Abstract. In this work, we have considered the interacting dynamical model taking the variable modified Chaplygin gas (VMCG) which plays as dark energy coupled to cold dark matter in the flat FRW universe. For the VMCG equation of state, we have chosen $B(a) = B_0 a^{-n}$. Since the nature of dark energy and dark matter is still unknown, it is possible to have an interaction between them and phenomenologically we choose the interaction term $Q = 3cH\rho$, where $c$ is the coupling parameter. We have converted all the equations in the dynamical system of equations by considering the dimensionless parameters and seen the evolution of the corresponding autonomous system. The feasible critical point has been found and for the stability of the dynamical system about the critical point, we linearize the governing equation around the critical point. We found that there exists a stable scaling (attractor) solution at late times of the Universe and found some physical range of $n$ and the interaction parameter $c$. We have shown that for our calculated physical range of the parameters, the Universe explores up to quintessence stage. The deceleration parameter, statefinder parameters, Hubble parameter and the scale factor have been calculated around the critical point. Finally, some consequences around the critical point, i.e., the distance measurement of the Universe like lookback time, luminosity distance, proper distance, angular diameter distance, comoving volume, distance modulus and probability of intersecting objects have been analyzed before and after the present age of the Universe.

1 Introduction

Recent observations of redshift and luminosity of type-Ia supernovae [1–4], WMAP [5], Chandra X-ray Observatory [6] etc. indicate that the universe is spatially flat and undergoing an accelerated expansion. The most important research field over the last few decades has been to find the existence of the dark energy which violates the strong energy condition, i.e., $p + 3\rho < 0$ [7–9]. The mystifying fluid, namely dark energy, is understood to dominate 70% of the Universe and have enough negative pressure to drive the current acceleration of 30% of dark matter (cold dark matters plus baryons). There are various candidates to play the role of the dark energy. The most obvious candidate for dark energy is the cosmological constant with the equation of state $p/\rho = -1$. The type of dark energy represented by a scalar field is often called quintessence. Other dark-energy candidates are namely tachyonic field [10], DBI-essence [11], Chaplygin gas [12], phantom, holographic dark energy, hessence dark energy [13], k-essence [14] and dilaton dark energy [15].

Recently the Chaplygin gas, also named quartessence, characterized by an exotic equation of state $p = -B/\rho$ ($B > 0$), was suggested as a candidate of a unified model of dark energy [12]. The Chaplygin gas behaves as pressureless fluid for small values of the scale factor and for large values of the scale factor as a cosmological constant, and tends to accelerate the expansion. The above equation was generalized to the form $p = -B/\rho^{\alpha}$, $0 \leq \alpha \leq 1$ [16–18]. Consequently this was modified to $p = A\rho - B/\rho^{\alpha}$, $0 \leq \alpha \leq 1$, $A > 0$ which is known as modified Chaplygin gas [19–21] and shows a radiation era ($A = 1/3$) when the scale factor $a(t)$ is vanishingly small and a $\Lambda$CDM model when the scale factor $a(t)$ is infinitely large. Variable Chaplygin gas first proposed by Guo and Zhang [22] with equation of state $p = -B/\rho$, where $B$ is a positive function of the cosmological scale factor “$a$” i.e., $B = B(a)$. This assumption is reasonable since $B(a)$ is related to the scalar potential if we take the Chaplygin gas as a Born-Infeld scalar field [23]. Afterward there are some

\textsuperscript{a} e-mail: bhadra.jhumpa@gmail.com
\textsuperscript{b} e-mail: ujjaldebnath@yahoo.com
works on variable Chaplygin gas model [25, 24]. Further, Debnath [26] introduced the variable modified Chaplygin gas (VMCG) for the acceleration of the universe. Several interesting features and physical interpretations of VMCG have been shown by several authors [27–30]. The dynamical system analysis of pure and generalized Chaplygin gas model and the nature of critical points have been analyzed for Einstein’s gravity and loop quantum gravity [31–36].

