Age-related hearing loss is a chronic degenerative disorder affecting one in two individuals above the age of 75. Current population projections predict a steady climb in the number of older individuals making the search for interventions to prevent or reverse this disorder even more critical. There is growing acceptance that aberrant activity of resident or infiltrating immune cells, such as macrophages, is a major factor contributing to the onset and progression of age-related degenerative diseases. However, how macrophage populations and their functionally-driven morphological characteristics change with age in the human cochlea remains largely unknown. In this study, we employed immunohistochemical approaches along with confocal and super-resolution imaging, three-dimensional reconstructions, and quantitative analysis to determine age-related changes in macrophage numbers and morphology as well as interactions with other cell-types and structures of the auditory nerve and lateral wall in the human cochlea. In the cochlea of human ears from young and middle aged adults those macrophages in the auditory nerve assumed a worm-like structure in contrast to those in the spiral ligament or associated with the dense microvascular network in the stria vascularis which exhibited a highly ramified morphology. Macrophages in both the auditory nerve and cochlear lateral wall showed morphological alterations with age. The population of activated macrophages in the auditory nerve increased in cochleas obtained from older donors. Dual-immunohistochemical staining with macrophage, myelin, and neuronal markers revealed increased interactions of macrophages with the glial and neuronal components of the aged auditory nerve. These findings implicate the involvement of abnormal macrophage-glia interactions in age-related physiological and pathological alterations in the human cochlea. There is clearly a need to further investigate the contribution of macrophage-associated inflammatory dysregulation in human presbyacusis.

Keywords: hearing loss, macrophage, aging, human temporal bone, cochlea

INTRODUCTION

Age-related hearing loss (ARHL), or presbyacusis, is one of the most prevalent chronic disorders affecting the older adult population in the US, with one in three individuals over the age of 60 and one in two individuals over the age of 75 reporting moderate-to-severe hearing loss (1). ARHL is characterized by reduced hearing sensitivity as measured by pure-tone thresholds with individuals...
often complaining of difficulties understanding speech, especially in noisy environments (2). This reduction in hearing may lead to quality of life changes such as social isolation and depression (3).

The most common treatment recommendation for ARHL is hearing aids. For those with moderate-to-profound hearing loss who no longer receive benefit from hearing aids, cochlear implants may be recommended. Cochlear implants are surgically placed devices which electrically stimulate the nerves of the inner ear directly. It has been shown that cochlear implantation may induce activation of both immune and non-immune cells, and thereby have a negative impact on the outcome of this therapeutic approach (4). Interrogation of the cochlear inflammatory response to implantation in a mouse model identified a significant up-regulation in the expression of pro-inflammatory cytokines such as IL-1β. A better understanding of the specific cellular and molecular mechanisms associated with ARHL, in particular the role of the immune system, is necessary to identify targetable cells and pathways for the development of new and novel approaches of remediation.

There is now growing acceptance that aberrant immune cell activity is a contributive factor in the onset and progression of age-related degenerative diseases (5, 6). This includes disorders such as cardiovascular disease, which has high prevalence among older individuals and is co-morbid with ARHL (7). Characterization of immune cell activity in cardiovascular disease pathology indicates atherosclerotic plaque formation is associated with the phagocytic uptake of lipid particles by macrophages (6, 8). Dementia, another chronic disorder which shows strong correlation with ARHL (9), is characterized by neurodegeneration in which the dysregulation of immune cell activity is a promising therapeutic target (5). For example, in Alzheimer’s disease, reduced degradation activity by microglia has been shown to contribute to the accumulation of amyloid-beta plaques and neurofibrillary tangles (10), which can be ameliorated by the presence of young microglial cells (11).

Previous studies on the cellular and molecular processes which contribute to ARHL have focused primarily on degenerative changes in sensory hair cells (12–14) and the auditory nerve (15, 16). Immunohistochemical analysis of immune cell distribution in the mouse and human cochlea, indicates that macrophages are largely excluded from the healthy adult organ of Corti, the cochlear region housing the inner and outer hair cells (17). Other studies have provided evidence demonstrating not only the presence of resident macrophages in the cochlear lateral wall and auditory nerve but also their direct interaction with the stria microvessels and spiral ganglion neurons in the human ear (18–20). Furthermore, recent studies indicate that activated microglia play an important role in the disruption of the blood-brain barrier and demyelination in the central nervous system (21, 22).

