We show how off-resonant light scattering can provide quantitative information on antiferromagnetic ordering of a two-species fermionic atomic gas in a tightly-confined two-dimensional optical lattice. We analyze the emerging magnetic ordering of atoms in the mean-field and in random phase approximations and show how the many-body static and dynamic correlations, evaluated in the standard Feynman-Dyson perturbation series, can be detected in the scattered light signal. The staggered magnetization reveals itself in the magnetic Bragg peaks of the individual spin components. These magnetic peaks, however, can be considerably suppressed in the absence of a true long-range antiferromagnetic order. The light scattered outside the diffraction orders can be collected by a lens a with highly improved signal-to-shot-noise ratio when the diffraction maxima are blocked. The collective and single-particle excitations are identified in the spectrum of the scattered light. We find that the spin-conserving and spin-exchanging atomic transitions convey information on density, longitudinal spin, and transverse spin correlations. The different correlations and scattering processes exhibit characteristic angular distribution profiles for the scattered light and, e.g., the diagnostic signal of transverse spin correlations could be separated from the signal by the scattering direction, frequency, or polarization. We also analyze the detection accuracy by estimating the number of required measurements, constrained by the heating rate that is determined by inelastic light scattering events. The imaging technique could be extended to the two-species fermionic states in other regions of the phase diagram where the ground state properties are still not fully understood.

I. INTRODUCTION

The two-species fermionic Hubbard model is one of the most studied models with strong correlation effects in condensed matter physics, particularly since Anderson proposed in 1987 [1] that the Hubbard model (or its strong coupling limit, the t-J model) is the minimum model to describe the physics of the high temperature superconductors [2]. It is well understood that at half-filling, i.e., at an average of one spin-1/2 fermion per site, the Hubbard model has the ground state which is a Mott insulator with antiferromagnetic (AFM) ordering. Away from half-filling, quantitatively accurate predictions are from the standard Feynman-Dyson perturbation series, can be detected in the scattered light signal. The staggered magnetization reveals itself in the magnetic Bragg peaks of the individual spin components. These magnetic peaks, however, can be considerably suppressed in the absence of a true long-range antiferromagnetic order. The light scattered outside the diffraction orders can be collected by a lens with a highly improved signal-to-shot-noise ratio when the diffraction maxima are blocked. The collective and single-particle excitations are identified in the spectrum of the scattered light. We find that the spin-conserving and spin-exchanging atomic transitions convey information on density, longitudinal spin, and transverse spin correlations. The different correlations and scattering processes exhibit characteristic angular distribution profiles for the scattered light and, e.g., the diagnostic signal of transverse spin correlations could be separated from the signal by the scattering direction, frequency, or polarization. We also analyze the detection accuracy by estimating the number of required measurements, constrained by the heating rate that is determined by inelastic light scattering events. The imaging technique could be extended to the two-species fermionic states in other regions of the phase diagram where the ground state properties are still not fully understood.

owing to exchange coupling between the atomic spin states. Magnetic ordering has also been observed in doublon formation in tilted lattice systems [10, 11]. On the other hand, entangled cluster states including singlet or triplet states [12] and resonating valence-bond states [13] have been controllably created and measured in systems of ultracold bosonic atoms trapped in optical superlattices.

Accurate diagnostic tools for ultracold atoms in lattices form key elements in emulating strongly-correlated physics of condensed-matter systems. Currently, advanced imaging provides a microscopic scanning technology of atoms with a single-site resolution [14–21] in which case each atom may resonantly scatter thousands of photons while being detected. The analogy between x-ray (or neutron) diffraction of crystalline structure in solids and off-resonant light scattering from an ultracold atomic gas in an optical lattice provides an alternative route. The periodic crystalline order leads to constructive interference and the emergence of sharp diffraction maxima, or Bragg peaks, revealing the underlying lattice structure. Importantly, diffuse background of scattered light in between the diffraction maxima can convey information on fluctuations of atomic positions. The far-field off-resonant imaging therefore provides a powerful probe of strongly-correlated ultracold atom systems in optical lattices, being sensitive, e.g., to correlations, excitations, and temperature.