In this work, we consider a model of interacting variable modified Chaplygin gas (VMCG) with dark matter in the framework of the Einstein gravity. We construct the formalism of the autonomous dynamical system of equations for this interacting model. Since the nature of dark energy and dark matter is still unknown, it is possible to have an interaction between them and we choose the interaction term phenomenologically. We convert them to dimensionless form and perform a stability analysis and solve them numerically. We obtain a stable scaling solution (which is also an “attractor”) of the equations in the FRW model. Some consequences, like lookback time, proper distance, luminosity distance, angular diameter distance, comoving volume, distance modulus and probability of intersecting objects of the solution around the critical point have been investigated. We discuss our results in the final section.

2 Dynamical model of interacting VMCG and dark matter

We consider a spatially flat universe with VMCG as dark energy and dark matter interacting through an interaction term. Thus the Einstein equations and continuity equation of VMCG and dark matter can be written, respectively, as (choosing $8\pi G = c = 1$)

\[ H^2 = \frac{1}{3} \rho, \]

\[ \dot{H} = -\frac{1}{2} (p + \rho), \]

and

\[ \dot{\rho} + 3H(\rho + p) = 0, \]

where $\rho = \rho_{\text{vmcg}} + \rho_{\text{dm}}$ and $p = p_{\text{vmcg}} + p_{\text{dm}}$ ($p_{\text{dm}}$ is a very small quantity, somewhere dark matter assumed as pressureless quantity) are the total cosmic energy density and pressure, respectively, with the subscripts $\text{vmcg}$ and $\text{dm}$ denoting the VMCG and dark matter, respectively. Since we consider that the VMCG and dark matter do not conserve separately, their continuity equations are

\[ \dot{\rho}_{\text{vmcg}} + 3H(p_{\text{vmcg}} + p_{\text{dm}}) = -Q \]

and

\[ \dot{\rho}_{\text{dm}} + 3H(\rho_{\text{dm}} + p_{\text{dm}}) = Q. \]

To obtain a suitable evolution of the Universe, an interaction is often assumed such that the decay rate should be proportional to the present value of the Hubble parameter for a good fit to the expansion history of the Universe as determined by the Supernovae and CMB data [37]. Here $Q$ is the interaction term which has dimension of density multiplied by the Hubble parameter. For a suitable choice of $Q$, where $Q = 3cH\rho$, $c$ is the coupling parameter denoting the transfer strength. The interaction term cannot be traced out from the first principles due to unidentified scenario of both the dark energy and dark matter. If $Q < 0$, then the energy density of the dark energy becomes negative at sufficiently early times, therefore, the second law of thermodynamics can be violated [38]. Thus $Q$ must be positive and small. Also, the observational data of 182 Gold type-Ia supernova samples, CMB data from the three-year WMAP survey and the baryonic acoustic oscillations from the Sloan Digital Sky Survey estimated that the coupling parameter between dark matter and dark energy must be a small positive value (of order unity), which satisfies the requirement for solving the cosmic coincidence problem and the second law of thermodynamics [39].

The VMCG equation of state is given by [26]

\[ p_{\text{vmcg}} = A\rho_{\text{vmcg}} - \frac{B(a)}{\rho_{\text{vmcg}}^{\alpha}}, \]

\[ \text{with } A, \alpha \text{ constants and } 0 \leq \alpha \leq 1, \]

where $B(a)$ is a positive function of the cosmological scale factor “$a$”. Now consider, for simplicity, $B(a) = B_0a^{-n}$, where $n$ and $B_0$ are constants. More precisely the restriction for the accelerating universe becomes $0 < n \leq 4$ [26].

The dark-matter equation of state is

\[ p_{\text{dm}} = w_{\text{dm}}\rho_{\text{dm}}, \]

where $w_{\text{dm}}$ is a small constant.