Based on the above observations, we hypothesized that macrophage function and activity in the cochlea changes with age and these changes may be a contributive factor to pathophysiological alterations of cochlear structures in ARHL. Here we have addressed this hypothesis by evaluating changes in the number and morphology of macrophages, together with observations of interactions between activated macrophages and other cochlear cell types and structures in the lateral wall and auditory nerve in an age-graded series of human inner ears.

### MATERIALS AND METHODS

#### Collection and Preparation of Cochlear Tissues

Human temporal bone samples were obtained from two sources; (1) the Medical University of South Carolina (MUSC) Hearing Research Program’s temporal bone collection generated from a longitudinal study of ARHL and (2) the MUSC Carroll A. Campbell, Jr. Neuropathology Laboratory Brain Bank. In all cases of HTB collection, written and informed consent was obtained from the next-of-kin in accordance with South Carolina laws and regulations. Temporal bone research was approved by the MUSC Institutional Review Board as not human subject research (Pro0030845). Table 1 lists the donors’ age, sex, and the time between death and fixation for the 12 human temporal bones used in this study. After removal of the specimen (23), scalar perfusion was performed with a 4% solution of paraformaldehyde as previously described (24, 25) and fixation was continued by immersion for 48–72 h. The bones were then rinsed with phosphate-buffered saline (PBS) and decalciﬁed in EDTA, for a period of 4–6 weeks as previously described (26, 27). Over this period, the specimens were trimmed to remove the hard bone covering the cochlea and vestibular apparatus of the inner ear. The inner ear portion of the trimmed temporal bones was processed for frozen sectioning and whole mount preparations as described previously (25, 28, 29).

For all analyses, the human cochlea samples were divided into two groups: younger group ranging in age from 20 to 65 years and older group ranging in age from 68 to >89 years (older).

#### Immunostaining and Quantitative Analysis of IBA1⁺ Cells

The whole mounts and frozen sections of inner ear tissue were subjected to immunofluorescence staining as described briefly below. Whole mounts were washed with PBS and incubated in 4:1:1 (methanol: 30% hydrogen peroxide: dimethyl

The numbers of IBA1\(^+\) cells located in the cochlear lateral wall and the auditory nerve within Rosenthal’s Canal were quantified on randomized sections (2–4 sections per sample) by researchers blinded to specimen age. In this study, cell counting was performed on the frozen cochlear sections that were developed with a fluorescence staining approach, but not the DAB immunoperoxidase secondary detection system (DAB150, Millipore). For dual-labeling, sections were processed using an avidin/biotin blocking kit (SP-2001, Vector) following the first staining reaction, according to the manufacturer’s instructions. After a 30-min incubation in 0.2% BSA in PBS, staining was continued overnight by incubation with a secondary primary antibody. Nuclear counterstaining was performed with either propidium iodide (PI) or 4′,6-diamidino-2-phenylindole (DAPI).

Image processing was performed using Zen Black or Zen 2012 Blue Edition (Carl Zeiss Microscopy), Adobe Photoshop CC (Adobe Systems), and GIMPshop (open source software).

RESULTS
Morphological Features of Macrophages Vary Between the Cochlear Lateral Wall and Auditory Nerve
To assess the morphology of resident macrophages in the human cochlea, we performed immunofluorescence staining using an antibody against the microglia/macroage specific protein, ionized calcium binding adaptor molecule 1 (IBA1). In young and middle-aged ears, marked differences in morphological characteristics were seen between macrophages in the stria vascularis (SV; Figures 1A,B) and those associated with the auditory nerve both in the osseous spiral lamina (Figures 1C,D) and Rosenthal’s canal (Figures 1E,F). Macrophages in the SV from 42- and a 55-year-old donor were characterized by cellular processes extending into the areas between marginal and basal cells, near the strial microvasculature (Figures 1A’,B’). This observation is in good agreement with a previous study showing strial macrophages interacting with the microvasculature (18). Observations of the auditory nerve in the same cochleas revealed macrophages in the osseous spiral lamina with a more bipolar architecture (Figure 1D, at this plane of view) and flat encroaching filopodia-like structures (Figure 1D’), suggesting interactions with peripheral neural projections. In Rosenthal’s canal, IBA1\(^+\) cells were observed with two distinct stellate forms, a less frequent form which was often oriented perpendicular to the axonal fibers (arrowhead, Figure 1F), and a more common “worm-like” cyto-architecture located near the neuronal soma (arrows, Figure 1F’). The differential characteristics of IBA1\(^+\) macrophages located in the auditory nerve and cochlear lateral wall were also revealed by peroxidase DAB immunohistochemistry with frozen sections (Figures 1G–J). These differences in macrophage morphology among different cochlear regions may indicate a variety of macrophage functions since each cochlear compartment contributes uniquely to auditory physiology.

