Reconstitution of nonnative, very-long-chain polyunsaturated fatty acid (VLC-PUFA) biosynthetic pathways in Arabidopsis thaliana was undertaken. The introduction of three primary biosynthetic activities to cells requires the stable coexpression of multiple proteins within the same cell. Herein, we report that C22 VLC-PUFAs were synthesized from C18 precursors by reactions catalyzed by Δ6-desaturase, an ELOVL5-like enzyme involved in VLC-PUFA elongation, and Δ5-desaturase. Coexpression of the corresponding genes (McD6DES, AsELOVL5, and PtD5DES) under the control of the seed-specific vicilin promoter resulted in production of docosapentaenoic acid (22:5 n-3) and docosatetraenoic acid (22:4 n-6) as well as eicosapentaenoic acid (20:5 n-3) and arachidonic acid (20:4 n-6) in Arabidopsis seeds. The contributions of the transgenic enzymes and endogenous fatty acid metabolism were determined. Specifically, the reasonable synthesis of omega-3 stearidonic acid (18:4 n-3) could be a useful tool to obtain a sustainable system for the production of omega-3 fatty acids in seeds of a transgenic T3 line 63-1. The results indicated that coexpression of the three proteins was stable. Therefore, this study suggests that metabolic engineering of oilseed crops to produce VLC-PUFAs is feasible.

1. Introduction

In both plants and animals, polyunsaturated fatty acids (PUFAs) are important membrane components that serve as universal cellular regulators, playing key roles in many cellular events. Very-long-chain (VLC) PUFAs are ≥20 carbons long (C20–C22) and have three or more methylene-interrupted cis double bonds in omega-3 (ω-3 or n-3) or omega-6 (ω-6 or n-6) arrangements (Table 1). Typically, VLC-PUFAs such as eicosapentaenoic acid (EPA; 20:5 n-3), arachidonic acid (ARA; 20:4 n-6), and docosahexaenoic acid (DHA; 22:6 n-3) are important nutritionally and as components of membrane phospholipids in specific tissues or as precursors for the synthesis of different groups of eicosanoid effectors. VLC-PUFAs are not only required for the development of the fetal nervous system but also contribute via a multiplicity of roles to the maintenance of health with increasing development and age, particularly by reducing the incidence of cardiovascular diseases [1, 2]. These fatty acids are either directly available as components of the diet or produced from the two essential fatty acids: α-linolenic acid (ALA; 18:3 n-3) and linoleic acid (LA; 18:2 n-6). Since mammals and human cells are unable to synthesize ALA and LA from precursors, they are defined as essential PUFAs. In humans, conversion of ALA and LA into their metabolites is extremely low and several factors, including age, gender, immune state, alcohol, and smoking, may influence LA and ALA metabolism. Thus, the major source of VLC-PUFAs is diet. Reliable dietary sources of VLC-PUFAs are fish oils, whereas ALA and LA are found predominantly in green vegetables and some plant oils, which do not contain VLC-PUFAs. Fish stocks are decreasing throughout the world, raising questions regarding the sustainability of this source of VLC-PUFAs, and this has resulted in strong interest in...
Figure 1: Metabolism of the two series of polyunsaturated fatty acids (PUFAs). Eicosapentaenoic acid (EPA, 20:5 n-3) is the main n-3 VLC-PUFA derived from the essential precursor α-linolenic acid (ALA, 18:3 n-3), and arachidonic acid (ARA, 20:4 n-6) is the main n-6 VLC-PUFA derived from the essential precursor linoleic acid (LA, 18:2 n-6). VLC-PUFAs are synthesized by successive elongations and desaturations. The key enzymes involved in this work are indicated in the pathway with large bold arrows.

The production of long-chain PUFAs in plants [3]. This goal may be realized by the introduction of VLC-PUFA biosynthetic pathways into annual oilseed crops.

The conversion of C18 PUFAs into EPA or ARA requires three consecutive enzymatic steps: Δ⁶-desaturation, PUFA elongation, and Δ⁵-desaturation (Figure 1). ALA and LA are desaturated by Δ⁶-desaturase to form stearidonic acid (STA; 18:4 n-3) and γ-linolenic acid (GLA; 18:3 n-6), respectively [4–7]. Next, STA and GLA are converted to eicosatetraenoic acid (ETA; 20:4 n-3) and dihomo-γ-linolenic acid (DGLA; 20:3 n-6), respectively, by an ELOVL5-like fatty acid elongase [8–11]. Finally, Δ⁵-desaturase converts ETA and DGLA into EPA and ARA, respectively [12–14]. Additionally, VLC-PUFAs such as EPA and ARA are further converted to docosapentaenoic acid (DPA; 22:5 n-3) and docosatetraenoic acid (DTA; 22:4 n-6) by ELOVL5 [10, 11, 15–19] or an ELOVL2-like fatty acid elongase [20] and then desaturated by Δ⁶-desaturase to give DPA and DHA [21, 22].

