(Dated: January 3, 2010)

Spin Hall effects intermix spin and charge currents even in nonmagnetic materials and, therefore, ultimately may allow the use of spin transport without the need for ferromagnets. We show how spin Hall effects can be quantified by integrating Ni80Fe20|normal metal (N) bilayers into a coplanar waveguide. A dc spin current in N can be generated by spin pumping in a controllable way by ferromagnetic resonance. The transverse dc voltage detected along the Ni80Fe20|N has contributions from both the anisotropic magnetoresistance (AMR) and the spin Hall effect, which can be distinguished by their symmetries. We developed a theory that accounts for both. In this way, we determine the spin Hall angle quantitatively for Pt, Au and Mo. This approach can readily be adapted to any conducting material with even very small spin Hall angles.

PACS numbers: 72.25.Rb, 75.47.-m, 76.50.+g

The spin-orbit interaction gives rise to spin-dependent scattering that can couple charge and spin currents in conducting materials. Resultant spin Hall effects1,2 may therefore display spin-dependent transport even in materials and device structures that do not contain ferromagnetic materials. The effectiveness of this spin-charge conversion can be quantified by the material-specific spin Hall angle $\gamma$, which is given by the ratio of spin Hall and charge conductivities $\gamma = \sigma_s / \sigma_{dc}$ and can be quantified by magnetotransport measurements.3 However, $\gamma$ values reported in the literature vary over several orders of magnitude even for nominally identical materials (i.e., Au: $\gamma < 0.022$4 and $\gamma = 0.113$5, and Pt: $\gamma = 0.0037$6 and $\gamma = 0.08$7). In order to better understand spin-dependent scattering and its potential use for spin-transport applications it is therefore highly desirable to find a robust method to quantify $\gamma$. Here we demonstrate an approach whose sensitivity can be adjusted to measure even very small values of $\gamma$.

Previous work on ferromagnetic resonance (FMR) in magnetic multilayers has shown that spin pumping can create pure spin currents in normal metals (N)12,14. Upon excitation of FMR, the time-varying magnetization inside the ferromagnet (F) generates an instantaneous spin current $j_s$ at the F|N interface given by15

$$j_s\hat{s} = \frac{\hbar}{8\pi} Re(2g_{\uparrow\downarrow}) \left[ \hat{m} \times \frac{\partial \hat{m}}{\partial t} \right],$$

where $\hat{m}$ is the unit vector of the magnetization, $\hat{s}$ is the unit vector of the spin current polarization, and $Re(g_{\uparrow\downarrow})$ is the real part of the spin mixing conductance. Under a simple precession17 the spin pumping induces a net dc spin current and by time-averaging Eq. (1) we get:

$$j_{s,dc}^0 = \frac{\hbar\omega}{4\pi} Re g_{\uparrow\downarrow} \sin^2 \theta,$$

where $\omega$ is the driving frequency and $\theta$ is the cone angle of the precession of $\hat{m}$. This spin current decays due to spin relaxation and diffusion in N, such that the spin current at distance $z$ from the interface is:

$$j_{s,dc}(z) = j_{s,dc}^0 \frac{\sin((z - t_N)/\lambda_{sd})}{\sinh(t_N/\lambda_{sd})}$$

where $\lambda_{sd}$ is the materials specific spin diffusion length and $t_N$ is the thickness of the N layer.

The spin current gives rise to a transverse charge current $j_{c,ISH}(z) = \gamma (2e/\hbar) [j_{s,dc}(z) \times \hat{\sigma}]$ due to the inverse spin Hall effect (ISHE). It has already been demonstrated that this transverse charge current can be observed as a dc voltage18–20. Here we show how an approach based on spin pumping can be applied to various F|N combinations. We identify two contributions to the dc voltage that stem from anisotropic magnetoresistance (AMR) and spin Hall effect, respectively, and can be distinguished by their symmetries. Furthermore, we present a self-consistent theory that enables quantification of the spin Hall angle with high accuracy.

We integrated F|N bilayers into coplanar waveguides with additional leads for measuring a dc voltage along the sample. This is shown in Fig. 1 for a Ni80Fe20(Pt) bilayer, with lateral dimensions of 2.92 mm × 20 µm and 15-nm thick individual layers. The bilayer was prepared by optical lithography, sputter deposition, and lift-off on a GaAs substrate. Subsequently we prepared Ag contacts for the voltage measurements, covered the whole structure with 100-nm thick MgO (for dc insulation between bilayer and waveguide), and defined a 30-µm wide and 200-nm thick Au coplanar waveguide on top of the bilayer. Similar samples were prepared with 60-nm thick Au and Mo layers replacing Pt.