To analyze the dynamical system, we convert the physical parameters into a dimensionless form as follows:

\[ x = \ln a, \quad u = \Omega_{\text{vmcg}} = \frac{\rho_{\text{vmcg}}}{3H^2} \quad \text{and} \quad v = \frac{p_{\text{vmcg}}}{3H^2}. \]
The equation of state of the VMCG can be expressed as
\[
   w_{vmcg}(x) = \frac{p_{vmcg}}{\rho_{vmcg}} = \frac{v}{u}
\]  
(9)

Defining the dimensionless density parameters of the dark matter \( \Omega_{dm} = \frac{\rho_{dm}}{3H^2} \) and using Friedmann equation (1), we obtain
\[
   \Omega_{dm} = 1 - \Omega_{vmcg} = 1 - u.
\]  
(10)

Thus for the flat universe, \( u \) must lie in the region \( 0 \leq u \leq 1 \), since the energies of VMCG and dark matter cannot be negative.

Now, we can cast the evolution equations in the following autonomous system of \( u \) and \( v \) in the form:
\[
   \frac{du}{dx} = -3c - 3(1 - v)u - v, \tag{11}
\]
\[
   \frac{dv}{dx} = \left\{ A(1 + \alpha) - \alpha \frac{v}{u} \right\} \left\{ -3c - 3 \left( 1 + \frac{v}{u} \right) u \right\} + n \left( A - \frac{v}{u} \right) u + 3v \left\{ \left( 1 + \frac{v}{u} \right) u + (1 + w_{dm})(1 - u) \right\} . \tag{12}
\]

2.1 Critical point

The critical points of the above system are the solution of the equations \( \frac{du}{dx} = \frac{dv}{dx} = 0 \). The only feasible critical point is obtained as
\[
   u_{crit} = \frac{n - 3(1 - c + w_{dm})(1 + \alpha)}{n - 3(1 + w_{dm})(1 + \alpha)}, \tag{13}
\]
\[
   v_{crit} = -\frac{n^2 - 3n(2 + w_{dm})(1 + \alpha) + 9(1 + w_{dm} + cw_{dm})(1 + \alpha)^2}{3(1 + \alpha)(1 + w_{dm})(1 + \alpha) - n}. \tag{14}
\]

Since in a spatially flat universe the physically meaningful range of \( u \) is \( 0 \leq u \leq 1 \), hence \( 0 \leq u_{crit} \leq 1 \) leads to the condition \( 0 < c \leq \frac{3(1 + w_{dm})(1 + \alpha)}{3(1 + \alpha)} \) along with \( n \leq \min\{3(1 + w_{dm})(1 + \alpha), 4\} \), [26] for the existence of the critical point. This condition of \( c \) represents that there is an energy transfer from to dark matter to VMCG.

2.2 Stability around critical point

For the stability of the dynamical system about the critical point, we linearize the governing equation around the critical point i.e., \( u = u_{crit} + \delta u \) and \( v = v_{crit} + \delta v \), we obtain
\[
   \delta \left( \frac{du}{dx} \right) = [3(v + w_{dm} - 2uw_{dm})]_{crit} \delta u + [3(-1 + u)]_{crit} \delta v, \tag{15}
\]
\[
   \delta \left( \frac{dv}{dx} \right) = \left[ -3w_{dm}v - \frac{3v(c + v)\alpha}{u^2} + A\{n - 3(1 + \alpha)\} \right]_{crit} \delta u + \left[ 3 - 3A - n + 6v + 3(1 - u)w_{dm} \right]_{crit} \frac{3(c + u - Au + 2v\alpha)}{u} \delta v. \tag{16}
\]

