ and $C(r, \mu)$ factorize. The latter equals

$$C(r, \mu) \propto (e^{-\mu} F'(Z))^r$$  \hspace{1cm} (57)$$
as first derived by Ambjørn et al [39] using diagrammatic arguments.

Let us now consider three examples, with $q_n$ chosen as in sects. IIF.1 - IIF.3 respectively.

**B. Examples**

**1. First example: $q_n = (n - 1)!$**

With this choice, that of sect. IIF.1, the function $H(x)$ reads $H(x) = x - x^2$ and has its maximum at $x = 1/2$. Hence $x_* = 1/2$. Since $F'(x_*) = 2$, the degree distribution calculated from (56) is now

$$\pi_n = 2^{-n}$$  \hspace{1cm} (58)$$
as in sect. IIF.3!

It is easy to check that for small $\delta \mu$ one has

$$e^{-\mu} F'(Z(\mu)) = 1 - \sqrt{\delta \mu}$$  \hspace{1cm} (59)$$

and therefore

$$C(r, \mu) \propto e^{-\sqrt{\delta \mu} r}$$  \hspace{1cm} (60)$$

which implies

$$\langle r \rangle_N \sim N^{1/2}$$  \hspace{1cm} (61)$$

Hence, $d_H = 2$, the generic value [39].

**2. Second example: $q_n = \Gamma(n + w)$**

With the choice of sect. IIF.2 the function $H(x) = \Gamma(w + 1)x(1 - x)^{w+1}$ has its maximum at $x_{\text{max}} = 1/(2 + w)$, which is smaller than the radius of convergence $\bar{x} = 1$ of the series $F(x)$ as long as $w > -1$. Thus $x_* = 1/(2 + w)$ and

$$\pi_n = \frac{2 + w}{\Gamma(1 + w)} \left( \frac{1 + w}{2 + w} \right)^{1+w} \frac{\Gamma(n + w)}{\Gamma(n)} \left( \frac{1}{2 + w} \right)^n$$  \hspace{1cm} (62)$$

The fall of the degree distribution is again exponential. One easily checks that again $d_H = 2$.

**3. Third example: $q_n = 1$**

With the choice of sect. IIF.3 the function $H(x) = xe^{-x}$ has its maximum at $x_{\text{max}} = 1$. Thus $x_* = 1$ and correspondingly

$$\pi_n = \frac{e^{-1}}{(n-1)!}$$  \hspace{1cm} (63)$$

One can easily check that this result holds for a more general family of weights $q_n = \alpha \beta^{n-1}$ independently of the values of $\alpha$ and $\beta$, as long as they are positive. Again $d_H = 2$.

**C. How to get identical degree distribution in the two models**

It is easy to adjust the input parameters of the two models to obtain identical degree distributions: Suppose that in the causal model the degree distribution is $\pi_n$. For a connected tree one necessarily has

$$\sum_n n \pi_n = 2$$  \hspace{1cm} (64)$$

Set in the maximally random model

$$q_n = (n - 1)! \pi_n$$  \hspace{1cm} (65)$$

Obviously

$$[H^{-1}]'(1) \equiv \sum_n (n - 2) \pi_n = 0$$  \hspace{1cm} (66)$$

and $[H^{-1}]''(1) > 0$. Thus, $H(x)$ has a maximum at $x = 1$. One easily convinces oneself that this is the only maximum of that function. Furthermore, by assumption (see (64)), the radius of convergence in $F(x)$ is $\geq 1$. Hence $x_* = 1$ and

$$\pi_n^{\text{random}} = \pi_n$$  \hspace{1cm} (67)$$

by virtue of eq. (56). However, the coincidence of the degree distributions does not imply that geometries are similar. On the contrary, as already emphasized, the graph linear sizes have generically a very different scaling behavior in the two models (see also some computer simulation results in [42]).

**IV. SUMMARY AND CONCLUSION**

The results of this paper are another illustration of the claim that the opposition between diachrony and synchrony is to large extent an illusion, except if one is interested in very specific phenomena, like aging, intrinsically reflecting the running of time. We have discussed the geometry of networks endowed with a causal structure.
using the conventional framework of equilibrium statistical mechanics. Hence, models that are usually described by specific master equations and static, maximum entropy models have been treated alike. We focused on tree graphs, because only for trees we are able to proceed analytically. We have derived general formulae describing the degree distribution, the ancestor-descendant correlation and the probability a node lives at a given geodesic distance from the root. Using this last results have shown that our causal networks have generically the small-world property, i.e., their Hausdorff dimension is finite.

We have also compared the causal model with the maximally random one, assuming the same microstate weights. Because of different symmetry properties of the graphs - in the causal model only a subclass of labelings is allowed - the geometries are dramatically different: in the causal model the degree distribution is qualitatively different, inter-node correlations are induced and the Hausdorff dimension becomes infinite instead of being finite.

[31] A classical reference to tree graphs is G. Polya, R.C. Read, Combinatorial enumeration of groups, graphs and chemical compounds, Springer, New York 1987. A modern and very accessible starting point for a study of analytic combinatorics is the book project by P. Flajolet and R. Sedgewick http://algo.inria.fr/flajolet/Publications/books.html.

[32] Compare this definition to that of ref. [3], where graphs are identified with the Feynman diagrams of a minifield theory. Individual microstates are given the same weight in both models, provided one sets $q_{n} = n!p_{m}$, where $p_{m}$ are the minifield theory couplings. However, in ref. [3] all labelings were accepted (maximum entropy model), while in this paper we impose the causality constraint satisfied within a sub-class of labelings only.

[33] The structure of a causal tree is determined if one gives the labels of the parents of each node. The root has label 1 and no parent. The node with label 2 has only one parent, the root. There are two candidates for being the parent of the node with label 3: the root and the node with label 2. There are three candidates for being the parent of the node with label 3, etc. Pursuing the argument and counting the number of distinct trees one obtains the result quoted in the text.

[35] In comparing our formulae to those appearing in the literature one should remember that our graphs are not assumed to be drawn in a plane. This is the origin of $1/k!$ in (11), $1/(n - 1)!$ in (17) etc. The physics is unchanged when going from unconstrained to planar trees one changes the node weights: $q_{n} / (n - 1)! \rightarrow q_{n}$.

[36] S.N. Dorogovtsev, J.F.F. Mendes, A.N. Samukhin, Phys. Rev. Lett. 85, 4633 (2000).

[37] For other kernels one could perhaps make the approximation done by the authors of ref. [6], i.e., assume that $A(t) = \mu N$.

[38] Those factors may be important if one wants to consider
the thermodynamic limit $N \to \infty$.