Spontaneously scattered off-resonant light was first proposed as a diagnostic tool for correlations of ultracold
atoms in an optical lattice in Ref. [22]. This study considered a two-species gas where the hopping element of the atoms between adjacent sites acquired an artificially constructed phase factor from the Peierls substitution. It was then shown that the resulting topological properties of edge states, which originate from nontrivial spin correlations, can be mapped onto fluctuations of scattered light and directly detected [22, 23]. Several other studies have addressed signatures of atom statistics in an optical lattice from the scattered light with [24, 25] and without [26–35] an additional optical cavity.

A two-species fermionic Hubbard model exhibits a Mott insulator state where the fluctuations of the total on-site atom number are suppressed [6, 7]. At sufficiently low temperatures the effective exchange coupling can generate magnetic ordering of the atomic spins within the Mott state. At half-filling with equal spin populations this leads to alternating checkerboard pattern of atom densities of individual spin components. The resulting doubling of periodicity of atom densities leads to the emergence of additional magnetic Bragg peaks of scattered light that have been proposed as a detection mechanism of AFM ordering [36]. The extra Bragg peaks in the optical signal of a two-species system were experimentally observed using an artificially constructed stripe pattern of atomic densities [37].

Here we analyze the far-field diffraction pattern for off-resonantly scattered light from a two-species fermionic atomic gas in an optical lattice. We consider a tightly-confined two-dimensional (2D) Hubbard model at half-filling with equal spin populations. We show how optical diagnostics can provide quantitative information on properties of strongly correlated states in a lattice. The time-ordered correlation functions that can be calculated using the Feynman-Dyson perturbation series are mapped onto the fluctuations of the scattered light and detected in the optical signal. We evaluate the relevant correlation functions in the mean-field theory (MFT) and in the random phase approximation (RPA) for the AFM ordered state. MFT provides information on single-particle excitations but fails to capture the effect of quantum fluctuations and collective excitations that are approximately incorporated in RPA. In the RPA calculations we follow the approach of Ref. [38].

The scattered light intensity may be separated into elastic and inelastic components. In the elastic scattering process the atom scatters back to its original state. The elastic part produces a diffraction pattern from a non-elastic component. In the elastic scattering processes, on the other hand, are those in which an atom scatters between two different quasimomentum states. The inelastically scattered light conveys information on correlations between the atoms and results in diffuse scattering of light outside the diffraction orders, generating fluctuations of the diffraction pattern. We collect the light in the near-forward direction with a lens and block the diffraction maxima, so that the amount of elastically scattered light entering the detector is suppressed [26]. This method is then extended to detection of light in the direction approximately perpendicular to the propagation direction of the incident field. In Ref. [26] detecting the near-forward light was shown to provide an experimentally feasible technique for measurements of temperature of fermionic atoms in a lattice. We find that in an AFM ordered two-species state the scattered light in the near-forward direction is not only sensitive to the temperature of the atoms but provides also a suitable probe of density and longitudinal spin correlations (from spin conserving atomic transitions). The scattering processes in which the atomic spin state changes, on the other hand, are prominent in the scattered light perpendicular to the light propagation direction and can be employed in detection of transverse spin correlations. Furthermore, we estimate the detection accuracy of the magnetic ordering in different measurement configurations. This is done by calculating the number of required experimental realizations of the lattice system to detect the order parameter above the shot noise of light at a desired accuracy. In each experimental realization the scattered light heats up the atomic sample and the total number of inelastic scattering events is constrained to be a small fraction of the total atom number. We find that a strong lattice and trap confinement is beneficial for the measurements in suppressing scattering of atoms to higher energy bands as compared with the inelastic lower energy band scattering.