We find the eigenvalues of the Jacobian matrix at the critical point (for simplicity we set \( \alpha = 1 \)) as in the following:
\[
   \lambda_{1,2} = \frac{1}{4} \left[ 3n - 6(3 + 2A + c + w_{dm}) + \frac{36c^2}{6c + n - 6(1 + w_{dm})} \right] \\
   \pm \frac{1}{4} \sqrt{\left\{ \frac{(6 - n)^2 + 72cw_{dm} - 36w_{dm}^2 + 12A(6 - 6c - n + 6w_{dm})}{6c + n - 6(1 + w_{dm})} \right\} \left\{ \frac{-144c^2 + (6 - n)^2 + 12A(6 - 6c - n + 6w_{dm}) - 36w_{dm}^2 - 24c(n - 6 - 9w_{dm})}{6c + n - 6(1 + w_{dm})} \right\} }. \tag{17}
\]
Fig. 1. The dimensionless parameters are plotted against e-folding time for different values of $n$. The initial condition is $v(0) = -0.16, u(0) = 0.6$. The other parameters are fixed at $c = 0.01, A = 0.3, w_{dm} = 0.01$ and $\alpha = 0.8$.

Fig. 2. The evolution of $w(x) = v/u$ for the interacting VMCG model, corresponding to the initial conditions $u(0) = 0.6, v(0) = -0.016$. The figure is drawn for different values of $n$, and the other parameters are fixed at $c = 0.01, A = 0.3, w_{dm} = 0.01$ and $\alpha = 0.8$, respectively.
If the real parts of the above eigenvalues are negative, the critical point is a stable node and is a stationary attractor solution; otherwise unstable and thus oscillatory. The physical meaningful range of $c$ is $0 \leq c \leq \frac{3(1+u_{dm})(1+\alpha) - n}{3(1+\alpha)}$ and in this range, the critical point $(u_{\text{crit}}, v_{\text{crit}})$ is stable and is a late-time stationary attractor solution. Here we plot some figures to show the properties of the evolution of the Universe controlled by the dynamical systems (11) and (12). The dimensionless parameters $u$ and $v$ have been drawn in fig. 1 in terms of $x = \ln a$. Also the EOS parameter $w_{\text{vmcg}} = \frac{u}{v}$ is drawn in fig. 2 for $n = 1, 2, 3$. We see that $u$ becomes positive but $v$ and $\frac{u}{v}$ explore to the negative level above $-1$. The phase-space diagrams have been shown in figs. 3 and 4 for $n = 1, 3$, respectively. We see that from the progressions of the phase-portrait, $u$ goes to 1 and $v$ tends to a negative value above $-1$ and hence the solution is a stationary attractor and the corresponding critical point is a stable node.

At the critical point, the deceleration parameter $q = -1 - \left( \frac{\dot{H}}{H^2} \right)$ is obtained as

$$q = -1 + \frac{3}{2} X, \quad X = 1 + v_{\text{crit}} + w_{dm}(1 - u_{\text{crit}}).$$

(18)

Integrating, we have the Hubble parameter as (ignoring the integrating constant)

$$H = \frac{2}{3Xt}.$$  

(19)

Again integrating (19), we get

$$a(t) = a_0 \left( \frac{t}{t_0} \right)^\frac{2}{3X},$$

(20)

which gives power law expansion of the universe, $a_0$ is the present value of the scale factor when $t = t_0$ is the present time which is given by $t_0 = \frac{2}{3XH_0}$. Since we have obtained the deceleration parameter $q$, the Hubble parameter $H$ and the scale factor $a(t)$ around the critical point, these are valid for the late stage of the evolution of the universe, i.e., when time $t$ is very large. Thus $X$ should be taken as a positive value for positivity of the Hubble parameter $H$, and, hence, the scale factor $a(t)$ is increasing function of time $t$. So from (18), we obtain $q \in (-1, 0)$ for the accelerating phase of the universe if $X \in (0, 2/3)$. So the VMCG couples with the dark matter filled in the universe always drives acceleration. Figure 5 shows the graph of $q$ against $x = \ln a$ for some particular values of $n = 1, 2, 3$. For $n = 0$, the VMCG model reduces to MCG and these couples with the dark matter filled in the universe always drives the acceleration and this model explores upto $\Lambda\text{CDM}$ stage ($q = -1$) (fig. 6).