Super-resolution imaging was also applied to visualize the morphological differences of the macrophages in the auditory nerve and the lateral wall. Figure 2 includes both the standard and super-resolution confocal images of IBA1\(^+\) macrophages taken from the same regions of the SV and auditory nerve in the middle-basal turn cochlea of a 55 year old donor. The enhancement in image quality and the power to resolve the...
Noble et al. Aged Macrophages in Human Cochlea

FIGURE 1 | Cochlear macrophages demonstrate unique morphologies in different regions of the human cochlea. Confocal imaging of immunofluorescence staining for ionized calcium-binding adaptor molecule-1 (IBA1⁺, green) identifies resident macrophages in the stria vascularis (A,B—SV), osseous spiral lamina (C,D—OSL), and Rosenthal’s canal (E,F—RC). Similar results were also revealed by peroxidase-DAB immunohistochemistry assay showing IBA1⁺ macrophages in the SV (G), OSL (H), and RC (I,J). Images in (A’,B’,D’,F’) are enlargements of the boxed areas in (A,B,D,F), respectively. The black and white image in the left of (A’) was included to show different cochlear locations. The image was taken from a cochlear section that was stained for Kir4.1 antibody (30) and the section was obtained from an 86-year-old donor (H55). Strial macrophages (A,B,G) emit cellular processes that extend short distances from the cell body (A’,B’). Macrophages in the OSL (C,D,H) are more worm-like in shape with thin cellular projections that sometimes wrap around structures (D’, arrowhead), most likely peripherally projecting axons, whereas macrophages in RC (E,F,I,J) typically have an elongated appearance (arrows); IBA1⁺ macrophages with multiple processes are also seen (arrowheads). Images were obtained from a 42-year-old donor (H109; A,C,E), a 55-year-old donor (H87; B,D,F,I) and a 57-year-old donor (H122; G,H,J). Locations in the cochlea are indicated on the cochlear map by a black and white image at the middle left. Scale bars in (A,B) = 20 µm; in (C) applies to (D–F) = 20 µm; in (G) applies to (H) = 30 µm, in (I) applies to (J) = 30 µm.

nanoscopic filaments extending from the subcellular elements of the macrophage is clearly visualized in the super resolution images (Figures 2A″,B″).

A recent human temporal bone study characterized a number of macrophage/microglia markers, including CD163, on celloidin embedded sections of temporal bones from normal individuals (19). CD163 is a scavenger receptor expressed on the cell surface of monocytes and macrophages (31) demonstrated to be responsive to pro- and anti-inflammatory stimuli (32). In the present study, frozen sections were stained with an antibody against CD163, and we assessed immunoreactivity and distribution in different cochlear regions. CD163⁺ macrophages were observed within the spiral ligament (SpL) of the cochlear lateral wall, osseous spiral lamina, and Rosenthal’s canal, as demonstrated by representative images in Figure 3. Immunostaining for CD163 appears to be less illustrative of the macrophage morphological features compared to IBA1 staining (Figure 1), thus IBA1 antibody was selected as the marker to evaluate macrophage morphology and quantitative analysis in the study.

Diversity of Macrophages Within the Cochlear Lateral Wall

Cochlear macrophage morphology was further examined in the suprastriatral, strial, and substrial regions of the cochlear
Age-Related Changes of Macrophages in the Cochlear Lateral Wall

Examination of the cochlear lateral wall from older donors revealed characteristic changes in IBA1+ macrophage morphology in the SV and SpL using both immunofluorescence staining (Figures 5A–D) and peroxidase DAB immunohistochemistry (Data not shown). In the SV of the younger donors, macrophages had little cytoplasm surrounding the nucleus and numerous projecting processes (Figure 5A). In contrast, in older donors the number of processes projecting from macrophages was reduced while cytoplasmic volume around the nucleus appeared to increase (Figure 5B). Macrophages in the adjacent SpL exhibited similar morphological alterations of increased cytoplasmic volume and reduced cellular processes in older donors (Figure 5D).