Indeed over recent years researchers have endeavored to reconstruct the VLC-PUFA biosynthetic pathways in plants [23–28]. In our previous study, we reconstructed the EPA and ARA biosynthetic pathways in yeast [11]. Here, we report the production of C22 VLC-PUFAs as well as EPA and ARA in seeds of transgenic Arabidopsis plants expressing appropriate heterologous enzymes under the control of seed-specific promoters. Our study reports a new gene set required to direct the efficient synthesis of these fatty acids in transgenic seeds.

2. Materials and Methods

2.1. Plant Material and Growth Conditions. Wild-type and transgenic plants were raised simultaneously from seeds in pots with soil. Arabidopsis thaliana, Columbia (Col-0) ecotype, was grown in a controlled environment chamber under the following conditions: 22°C day/18°C night, 70% humidity, and a 16 h photoperiod (250 μmol m⁻² s⁻¹).
2.2. Construction of the Expression Vector. To produce VLC-PUFAs from ALA and LA through the n-3 and n-6 pathways, we needed a Δ6-desaturase, a fatty acid elongase, and a Δ5-desaturase. We identified genes encoding these enzymes in a variety of VLC-PUFA-producing organisms such as fish and algae in previous research [6, 7, 10]. We engineered a series of plant transformation constructs containing a Δ6-desaturase gene (D6DES) from the pike eel, Muraenosex cinereus [7]; a polyunsaturated fatty acid elongase gene (ELOVL5) from blackhead seabeam, Acanthopagrus schlegelli [10]; and a Δ5-desaturase gene (D5DES) from a microalgae, Phaeodactylum tricornutum strain KMCC B-128 (GenBank accession number GQ352540), all under the control of seed-specific promoters. The vector pGEM7Zf was used for construction of intermediate expression vectors. The primer sequences and other PCR-related information are summarized in Table 2.

For the construction of expression vectors containing McD6DES, AsELOVL5, or PtD5DES under a seed-specific vicilin promoter, an expression construct containing a vicilin promoter, multiple cloning site, and octopine synthase (OCS) terminator from a vicilin cloning cassette was incorporated into pGEM7Zf. The individual McD6DES, AsELOVL5, and PtD5DES coding sequences were inserted into the HindIII and BamHI or ClaI and BamHI sites of the modified pGEM7Zf vector (Figure 2(a); Table 2 for primer set II). The fragment containing the vicilin promoter, McD6DES, and OCS terminator was isolated from the modified pGEM7Zf vector using a unique XbaI site and then ligated into the plant transformation vector pCAMBIA3300 (Canberra, Australia) to form the seed-specific expression vector pCAM::McD6DES.

For the easy coexpression of the three genes in a single transformation step, one recombinant plasmid containing all three expression cassettes was constructed using an Infusion Advantage PCR Cloning Kit (Clontech, Mountain View, USA) according to the manufacturer’s instructions. The vector was linearized with restriction enzymes. To amplify a target gene expression cassette, the 5' end of the primer was designed to contain a 15 bp sequence homologous to the sequence at one end of the linearized vector. The 3' end of the primer contained a sequence specific to the target gene (see primer set III in Table 2). The PCR product P

\[ \text{P}_{\text{vic}} \text{AsELOVL5OCS} \]

was subcloned into pCAM::McD6DES linearized at the unique SacI site to yield the plasmid pCAM::McD6DES–AsELOVL5. Finally, the recombinant plasmid pCAM::D6ELD5 was generated by inserting the P

\[ \text{P}_{\text{vic}} \text{PtD5DESOCS} \]

fragment into pCAM::McD6DES–AsELOVL5 linearized at the unique PvuI site introduced into P

\[ \text{P}_{\text{vic}} \text{AsELOVL5OCS} \]

(Figure 2(b)).

2.3. Plant Transformation. The engineered expression construct was transformed into Agrobacterium tumefaciens strain GV3101 [29] by the freeze-thaw method and cultured at 28°C on a rotary shaker to the appropriate growth phase. A. thaliana ecotype Columbia was transformed with the pCAM::D6ELD5 construct by the floral dipping method [30, 31]. Briefly, freshly opened flower buds were dipped in A. tumefaciens solution for 15 s, wrapped in plastic film, and
Table 2: Primers used for this study. The data include sequences and annealing temperatures ($T_a$) for the primer pairs.