2.3 Statefinder parameters

We also determine the dimensionless pair of the cosmological diagnostic pair $r, s$ dubbed as statefinder parameters introduced by Sahni et al. [21]. The two parameters have a great geometrical significance since they are derived from the cosmic scale factor alone, though one can rewrite them in terms of the parameters of dark energy and matter. Furthermore, the pair characterizes the properties of dark energy in a model-independent manner, i.e., independent of the theory of gravity. Also, this pair generalizes the well-known geometrical parameters like the Hubble parameter and the deceleration parameter. The parameter $r$ forms the next step in the hierarchy of geometrical cosmological parameters $H$ and $q$. The parameters are given by

$$r \equiv \frac{\ddot{a}}{aH^3} = \left(1 - \frac{3X}{2} \right) (1 - 3X), \quad s \equiv \frac{r - 1}{3(q - 1/2)} = X,$$

(21)

where $X$ is obtained in eq. (18). Since we have already obtained that for accelerating universe, $X < 2/3$. In this range, $s$ is always positive. But $r > 0$ for $X < 1/3$ and $r < 0$ for $1/3 < X < 2/3$. (Figures 7 and 8 show that the statefinder parameters $r$ and $s$ remain positive for different choice $n = 1, 2, 3$.)

3 Consequences: Distance measurement of the Universe

In cosmography (the measurement of the Universe) there are many ways to specify the distance between two points, because in the expanding and accelerating Universe, the distances between comoving objects are constantly changing, and Earth-bound observers look back in time as they look out in distance. The unifying aspect is that all distance measures somehow measure the separation between events on radial null trajectories, i.e., trajectories of photons which terminate at the observer. Here we will compute various cosmological distance measures. In this section, we shall discuss the lookback time, luminosity distance, proper distance, angular diameter distance, comoving volume, distance modulus and probability of intersecting objects.
Fig. 3. The phase-space diagram of the parameters depicting an attractor solution. The initial conditions chosen are: \( v(0) = -0.16, u(0) = 0.6 \) (green); \( v(0) = -0.12, u(0) = 0.6 \) (blue); \( v(0) = -0.08, u(0) = 0.7 \) (red); \( v(0) = -0.4, u(0) = 0.8 \) (brown). The other parameters are fixed at \( c = 0.01, A = 0.3, w_{dm} = 0.01, \alpha = 0.8, n = 1 \).

Fig. 6. The deceleration parameter $q$ is plotted against the evolution of the universe for $n = 0$. The other parameters are fixed at $c = 0.01$, $A = 0.3$, $w_{dm} = 0.01$, and $\alpha = 0.8$. 
Fig. 7. The statefinder parameter $r$ is plotted against the evolution of the universe for different values of $n$. The other parameters are fixed at $c = 0.01$, $A = 0.3$, $w_{dm} = 0.01$, and $\alpha = 0.8$.

Fig. 8. The statefinder parameter $s$ is plotted against the evolution of the universe for different values of $n$. The other parameters are fixed at $c = 0.01$, $A = 0.3$, $w_{dm} = 0.01$, and $\alpha = 0.8$. 
3.1 Lookback time

The lookback time to an object is the difference between the age of the Universe now (at observation) and the age of the Universe at the time the photons were emitted (according to the object). As light travels with finite speed, it takes time for it to cover the distance related to the redshift it encountered. So, a look into space is always a look back in time. It is used to predict properties of high-redshift objects with evolutionary models, such as passive stellar evolution for galaxies. Thus if a photon emitted by a source at instant \( t \) and received at time \( t_0 \), then the photon travel time or the lookback time \( t_0 - t \) is defined by \([40–44]\)

\[
t - t_0 = \int_{a_0}^{a} \frac{da}{\dot{a}},
\]

(22)

where \( a_0 \) is the present value of the scale factor of the universe and can be obtained from (20) at \( t = t_0 \). The redshift is an important observable as they can be measured easily from the spectral lines and the redshift increases of an object with its distance from us. Lookback time is used to predict properties of high-redshift objects with evolutionary models, such as passive stellar evolution for galaxies. The redshift \( z \) can be defined by

\[
a_0 a = 1 + z = \left( \frac{t_0}{t} \right)^{\frac{1}{X}},
\]