In order to quantitatively assess changes in the cellular properties of macrophages in the SpL, IBA1+ cells were counted...
in two age groups, younger vs. older donors (n = 5/group). The number of macrophages are reported as cell number per observed area, which included the entire cochlear turn. In the apical turn, the number of IBA1+ macrophages was very similar in the younger and older groups (2.7 ± 1.0 vs. 2.9 ± 1.0 cells, respectively, p = 0.34). Quantification of macrophage numbers in the middle (7.8 ± 3.5 vs. 10.7 ± 3.8 cells) and basal turn (11.3 ± 6.5 vs. 14.5 ± 6.1 cells) of younger vs. older ears, respectively, indicates a trending increase in both of these regions in the older group, but this change failed to reach statistical significance (p-values = 0.12 and 0.23, respectively). The results of cell counting from individual donors, listed in Table 3, reveal a large amount of variability in the younger control group. Activated macrophages, defined as IBA1+ cells with no or only a few cellular processes, were also quantified to determine if the number of activated macrophages changes with age. Table 4 lists these results from individual donors. No statistically significant differences were found. In the apical turn, the presence of activated macrophages in the SpL was unchanged (1.0 ± 1 vs. 1.0 ± 0.5 cells, p = 0.50); though a trending increase in the number of activated macrophages was noted for the middle (4.0 ± 3.3 vs. 6.4 ± 2.4 cells, p = 0.11) and basal turns (4.9 ± 3.0 vs. 7.9 ± 3.5 cells, p = 0.09) of the older group.

**Diverse Morphology of Macrophages in the Auditory Nerve**

A recent study employing super-resolution imaging in the human cochlea demonstrated that resident macrophages in the auditory nerve make contact with spiral ganglion neurons (18). Here we assessed the cellular morphology of the IBA1+ macrophages in the auditory nerve from an 87-year-old donor (Figure 6). In the middle turn (Figure 6A), the macrophages had thin cellular processes with little cytoplasm around the nucleus, an architecture possibly reflecting interactions with axons and neuronal cell soma. Macrophages in the basal turn from the same donor exhibit a markedly different appearance having amorphous or round shapes with less evidence of extended cellular projections (Figure 6B). Interestingly, no noticeable loss of β-Tubulin+ spiral ganglion neurons was identified in the basal turn of the auditory nerve of this donor (Figures 6C,D). These observations suggest the morphology and activity of macrophages may be dependent on not only cell death, but also location and physiological and/or pathological activity along the cochlear axis.

**Age-Related Changes in Number and Cellular Interactions of Macrophages in the Auditory Nerve**

We have previously demonstrated the presence of myelination in the parikarya of some Type I spiral ganglion in the human auditory nerve (24) and provide further evidence of this phenomenon (Figures 7A,B,D,E) in the current study. To assess macrophage interactions with components of the human auditory nerve, we performed dual labeling immunohistochemistry. Antibodies against either neurofilament 200 (NF; Figure 7C) or myelin basic protein (MBP;
Figures 7B,D–F) were used in combination with an anti-IBA1 antibody to label auditory nerve components and macrophages, respectively. Macrophages with a variety of morphologies interact with myelin or axons of the auditory nerve. The filopodia-like structures of IBA1+ macrophages are seen at discontinuities in the neurofilament bundles (Figure 7CI), running parallel to filamentous strands (Figure 7CII) as well as associated with the NF+ neuronal cell elements (Figure 7CIII). Analysis of IBA1+ macrophage interactions with MBP+ myelin (Figure 7D) revealed the encroachment of macrophage processes onto node of Ranvier-like structures (Figure 7DII) or spaces (Figure 7DIII) in the ensheathing membrane. IBA1+ macrophages with a rounded morphology were also observed interfacing directly with a myelinated axon (Figure 7DIII). Three-dimensional reconstructions of confocal image stacks from dual labeling with MBP and IBA1 provided further evidence supporting macrophage interactions with the myelin around the spiral ganglion neuron soma (Figure 7E). These macrophage-myelin interactions are also observed in the osseous spiral lamina, where macrophage processes encircle MBP+ myelin elements (shown in Figure 7F), as seen in the apical turn of a 42-year-old donor (H109).

To determine if age-associated alterations in morphology or cellular interactions occur in auditory nerve macrophages, dual labeling immunohistochemistry was applied using antibodies against IBA1 and MBP. Macrophages in the cochlea of a 31-year-old donor (Figure 8A) display an elongated shape, while those in the cochleas from 86- and 87-year-old donors (Figures 8B,C) have a more rounded or ovoid shape. Furthermore, macrophage processes in both older subjects demonstrated ensheathing behavior evidenced by IBA1+ processes encompassing myelinated axonal fibers (Figure 8B'). Quantification of IBA1+ cells in the middle turn of younger (n = 5) vs. older (n = 7) cochleas revealed a statistically significant increase in macrophage numbers in the auditory nerve with age (14.1 ± 4.0 vs. 19.0 ± 3.3 cells; p = 0.021). Results of the quantification for each donor sample are presented in Table 3.