Restriction enzyme sites are underlined.

Quantitative RT-PCR (qRT-PCR) was used to measure the coexpression of the three genes. At 9-10 days after flowering, siliques were taken from nine transgenic Arabidopsis plants differing in LC-PUFA output, and total RNA was extracted according to the method of Oñate-Sánchez and Vicente-Carbajosa [32]. Total RNA (1 μg) was reverse-transcribed into cDNA using the PrimeScript RT Reagent Kit with gDNA Eraser (Takara Bio, Shiga, Japan). The expression of the three genes was investigated with qRT-PCR using the specific primers shown in Table 2. The PCR product size was 150 bp for all three genes. The samples were amplified using SYBR Premix Ex Taq II (Takara) under the following conditions: 30 s of initial denaturation at 95 °C and 40 cycles of 5 s at 95 °C and 34 s at 60 °C. All reactions were performed in triplicate. The relative amounts of mRNA were calculated using the comparative C$_{\text{t}}$ method (User Bulletin number 2; Applied Biosystems, Foster City, CA, USA). The mRNA levels were normalized to that of ACTIN1, a housekeeping gene. Thermal cycling and fluorescence detection were performed with a 7300 Real-Time PCR System (Applied Biosystems).

2.6. Fatty Acid Analysis. One hundred milligrams of seeds were homogenized using a mortar and pestle with 5 mL of MeOH/CHCl$_3$ (2:1, v/v) and 1 mg PDA (pentadecanoic acid in MeOH) as an internal standard. Fatty acid methyl esters (FAMEs) were prepared with a lipid extraction method and analyzed by gas chromatography (GC) according to our
of genomic DNA revealed the presence of all three genes in transgenic lines were selected with Basta. PCR analysis of resultant clones and introduced into Arabidopsis was verified by restriction analysis and sequencing of the gene. To reconstitute the biosynthetic pathway of C 18 VLC-PUFAs in oilseed plants, we conducted a stepwise engineering approach to generate a range of transgenic Arabidopsis lines carrying three genes, with each gene under the control of a seed-specific promoter. The expression construct (designated pCAM::D6ELD5) contained the minimal set of genes required for the synthesis of n-3 and n-6 C18 VLC-PUFAs (e.g., DPA and DTA) from endogenous C18 substrates (represented schematically in Figures 1 and 2(b)). The construct was verified by restriction analysis and sequencing of the resultant clones and introduced into Arabidopsis plants via floral dip transformation. From the T1 plants, 160 independent transgenic lines were selected with Basta. PCR analysis of genomic DNA revealed the presence of all three genes (McD6DES, AsELOVL5, and PtD5DES) in 104 of the selected plants (data not shown). Mature seeds from Basta-selected T2 plants were analyzed by GC for total fatty acid composition. No attempt was made to isolate homozygous lines from subsequent Basta-selected progeny.

3. Results and Discussion

3.1. Establishment of the Recombinant Plasmid pCAM::D6ELD5 in Arabidopsis. To optimize the production of VLC-PUFAs in oilseed plants, we conducted a stepwise engineering approach to generate a range of transgenic Arabidopsis lines carrying three genes, with each gene under the control of a seed-specific promoter. The expression construct (designated pCAM::D6ELD5) contained the minimal set of genes required for the synthesis of n-3 and n-6 C18 VLC-PUFAs (e.g., DPA and DTA) from endogenous C18 substrates (represented schematically in Figures 1 and 2(b)). The construct was verified by restriction analysis and sequencing of the resultant clones and introduced into Arabidopsis plants via floral dip transformation. From the T1 plants, 160 independent transgenic lines were selected with Basta. PCR analysis of genomic DNA revealed the presence of all three genes (McD6DES, AsELOVL5, and PtD5DES) in 104 of the selected plants (data not shown). Mature seeds from Basta-selected T2 plants were analyzed by GC for total fatty acid composition. No attempt was made to isolate homozygous lines from subsequent Basta-selected progeny.