The FMR was excited by a 4-GHz, 100-mW rf excitation, while applying a dc magnetic field $\vec{H}_{dc}$ at $\alpha = 45^\circ$ with respect to the waveguide [see Fig. 1(c)]. The FMR signal was determined from the impedance of the waveguide21: simultaneously the dc voltage was measured as
a function of $\tilde{H}_{dc}$. Figure 2 shows this for a Py/Pt bilayer and a Py single layer, where both FMR peak positions are similar and consistent with the Kittel formula:

$$\left(\frac{\omega}{\gamma_g}\right)^2 = H_{dc}(H_{dc} + 4\pi M_s),$$

where $\gamma_g = g e/2mc$ is the gyromagnetic ratio, $g$ is the electron g-factor and $M_s = 852$ G is the saturation magnetization for Py. The FMR linewidths (HWHM) extracted from fits to Lorentzian absorption functions are $\Delta H_{Py/Pt} = 16.9$ Oe for Py/Pt and $\Delta H_{Py} = 12.9$ Oe for Py. The difference in FMR linewidth can be attributed to the loss of spin momentum in Py due to relaxation of the spin accumulation in Pt. This permits the determination of the additional interface damping due to spin pumping [22], which in turn provides the interfacial spin mixing conductance as:

$$g_{\uparrow\downarrow} = \frac{4\pi\gamma_g M_s d_{Py}}{g\mu_B \omega} (\Delta H_{Py/Pt} - \Delta H_{Py}),$$

where $d_{Py}$ is the Py layer thickness and $\mu_B$ is the Bohr magneton (spin backflow being disregarded since Pt is an efficient spin sink). The calculated value for $g_{\uparrow\downarrow} = 2.1 \times 10^{19}$ m$^{-2}$ is somewhat smaller than the previously reported $2.58 \times 10^{19}$ m$^{-2}$ [22, 24], but Cao et al. [25] showed that for high power rf excitation, the spin mixing conductance is reduced due to the loss of coherent spin precession in the ferromagnet.

Figure 2(c) shows the $dc$ voltage measured along the samples. For the Py/Pt sample we observe a resonant increase in the $dc$ voltage along the sample at the FMR position. However the lineshape is complicated: below the resonance field the voltage is negative, it changes sign just before the FMR resonance field, and has a positive tail in the high field region. In contrast, the single layer Py sample, which is not affected by spin pumping, shows a voltage signal that is purely antisymmetric with respect to the FMR position. The voltage due to ISHE depends only on the cone angle of the magnetization precession [see Eq. (2)] and thus must be symmetric with respect to the FMR resonance position. This means that the voltage measured in the Py/Pt sample has two contributions: (i) a symmetric signal due to ISHE and (ii) an antisymmetric signal of the same origin as in the Py control sample.

The antisymmetric voltages observed in both Py and Py/Pt originate from anisotropic magnetoresistance (AMR). Although the MgO provides $dc$ insulation be-
is zero well below the FMR resonance, $\pi/2$ at the peak, and $\pi$ far above the resonance \cite{27}. Thus $\cos \varphi_0$ changes sign upon going through the resonance and this gives rise to an antisymmetric $V_{AMR}$ as observed in both Py and Py$|$Pt samples. Following Guan \emph{et al.} \cite{27} we calculate the cone angle $\theta$ and $\sin \varphi_0$ as a function of the applied field $H_{dc}$, FMR resonance field $H_r$, FMR linewidth $\Delta H$ and $rf$ driving field $h_{rf}$: 

$$\theta = \frac{h_{rf} \cos \alpha}{\Delta H \sqrt{1 + \left(\frac{(H_{dc}-H_r)(H_{dc}+H_r+4\pi M_s)}{\Delta H \pi M_s}\right)^2}} \text{, and}$$ \hspace{1cm} (7)

$$\sin \varphi_0 = \frac{1}{\sqrt{1 + \left(\frac{(H_{dc}-H_r)(H_{dc}+H_r+4\pi M_s)}{\Delta H \pi M_s}\right)^2}} \text{.} \hspace{1cm} (8)$$

Using Eqs. (7 and 8) and taking a measured 0.95\% value for $\Delta R_{AMR}$ fits the Py data [see Fig. (b)] with only one adjustable parameter $h_{rf} = 4.5$ Oe.

