Rotated ripple structures (RRS) on sputter eroded surfaces are potential candidates for nanoscale wire fabrication. We show that the necessary condition for RRS formation is that the width of the collision cascade in the longitudinal direction has to be larger than that in the transverse direction, which can be achieved by using high energy ion beams. By calculating the structure factor for the RRS we find that they are more regular and their amplitude is more enhanced compared to the much studied ripple structure forming in the linear regime of sputter erosion.

The fabrication of nanoscale surface structures such as quantum dots (QDs) and quantum wires (QWs), have attracted considerable attention due to their applications in optical and electronic devices. These nanostructures form thanks to various self-assembled mechanisms, induced by the combined effect of strain and growth kinetics. Yet, the strained nanostructures obtained by lithographic methods are often considered prime candidates to overcome these shortcomings, but their limited resolution offers further challenges. Consequently, there is continued high demand for alternative methods that would allow low cost and efficient mass fabrication of nanoscale surface structures. In the light of these technological and scientific driving forces, the recent demonstration by Facsko et al. that low-energy (40 eV ~ 1.8 keV) normal incident Ar⁺ sputtering on GaSb (100) surfaces leads to nanoscale islands which display remarkably good hexagonal ordering and have a uniform size distribution, has captured the interest of the scientific community.

It is known that the morphological evolution of a sputter eroded surface is well approximated by the noisy nonlinear Kuramoto-Sivashinsky (KS) equation,

\[ \partial_t h = \nu_x \partial^4_x h + \nu_y \partial^4_y h - D_{xx} \partial^2_x h - D_{yy} \partial^2_y h - D_{xy} \partial^2_x \partial^2_y h + \frac{\lambda_x}{2} (\partial_x h)^2 + \frac{\lambda_y}{2} (\partial_y h)^2 + \xi(x, y, t), \]  

where \( \nu_x \) and \( \nu_y \) describe the tilt-dependent erosion rates in each direction; and \( \xi(x, y, t) \) is an uncorrelated white noise with zero mean, mimicking the randomness resulting from the stochastic nature of ion arrival to the surface. At low temperatures all the coefficients in Eq. (1) depend on experimental parameters such as the ion beam flux \( f \), the ion beam energy \( \epsilon \), and the incidence angle of ion beam \( \theta \). At high temperatures \( D \) depends on surface temperature. For the sputter erosion process \( \nu < 0 \) and \( D > 0 \), while the signs of \( \lambda_x \) and \( \lambda_y \) vary depending on the incident angle of the ion beam.

Recently numerical simulations have shown that there is a clear separation of the linear and nonlinear regimes in time. Up to a crossover time \( \tau_1 \) the surface is eroded as if the nonlinear terms would be completely absent, following the predictions of the linear theory (i.e. \( \lambda_x = \lambda_y = 0 \) in Eq. (1)). After \( \tau_1 \), however, the nonlinear terms with coefficients \( \lambda_x \) and \( \lambda_y \) take over and completely determine the surface morphology. The transition from the linear to the nonlinear regime can be seen either by monitoring the surface width (which is proportional to the ripple amplitude) or the erosion velocity.

In the nonlinear regime the case \( \lambda_x \lambda_y < 0 \) is in particular interesting. The surface morphology in this case exhibits another transition from kinetic roughening to a rotated ripple structures (RRS) at a second crossover time \( \tau_2 \) (\( \tau_2 > \tau_1 \)), as first predicted by Rost and Krug and observed numerically. Moreover, it was found that the RRS is straighter than the ripple pattern forming in the linear regime, making it a potential candidate for nanowire fabrication. In this Letter we investigate the necessary conditions for the formation of RRSs and the impact of the various experimentally controllable parameters on the morphology of the RRS. We find that at low temperatures the RRSs form when the longitudinal width \( \sigma \) of the damage cascade generated by the ion beam is larger than the transverse width \( \mu \), which can be achieved for high energy \( \epsilon \). When the energy is too high, however, the crossover time \( \tau_2 \) becomes too long. Thus, we predict that the RRS structure could be obtained in a moderate range of the incident energy, using an appropriate exposure time and low temperatures.