(23)

which gives the lookback time in the following form:

\[
t - t_0 = \frac{2}{3XH_0} \left\{ \frac{1}{(1 + z)^{\frac{3X}{2}}} - 1 \right\}.
\]

(24)

For the accelerating universe we have already got \( X < \frac{2}{3} \). Early universe is represented by \( z \to \infty \), which implies \( t \to 0 \) and late universe \( z \to -1 \), which equivalently implied \( t \to \infty \). Also \( z \to 0 \) gives the present age \( t \to t_0 \) of the universe.

3.2 Proper distance

As light needs time to get from an object to the observer, one can define a distance that may be measured between the observer and the object with a ruler at the time the light was emitted, the proper distance. When a photon emitted by a source and received by an observer at time \( t_0 \) then the proper distance between them is defined by \([40–43,45,46]\)

\[
d = a_0 \int_{a}^{a_0} \frac{da}{a} = a_0 \int_{t}^{t_0} \frac{dt}{\dot{a}},
\]

(25)

which gives

\[
d = \frac{2}{H_0(3X - 2)} \left\{ \frac{1}{(1 + z)^{\frac{3X}{2}}} - 1 \right\}.
\]

(26)

The proper distance may also called the comoving distance (line of sight) of the Universe in today. So between two nearby objects in the Universe, the distance between them, which remains constant with the epoch if the two objects are moving with the Hubble flow. In other words, it is the distance between them which would be measured with rulers at the time they are being observed, divided by the ratio of the scale factor of the Universe then to now. The next thing to be defined is the transverse comoving distance, which is a quantity used to get the comoving distance perpendicular to the line of sight. For a flat universe, the transverse comoving distance is always identical to the comoving distance (line of sight). This means that the transverse comoving distance = proper distance = \( d \), for our model of the flat FRW Universe.

3.3 Luminosity distance

If \( L \) is the total energy emitted by the source per unit time and \( \ell \) is the apparent luminosity of the object, then the luminosity distance is defined by \([40–42,45,46]\)

\[
d_L = \left( \frac{L}{4\pi \ell} \right)^{\frac{1}{2}} = d(1 + z) = \frac{2}{H_0(3X - 2)} \left\{ (1 + z) - \frac{1}{(1 + z)^{\frac{3X}{2}}} \right\}.
\]

(27)
Fig. 9. Lookback time, proper distance, luminosity distance and angular diameter distance as a function of the redshift assuming $H_0 = 72 \text{km/s/Mpc}$ before the present age of the universe.

Fig. 10. Lookback time, proper distance, luminosity distance and angular diameter distance as a function of the redshift assuming $H_0 = 72 \text{km/s/Mpc}$ after the present age of the universe.

3.4 Angular diameter distance

The angular diameter of a light source of proper distance $D$ observed at $t_0$ is defined by [40–43,45,46]

$$\delta = \frac{D(1+z)^2}{d_L}. \quad (28)$$

The angular diameter distance ($d_A$) is defined as the ratio of the source diameter to its angular diameter (in radians) as

$$d_A = \frac{D}{\delta} = d_L(1+z)^{-2} = d(1+z)^{-1}. \quad (29)$$

For our model, the angular diameter distance ($d_A$) is given by

$$d_A = \frac{2}{H_0(3X-2)} \left\{ \frac{1}{1+z} - \frac{1}{(1+z)^{\frac{3X}{2}}-2} \right\}. \quad (30)$$