3.2. Functional Analysis of pCAM::D6ELD5 in Arabidopsis. We examined the effect of this construct on functionality by examining the fatty acid composition in transgenic seeds. To reconstitute the biosynthetic pathway of C18 VLC-PUFAs from C18 precursors, the McD6DES, AsELOVL5, and PtD5DES open reading frames (ORFs) were coexpressed in Arabidopsis (Figure 2(b)). The transgenic seeds coexpressing the three ORFs produced DPA and DTA, in addition to STA, ETA, and EPA of n-3 PUFA and GLA, DGLA, and ARA of n-6 PUFA (Figure 1 and Table 3). These non-native PUFA were not detected in wild-type Arabidopsis seeds. These results demonstrate that the coexpression of M. cinereus Δ6-desaturase (McD6DES), an ELOVL5-like enzyme involved in VLC-PUFA elongation (AsELOVL5), and Δ5-desaturase (PtD5DES) successfully reconstituted the n-3 and n-6 pathways in a heterologous system. Unexpectedly, however, our product of LC-PUFA was detected with only low levels in seeds (Table 3). As seen in Table 4, these experiments demonstrated the viability of using transgenic manners to modify seed oil PUFA content. Abbadi et al. [23] showed the analysis of transgenic seeds for tobacco and linseed. They described that different substrate requirements, namely, phospholipid-linked substrates for desaturases and acyl-CoA for elongases, resulted in a rate-limiting flux through the alternating desaturation and elongation steps. In addition, Kinney et al. [24] demonstrated that use of the endogenous acyltransferases which could accept non-native substrates produced high level EPA in transgenic soybean (Glycine max). Cheng et al. [25] investigated the effects of host species on EPA biosynthesis using Brassica carinata. Moreover, Robert et al. [26] used the way to target both desaturase and elongase activities in one pool for bypassing the acyl exchange bottleneck. Hoffmann et al. [27] also tried to avoid the acyl exchange bottleneck by using acyl-CoA-dependent desaturases. However, disappointingly the seed levels of target VLC-PUFAs were low like our seeds. Our M. cinereus Δ6-desaturase displayed preference for the n-3 substrate ALA, acting on this substrate with an efficiency of 21.3% compared to the n-6 substrate LA, of which only 7.0% was converted (Table 4). The A. schlegelii VLC-PUFA elongase demonstrated that this gene product has highly efficient activities (C18-elo and C20-elo). Yet although 42.6% of STA was elongated, only 6.5% of ETA was converted to EPA. It could be a likely explanation that repeat identical cassettes in the same orientation tend to be unstable, especially for the third cassette onward (D5-des in this case; Figure 2(b)). In addition, another approach is to use a strong acyl-CoA-dependent Δ5-desaturase. We will be interested in seeing the capacity to identify another optimal combination of FA biosynthetic activities for the production of VLC-PUFAs in plants using methods of Petrie et al. [28].

3.3. Selection of Transgenic Arabidopsis. The 160 independent lines from the first Basta selection were grouped together in 65 groups of two or three lines. Analysis of total FAMEs from the seeds of T2 lines in 28 of the 65 groups indicated that plants expressing the pCAM::D6ELD5 construct accumulated nonnative VLC-PUFAs (n-3 PUFA: STA, ETA, EPA, and DPA; n-6 PUFA: GLA, DGLA, ARA, and DTA) (Table 3). In lines of groups 12, 18, 33, 63, and 64 (named EPA group lines), EPA represented about 0.2% of total fatty acids; this level was higher than that observed in other Arabidopsis T2 lines. EPA accounted for 0.1% of total fatty acids in transgenic lines of groups 11, 14, 15, 20, 21, 23, 27, 41, 44, and 65. No EPA or only trace levels of EPA were detected in transgenic lines of groups 1, 2, 5, 6, 24, 26, 28, 39, 43, 45, 57, 61, and 62. The levels of ARA (n-6) were similar to those of EPA (n-3). Other nonnative PUFAs of STA, ETA, and DPA were shown by 4%, 3%, and 0.4% of total fatty acids in EPA group lines, respectively. Otherwise GLA, DGLA, and DTA were about 2%, 3%, and 0.1% of total fatty acids, respectively. These fatty acids are active in substrate of EPA or ARA products in metabolism of VLC-PUFAs (but not DPA and DTA) (Figure 1). The EPA group lines preferentially produced omega-3 (n-3) PUFA rather than omega-6 (n-6). These results were to investigate the effect of introduction of the McD6DES gene which could be a useful tool for omega-3 synthesis. Our previous study reported that the McD6DES gene was a sustainable system for the production of dietary omega-3 fatty acids [7]. For subsequent experiments, we selected transgenic lines of groups 33, 44, 63, and 64, which produced some DPA and DTA in addition to EPA and ARA.