Rotated ripple structures form when \( \lambda_x \lambda_y < 0 \) and the rotation angle is given by \( \phi_c = \tan^{-1} \sqrt{-\lambda_x/\lambda_y} \). As shown in Fig. 1, the angle \( \phi_c \) increases with the ratio \( a_\mu = a/\mu \), but decreases with the incident angle \( \theta \), where \( a \) denotes the penetration depth of the ion beam and \( a_\mu \) depends on the ion beam energy \( \epsilon \). The KS equation in the rotated frame can be written in the same form as Eq. (1) except that the coefficients \( \nu, D, \) and \( \lambda \) are replaced by \( \nu', D', \) and \( \lambda' \), which are functions of those in the original frame and the angle \( \phi_c \). In the rotated frame one of the coefficients of the nonlinear terms, say \( \lambda'_x \), is equal to zero, and the other is given by \( \lambda'_y = \lambda_x + \lambda_y \). Where \( (x', y') \) represents the coordinates in the rotated frame. Since \( \lambda'_y \) vanishes, the dynamic equation in the
$x'$ direction becomes linear. Consequently, the ripple pattern is along the $x'$ direction as long as (i) $\nu_{x'} < 0$; (ii) $D_{x',y'} > 0$; and (iii) $\lambda_{x}\lambda_{y} < 0$. Therefore the conditions (i), (ii), and (iii) are the necessary conditions for the formation of the RRS.

We investigate the satisfiability of these conditions in the parameter space ($\theta, a_{\mu} = a/\mu$) for different values of $a_{\sigma} = a/\sigma$. We find that when $a_{\mu} > 1$ and $a_{\sigma} = 1$ or $a_{\mu} > 2$ and $a_{\sigma} = 2$, the RRS can form in the region depicted in Fig. 2. For $a_{\mu} < 1$ given $a_{\sigma} = 1$, the shaded region satisfying (i) – (iii) scarcely exists, so that the formation of RRS is less likely. That means the RRSs are expected to form when the longitudinal width $\sigma$ is larger than the transverse width $\mu$, that is, $\sigma > \mu$. Recent experimental results indicate that for graphite surfaces the use of a high energy ion beam increases the wavelength of the RRSs occurring during low energy ion beam sputtering. Since high energy ion beam causes longer crossover time for the formation of nanoscale dots [10].

In summary, we examined the necessary conditions for the formation of RRSs, potential candidates for nanowires for electron transport. We predict that the RRS can be generated under high energy ion beam, in contrast with the formation of nanoscale dots structure occurring during low energy ion beam sputtering. Since high energy ion beam causes longer crossover time for the formation of the RRS, exposure time of the ion beam has to be adjusted to obtain the desired RRS.

FIG. 1. The rotation angle $\phi_c$ as a function of $a_\mu$ at $\theta = 50^\circ$. The inset shows $\phi_c$ versus $\theta$ for $a_\mu = 1.5$. The rotation angle increases as the ratio $a_\mu$ increases, but decreases with the incident angle $\theta$.

FIG. 2. The shaded region in the parameter space ($\theta, a_\mu$) for $a_\sigma = 1$ (inset: for $a_\sigma = 2$) corresponds to the region where the RRS can form.

FIG. 3. Surface morphology of the RRS, as generated by numerical simulations, with $a_\mu = 1.3$, $a_\sigma = 1$ and $\theta = 43.56$ degree.

FIG. 4. The amplitude of the structure factor $|S(q')|$ for the RRS shown in Fig. 3. The peak of the structure factor is at $aq'_x, c = 0.33$ and $q'_y, c = 0$, implying that the wire structure is straight along the $y'$ axis. The inset shows the comparison between the amplitudes of the structure factor for the RRS (solid line) and for the linear ripple (dotted line), implying the amplitude of the RRS is about a factor of $10^7$ larger compared to that of the ripple structure formed in the linear regime.

FIG. 5. The wavelength of the RRS in units of $a$ as a, showing function of $a_\mu$ ($\theta = 50^\circ$ degree). Inset: The wavelength versus $\theta$ at $a_\mu = 1.5$. 

FIG. 6. The shaded region in the parameter space ($\theta, a_\mu$) for $a_\sigma = 1$ (inset: for $a_\sigma = 2$) corresponds to the region where the RRS can form.