It is used to convert angular separations in telescope images into proper separations at the source. It is famous for not increasing indefinitely as $z \to \infty$; it turns over at $z \sim 1$ and, thereafter, more distant objects actually appear
The angular diameter distance is maximum at

$$z_{\text{max}} = \left( \frac{2}{3X - 2} \right)^{\frac{2}{3X - 2}} - 1, \tag{31}$$

and the corresponding maximum angular diameter $d_A|_{\text{max}}$ takes the form

$$d_A|_{\text{max}} = \frac{1}{H_0(3X - 2)} \left[ 2^1 + \frac{2}{(3X - 2)^2} \left( \frac{1}{3X - 4} \right)^{\frac{2}{3X - 2}} - 2 \left\{ 4^{\frac{1}{3X - 2}} \left( \frac{1}{3X - 4} \right)^{\frac{2}{3X - 2}} \right\}^{\frac{2 - 2X}{3X - 2}} \right]. \tag{32}$$

Lookback time, proper distance, luminosity distance and angular diameter distance before and after the present age of the universe are, respectively, drawn in figs. 9 and 10.

### 3.5 Comoving volume

The *comoving volume* $V_C$ is the volume measure in which number densities of non-evolving objects locked into the Hubble flow are constant with redshift as $[42, 43, 45]$

$$dV_C = D_H (1 + z)^2 d_A d\Omega dz = \frac{1}{H_0} (1 + z)^{2 - \frac{3X}{3X - 2}} d_A^2 d\Omega dz, \tag{33}$$
3.6 Distance modulus

The distance modulus is defined by

$$D_M = 5 \log \left( \frac{d_L}{10\text{pc}} \right),$$

(34)

because it is the magnitude difference between an object’s observed bolometric (i.e., integrated over all frequencies) flux and what it would be if it were at 10 pc (this was once thought to be the distance to Vega) and $d_L$ is the luminosity distance. The distance modulus $D_M$ as a function of redshift before and after the present age of the universe are shown in figs. 13 and 14. We see that for $z > 0$, $D_M$ decreases as $z$ decreases but for $z < 0$, $D_M$ increases as $z$ decreases upto a certain stage (about $z \sim -0.6$) and after that $D_M$ decreases as $z$ decreases.
3.7 Probability of intersecting objects

The incremental probability \( dP \) that a line of sight will intersect one of the objects in redshift interval \( dz \) at redshift \( z \) is given by [42,43]

\[
dP = n(z)\sigma(z)D_H \frac{(1 + z)^2}{E(z)} dz,
\]

where \( n(z) \) is the comoving number density and \( \sigma(z) \) the areal cross-section. Assuming \( n(z)\sigma(z) = 1 \), we obtain

\[
dP = \frac{1}{H_0} (1 + z)^2 - \frac{3X}{2} dz.
\]

For our model the expression of Probability of intersecting objects becomes

\[
P = \frac{2}{H_0(6 - 3X)} \left\{ (1 + z)^3 - \frac{3X}{2} - 1 \right\}.
\]

In figs. 15 and 16 we draw the intersection probability \( P \) as a function of redshift before and after the present age of the universe, respectively. We see that for \( z > 0 \), \( P \) decreases as \( z \) decreases and for \( z < 0 \), \( P \) increases as \( z \) decreases.
4 Discussions

In this work, we have considered the flat FRW model of the universe in Cosmology. We have assumed that the dark energy can be considered in the form of the variable modified Chaplygin gas (VMCG). The interaction between dark matter and VMCG has been investigated in this model. To analyze the dynamical system, we have converted the physical parameters into dimensionless form. We have made a comprehensive phase-plane analysis for the VMCG model. Our main aim was to investigate the properties of critical point of the dynamical system which play crucially important roles for this interacting model. We have found only one critical point which is physically justified. Next we consider small fluctuation about the critical point \((u_{\text{crit}}, v_{\text{crit}})\) and found the eigen values of the corresponding Jacobian matrix for \(\alpha = 1\). It has been observed that the all eigen values are negative for all physical choices of parameters and a stable attractor scaling solution is obtained.