DISCUSSION

Here for the first time we report observations of morphological diversity and age-related changes of macrophages in different regions of the human cochlea. Previous studies have characterized the expression of a number of key cellular markers—MHCII, CD11b, CD68, CD163, and IBA1—in macrophages of the human cochlea (18–20). Additionally, these reports described the morphological heterogeneity of macrophages within the human cochlea. However, none of these studies were able to conduct a quantitative analysis of age-related changes in either morphology or numbers of cochlear macrophages. The specimens used in the present study included 12 human donors from both sexes, with an age gradation of 20–89-years old allowed analysis of age-related changes in macrophage morphology and numbers in the different cochlear compartments, together with observations of interactions between macrophages and other cell types.

Confocal analysis of frozen sections and whole mount samples from younger ears stained for the macrophage specific marker IBA1 provided evidence to support the morphological diversity of resident immune cells in the lateral wall, as well as in the auditory nerve. In the stria vascularis, macrophages were found to possess diverse cellular phenotypes, reflective of their close interaction with the microvascular network in both mice and humans (34, 35). Here we provide evidence from 12 human temporal bone samples showing that macrophages located in the lateral wall are morphologically distinct from those observed in the auditory nerve. Immune cells in the osseous spiral lamina and Rosenthal's canal were typically “worm-like” in appearance whereas the cyto-architecture of macrophages in the stria vascularis and spiral ligament was more variable and differed from that in the auditory nerve.

It has been well-established that the function of immune cells, especially the macrophage, has a significant impact on its morphology. Macrophages in “surveillance-mode” are typified by a highly branched morphology, while those en route to a location...
Older and the extension of no or only a few cellular processes (of injury or performing phagocytosis possess an amoeboid shape and the extension of no or only a few cellular processes (33, 36). In the lateral wall, the more prevalent highly ramified cellular morphology of macrophages may be a reflection of their need to receive external stimuli to guide activity, whereas, the "worm-like" structure of the macrophages found in the auditory nerve, is more conducive to motility within this particular cochlear compartment, as suggested by their direct contact with the plasmolemma of glial cells ensheathing axons and neurons which agrees with the direct interaction of macrophages with ganglion neuron cell bodies in mice and humans (29, 37). These differences in morphology likely relate to differences in functional activity in the separate regions of the cochlea.

The diversity in macrophage morphology identified in the different sub-regions of the lateral wall in a single ear may be directly related to the local tissue microenvironment. The suprastrial region (above Reissner's membrane) and the substral region (below the basilar membrane) of the spiral ligament are largely occupied by type V and IV fibrocytes, respectively, that are bathed in perilymph (38). In these tissue spaces, resident immune cells were predominantly round or elongated in appearance with a few long processes extending from the cell body or, in some instances, more planar with the cytoplasm dispersed uniformly throughout the cell body. It is possible that variations in the architecture of the extracellular matrix or degree of spiral ligament involution could contribute to irregularities in macrophage cell shape (39). Interestingly, the expression pattern of ion transport enzymes by fibrocytes in the spiral ligament has been observed to change relative to the degree of strial atrophy in the aged gerbil cochlea (40).

The cells in the intrastrial space are exposed to an endolymph-like solution, where potassium is sequestered through an electrochemical gradient generated by the parenchymal cells of the stria vascularis and fibrocytes of the spiral ligament. Macrophages found in the intrastrial space are typically ramified
in appearance with long cellular processes extending from a central body. In contrast macrophages in the spiral ligament, strial macrophages are typically observed interacting with the microvasculature. While macrophages found in the spiral ligament most likely execute canonical tissue macrophage functions, such as phagocytic uptake and degradation of dead cells and debris, the exact role of intrastrial macrophages remains unknown. The current literature provides conflicting reports regarding macrophage contributions to regulation of blood-labyrinth barrier permeability (34, 41). However, depletion of macrophages during cochlear development in the postnatal mouse results in severe abnormalities of the stria vascularis, implying a role for macrophages in the structural maturation of this specialized epithelium (29). Therefore, further study of changes in macrophage morphology and intercellular dynamics under steady state conditions are needed to understand how this process is regulated.