In order to understand the Py$|$Pt voltage data we have to include an additional contribution due to ISHE. In an open circuit an electric field $\vec{E}$ is generated leading to a total current density $\vec{j}(z) = \vec{j}_{ISH}(z) + \sigma_N \vec{E}$ with $\int \vec{j}(z) dz = 0$ where $\sigma_N$ is the N conductivity. When the wire is much longer than thick, the electric field is constant in the wire and the component of the electric field along the measurement direction $y$ is:

$$E_y = -\frac{\gamma}{\sigma_N} \frac{c \omega}{2 \pi} \frac{g_{\uparrow \downarrow}}{t_N} \sin \alpha \sin^2 \frac{\gamma \lambda_{sd}}{t_N} \tan \left(\frac{t_N}{2 \lambda_{sd}}\right) \text{.} \hspace{1cm} (9)$$

Using Eq. (9) we calculate the voltage due to ISHE generated along the sample with length $L$:

$$V_{ISH} = -\frac{\gamma}{2 \pi \sigma_N t_N} \frac{c L \lambda_{sd} \omega}{\sin \alpha \sin^2 \theta} \tan \left(\frac{t_N}{2 \lambda_{sd}}\right) \text{.} \hspace{1cm} (10)$$

Note that this voltage is proportional to $L$ and thus measurements of small $\gamma$ can be achieved by increasing the sample dimension. We used Eqs. (10) and (10) to fit the voltage measured for the Py$|$Pt sample, see solid line in Fig. (c). The dashed and dotted lines in Fig. (c) are the AMR and ISHE contributions, respectively. By using a literature value for Pt of $\lambda_{sd} = 10 \pm 2$ nm \cite{27}, the only remaining adjustable parameters are the $rf$ driving field $h_{rf} = 4.5$ Oe and the spin Hall angle $\gamma = 0.0067 \pm 0.0006$. Note that through the cone angle $\theta$, $h_{rf}$ enters both the AMR and ISHE contributions; this puts an additional constraint on this parameter, and, in fact, as seen from the fit to the control Py sample, it is already determined by the negative and positive tails of the AMR part.

This technique can be readily applied to determine $\gamma$ in any conductor. In Fig. 4 we show voltages measured for Py$|$Au and Py$|$Mo. The spin Hall contributions in Au and Mo are smaller than in Pt, and note that for Mo the spin Hall contribution changes its sign. Fitting of the
Note the opposite sign of ISHE contributions for Au and Mo.

Fig. 4: (Color online) Voltage measured for (a) Py/Au and (b) Py/Mo. Shown are data (symbols), combined fits (solid lines) and individual AMR and ISHE contributions, with dotted (overlapping with solid) and dashed lines, respectively. Note the opposite sign of ISHE contributions for Au and Mo.

Table I: Spin Hall angle $\gamma$ determined using $\lambda_{sd}$ and $\sigma_N$.

| Normal metal $\lambda_{sd}$ (nm) | $\sigma_N$ $1/(\Omega m)$ | $\gamma$ |
|--------------------------------|--------------------------|---------|
| Pt 10±2                        | (2.42±0.19)×10$^6$       | 0.0067±0.0006 |
| Au 35±3                        | (5.52±0.13)×10$^7$       | 0.0016±0.0003 |
| Mo 35±3                        | (4.66±0.23)×10$^6$       | -0.00023±0.00005 |

Data enabled us to extract the values of $\gamma$ for Au and Mo, see Table I. Note that the determination of $\gamma$ requires $\sigma_N$ and $\lambda_{sd}$ as input parameters. $\sigma_N$ was measured using four-probe measurements for all samples. Reported values for $\lambda_{sd}$ vary considerably. We choose a conservatively low literature value for Pt from Ref. 28 and Au from Ref. 14 and for Mo we assumed that $\lambda_{sd}$ is comparable to Au. Even though this latter assumption may not necessarily hold, the sign change is consistent with earlier measurements. Furthermore, our observed values for $\gamma$ are in good agreement with values reported by Otani et al. 9, 29 from measurements in lateral spin valves, but conflict with more optimistic values reported by other groups 8, 11. We note that in lateral spin valves it is important to also understand the charge current contribution in order to rule out additional non-local voltage contributions 10. In contrast, in our approach the spin pumping creates a uniform, macroscopic and well-defined spin current across the whole sample, and the voltage signal from spin Hall effects can readily be increased through use of longer samples, since $V_{ISH} \propto L$. Furthermore, using an integrated coplanar waveguide architecture provides control over parameters, such as the rf driving field distribution. This enables us to carry out a quantitative analysis of the data, in contrast to the more qualitative description of the ISHE in Refs. 18 and 19.

In conclusion, we performed FMR with simultaneous transverse voltage measurements in ferromagnetic/normal metal bilayers. From this we accurately determine the spin Hall angle for Pt, Au and Mo by fitting the experimental data to a theory, which accounts for both the anisotropic magnetoresistance and inverse spin Hall effect contributions. The combination of spin pumping and spin Hall effects provides a valuable technique for measuring spin Hall angle in many different materials.

We would like to thank R. Winkler, G. Mihajlović and M. Dyakonov for valuable discussions. This work was supported by U.S. DOE-BES under Contract No. DE-AC02-06CH11357.