In fig. 1, we plot the dimensionless parameters \(u\) and \(v\) with respect to \(x = \ln a\). We notice that \(u\) converges toward \(u = 1\) in the region \(0 < n < 4\) (in particular, for \(n = 1, 2, 3\), also \(v\) decreases simultaneously and keeps the negative sign in near future. This signifies that the universe is dominated by dark energy flows from all dark matter to dark energy. Also, if we change the values of \(\alpha\), then it may be seen that nature of the dimensionless quantities \(u\) and \(v\) do not sensitively depend on the change of \(\alpha\). Figure 2 depicts that the ratio \(v/u = w_{\text{vmcg}}\) gets the same nature with the variation of \(n\). Since, in a spatially flat universe, the physically meaningful range of \(u_{\text{crit}}\) is \(0 \leq u_{\text{crit}} \leq 1\), this leads to the condition \(0 < c \leq \frac{3(1+w_{\text{dm}})(1+\alpha)-n}{n(1+\alpha)}\) along with \(n \leq \min\{3(1 + w_{\text{dm}})(1 + \alpha), 4\}\), for the existence of the critical point. This condition of \(c\) represents there is an energy transfer from to dark matter to VMCG. The phase diagram in \(u-v\) space (figs. 3, 4) shows the attractor solution for \(n = 1\). In the above range, the critical point \((u_{\text{crit}}, v_{\text{crit}})\) is stable. Thus the present state and the future evolution do not depend sensitively on the choice of the initial condition. Our model cannot cross the phantom divide, which is consistent with the previous work [26], since we have chosen power law form of \(B(a)\). If we choose another form of \(B(a)\), then the VMCG model may cross the phantom barrier, which is more difficult than this one. We may consider this type of problem in near future.

Moreover, the expansion of the universe is governed by a power law form around the critical point. Hence the expansion will go on forever with an ever increasing rate. We have also studied the evolution of the deceleration parameter \(q(x) = -\frac{\ddot{a}}{a^2}/H_0^2 = -1 + \frac{1}{2}(1 + v(x) + w_{\text{dm}}(1 - u(x)))\) for the interacting VMCG model with dark matter. The result is shown in fig. 5 with different parameters value ranging from \(n = 1\) to \(n = 3\). Therefore, one can observed that for \(n = 1, 2, 3\) the values of \(q\) decrease from positive value to negative value but cannot reached \(-1\). On the other way, fig. 6 shows that \(q\) decreases from positive value to \(-1\) for \(n = 0\). So VMCG \((n \neq 0)\) generates quiessence scenario for late stage but only MCG \((n = 0)\) generates the \(\Lambda\)CDM model for late stage of the Universe. Also, we have obtained the statefinder parameters at the critical point. Around the critical point, the nature of the parameters are drawn in figs. 7 and 8. In all the above figures, we have chosen \(c = 0.01, A = 0.3, w_{\text{dm}} = 0.01\) and \(\alpha = 0.8\).

The distance measurements of the Universe around the critical point have been discussed. The lookback time, proper distance, luminosity distance, angular diameter distance, comoving volume, distance modulus and probability of intersecting objects before and after the present age of the universe have been calculated in terms of \(z\), \(X\) and \(H_0\) and their progressions are shown in figs. 9–16. For all figures, we have assumed \(H_0 = 72\) km/s/Mpc. The maximum angular diameter distance has been found for a particular value of redshift \(z\). Comoving volume element \(dV_c/dz\) before and after the present age of the universe are, respectively, drawn in figs. 11 and 12. We see that when \(z > 0\), the volume element decreases as \(z\) decreases and when \(z < 0\), the volume element increases as \(z\) decreases. Distance modulus \(D_M\) as a function of redshift before and after the present age of the universe have been shown in figs. 13 and 14. We see that for \(z > 0\), \(D_M\) decreases as \(z\) decreases but for \(z < 0\), \(D_M\) increases as \(z\) decreases upto a certain stage (about \(z \sim -0.6\)) and after that \(D_M\) decreases as \(z\) decreases. In figs. 15 and 16 we draw the intersection probability \(P\) as a function of the redshift before and after the present age of the universe, respectively. We see that for \(z > 0\), \(P\) decreases as \(z\) decreases and for \(z < 0\), \(P\) increases as \(z\) decreases. So these are the main consequences of the power law form of scale factor.