In this study, results from observations of cochleas from older donors indicated that alterations in macrophage morphology may differ in locations along the tonotopic axis. Interestingly, profiles characteristic of activation were typically observed in the basal turns of the aged cochleas. Quantitative analysis revealed a trending increase in the number of macrophages in the middle and basal turns of the spiral ligament. This increase was accompanied by an increase in the number of macrophages lacking or having very few cellular processes. This finding agrees with observations in mice, showing that a larger proportion of resident immune cells underlying the basilar membrane along the cochlear spiral become more amoeboid in shape with age, indicative of a more active vs. an inactive state (33, 42). To date, in vitro evidence of inflammatory cytokine secretion by spiral ligament fibrocytes (43) suggests a possible mechanism for the production of chemotactic factors with age that may induce recruitment of macrophages. Additionally, observations of intravascular monocyte-like cells in the human cochlear lateral wall implicates blood vessels as a likely site of immune cell extravasation (18). In light of these findings, future studies should aim to identify the molecular mediators of macrophage recruitment and infiltration in the aging cochlear lateral wall.

Here we present evidence of macrophage interactions with the glial cell-associated myelinated axonal projections of the type I spiral ganglion neurons and cell bodies in the human cochlea. The increasing frequency of these interactions with age suggests that macrophage activation and abnormal macrophage-glia interactions may be a contributing factor to age-related auditory nerve degeneration. Interestingly, work by Wu et al. (44) assessing cochlear neuropathy in a cohort of 20 human cochleas from “normal-hearing” individuals (0–89 years old), identified the loss of peripherally projecting axonal fibers, which are myelinated by Schwann cells, as a primary pathological process associated with hair cell and spiral ganglion neuron loss.

**FIGURE 6** | IBA1+ macrophages located in the auditory nerve demonstrate spatially-dependent alterations in morphology. These images from the auditory nerve (AN) of an 87-year-old donor (H33) demonstrate region-dependent changes in macrophage morphology. IBA1+ macrophages in the middle turn (A) have an elongated spiral shape (arrows) whereas many cells in the basal turn (B) extend numerous short cellular projections (arrowheads), although there is no evidence supporting a robust loss of β-Tubulin+ SGNs (C,D), which appear in the same area of the AN. An inserted black and white image in the bottom-left of (A) shows the location of the AN in the cochlea. Scale bar in (B) applies to (A) = 20 µm; in (D) applies (C) = 20 µm.
We have shown previously in mice that cochlear macrophages in auditory nerves participate in modulation of glial cell numbers during postnatal development (29). In the present work, we provide evidence of direct interactions of macrophage with the myelinating glia of the auditory nerve in both Rosenthal's canal and the osseous spiral lamina. Quantitative analysis of an age-graded series of human cochleas as performed in this study indicated a statistically significant increase in macrophage numbers in the auditory nerve of the older group, suggesting macrophage activation occurs in the aged auditory nerve.
Recent immunohistochemical studies in mice have revealed the complex vascular network associated with the peripheral auditory nervous system, which may be the source of monocyte extravasation to the neural cochlear sub-compartment (45). Further work identifying the molecular components mediating macrophage-glia interactions and structural elements involved in immune cell infiltration are needed to better understand the role of resident and non-resident macrophages in the neural compartment.

“Inflammaging” describes the recently accepted phenomena by which human subjects, typically at the age of 65 and above, present with immune system dysregulation characterized by elevated levels of pro-inflammatory cytokines systemically and an impaired immune response (46–49). A limitation to the current study is the lack of evaluation for infiltration of other inflammatory cell types as lymphocyte infiltration is typically observed in neurodegenerative diseases (42, 50). The presence of CD4+ and CD8+ T-cells in the peripheral regions of Rosenthal’s canal and the spiral ligament of freshly frozen temporal bones has recently been reported (20). Macrophages expressing antigen presentation proteins, such as MHCII, and their interaction with the aforementioned T lymphocytes suggests that adaptive immunity is amongst the cellular immune response processes initiated within the cochlea (20, 51). Nonetheless, the morphological changes and increased numbers of cochlear macrophages observed with age in the lateral wall and auditory nerve is in agreement with functional activation and structural changes of microglia in the central nervous system (52). Future work should address the age-related degenerative pathology occurring in the auditory nerve and the lateral wall focusing on factors which may initiate or exacerbate the potential cochlear inflammaging phenomenon.