3.4. Quantification of Fatty Acids. Accumulation of nonnative fatty acids was monitored in the T3 generation derived...

Each value is the mean ± SD from three independent experiments. Total lipid is mg lipid g⁻¹ dry cells.
from the selected T2 plants (Table 5). Seeds of the transgenic T3 line 63-1 had the highest level of EPA, at 0.4% of total seed fatty acids; this represented a twofold increase in EPA level compared with seeds of the transgenic T2 line (Tables 3 and 5). The level of ARA in seeds of line 63-1 was 0.3% of total fatty acids, which was similar to the level found in T2 seeds. Levels of EPA and ARA in transgenic lines 33-1, 33-2, 33-4, 63-5, and 64-3 were half of those in line 63-1, in the range of 0.1–0.3% of total fatty acids (Table 5). Transgenic lines 44-1, 44-4, and 44-5 had only minor levels of EPA and ARA, in addition to DPA and DTA. In addition to having a higher level of EPA, seeds of line 63-1 also displayed increased levels of other LC-PUFAs, suggesting variation in the endogenous channeling of fatty acids into either pathway.

STA and GLA are intermediates in the early stages of EPA and ARA synthesis [33, 34], respectively, in the metabolism of VLC-PUFAs (Figure 1). STA in seeds of line 63-1, at 5.6% of total seed fatty acids, represented one and a half times increase compared with seeds of the transgenic T2 line (Tables 3 and 5). The level of STA was a threefold increase compared with seeds of the transgenic T2 line (Table 5). This work [63 transgenic T2 line in Table 3] compared with seeds of the transgenic T2 line (Tables 3 and 5). The level of STA was a threefold increase compared with seeds of the transgenic T2 line (Table 5). The level of ETA in seeds of line 63-1, at 5.6% of total seed fatty acids, represented one and a half times increase compared with seeds of the transgenic T2 line (Table 3).

### Table 4: Comparison of published transgenic lines producing VLC-PUFAs and biosynthetic intermediates.

and EPA → DPA in the n-3 pathway and GLA → DGLA and ARA → DTA in the n-6 pathway, provide an abundance of precursor fatty acids for EPA and ARA synthesis (in the first reaction) and a progenitor of DHA (in the second reaction). Because the ELOVL5-like elongase yields both product and substrate, the high level of expression of AsELOVL5 could provide some insight into the reasons for variation in the output of LC-PUFAs. Use of the efficient \( A. \) schlegelii VLC-PUFA elongase resulted in substrates conversion from STA and EPA to ETA and DPA reaching 40.4% and 42.9% in the n-3 pathway and from GLA and ARA to DGLA and DTA reaching 58.2% and 25.0% in the n-6 pathway, respectively (Table 5).

The step catalyzed by \( \Delta^6 \)-desaturase is considered the rate-limiting step in the conversion of dietary ALA or LA to VLC-PUFAs [39, 40]. STA and GLA are produced with the desaturation of ALA and LA, respectively, by \( \Delta^6 \)-desaturase (McD6DES). McD6DES was most highly expressed in line 63-1, and STA and GLA accumulated in this line. The STA accumulation was, as stated above, higher than GLA. These results were also shown in the conversion efficiency. Use of the efficient \( M. \) cinereus \( \Delta^6 \)-desaturase of line 63-1 resulted in substrates conversion from ALA and LA to STA and GLA reached 26.8% and 7.7%, respectively (Table 5). However, the accumulation of EPA and ARA, which are products of ETA and DGLA desaturation, respectively, could not be directly related to the level of \( PtDS5DES \) expression. Although increased levels of EPA and ARA were observed in line 63-1, the expression level of \( PtDS5DES \) in line 63-1 was below that in line 33-1. It may be that a number of different factors regulate the accumulation of \( \Delta^5 \)-desaturated fatty acids in the seeds. Therefore, the abundance of STA enabled abundant accumulation of EPA, and high expression of \( AsELOVL5 \) resulted in the accumulation of EPA and DPA.

4. Conclusion

The modification of the lipid profile of oilseeds is an area of interest because the end-products have significant commercial value including foods, pharmaceuticals, or industrial raw material. However, the manipulation of plant seed oil composition is still a challenge. Because higher plants have no endogenous capacity for synthesis of VLC-PUFAs, we constructed a single recombinant plasmid from three gene expression cassettes to coexpress three genes using a single transformation step. The three primary enzymes needed for biosynthesis of VLC-PUFAs were expressed in transgenic \( A. \) thaliana seeds as discrete transcription and translation products. The metabolism of endogenous cellular products, ALA and LA, to VLA-PUFAs was achieved in transgenic seeds by a series of desaturation and elongation reactions. Particularly, the introduction of the \( McD6DES \) gene could be a useful tool for omega-3 (n-3) STA synthesis is thought to be a rate-limiting step. Therefore, this study demonstrates that the success of this required expression of multiple genes, as three sequential nonnative enzymatic reactions are involved in the conversion of native plant FAs to VLC-PUFAs.

Conflict of Interests

The authors declare that they have no competing interests.