We also calculate the spectrum of the scattered light and show how it reveals the excitation of the system that could be measured using optical heterodyne techniques [39]. The differences between the MFT and RPA treatments are especially prominent in the spectrum of transverse spin correlations: The low-energy collective

\[
\lambda > \lambda/\sqrt{2}
\]
mode excitations manifest themselves as a well-separated peak (at sufficiently strong interaction energy) from the gapped single-particle excitations.

The optical setup that blocks the Bragg diffraction maxima in the measured signal can considerably reduce the scattered light that is insensitive to correlations, therefore improving the signal-to-noise efficiency. Similar separation of less important part of the signal, for instance, in atom shot-noise correlation measurements [40, 41] would be challenging. We estimate the detection accuracy of the AFM ordering in the scattered light intensity by calculating the number of experiments needed to achieve a given measurement accuracy of the magnetic order parameter, when the heating rate of the atoms limits the total number of possible scattering events.

The proposed technique differs from the simple angle-resolved imaging of the diffraction peaks, since we collect the inelastically scattered light with a lens that has a relatively large numerical aperture (NA). By analyzing the spectrum of the scattered light using the realistic optics setup, we show that the essential features of the excitation spectrum can be captured even when the light is collected over a range of scattering angles. A large lens provides a stronger signal even when the number of inelastically scattered photons remains a small fraction of the total atom number. In less demanding detection scenarios (e.g., in large lattices and at high temperatures) even a single experimental realization of the lattice system can then be sufficient to determine, e.g., the approximate temperature of the atoms in the lattice. This contrasts with the single-site microscopy [14, 42] in which case typically several thousands of photons are scattered from each atom and the light is also simultaneously used to cool down the atoms. The microscopy also requires a scanning of the lattice sites that in very large lattice systems may become less practical. The off-resonant light scattering, on the other hand, becomes more efficient as the size of the system increases. Other advantages of the off-resonant imaging include the possibility for spectral measurements of excitations and the access to correlation functions that include combinations of different spin states via spin-exchanging scattering processes. Finally, the diffractive far-field imaging does not need to be limited to probing the atoms only by light, but also matter-wave probes are possible [43].

The remainder of the paper is organized as follows: Section II presents a summary of the key results. We then start in Sec. III by introducing the basic formalism of the lattice system. We continue in Sec. IV, where the MFT and RPA results for the lattice system are presented. The scattered light as a diagnostic tool is introduced in Sec. V. In Sec. VI we present results for the scattered light intensity for $^{40}$K atoms. The specific experimental setups for the optical detection and the estimates for the measurement accuracy are considered in Sec. VII. The scattered spectrum is studied in Sec. VIII and some concluding remarks are made in Sec. IX. Finally, a diagrammatic description of the RPA susceptibilities is presented in Appendix A and the finite temperature MFT susceptibilities are given in Appendix B.

II. SUMMARY OF KEY RESULTS

In this Section we briefly highlight the main findings of the paper. We study the AFM ground state of the Mott insulator in a two-species fermionic atomic gas trapped in a tightly-confined 2D optical lattice (Sec. III). We assume equal spin populations and that on average, there is one atom per site in the lattice.

We show how quantum statistical correlations of the atoms can be mapped onto fluctuations of the scattered light. Measurements on the scattered light therefore convey information about the correlated phases of the ultracold atoms in the lattice (Secs. VA and V). We consider two electronic ground states $|\uparrow\rangle = |4S_{1/2}, F_g = 9/2, m_F = -7/2\rangle$ and $|\downarrow\rangle = |4S_{1/2}, F_g = 9/2, m_F = -9/2\rangle$ of $^{40}$K (Sec. VIIB), excited by the $\sigma^-$ polarized incident light, such that $|\downarrow\rangle$ undergoes a cycling transition and the atoms in $|\uparrow\rangle$ may either scatter back to $|\uparrow\rangle$ (spin-conserving transition) or to $|\downarrow\rangle$ (spin-exchanging transition).

The scattered light intensity contains contributions from the elastic and inelastic scattering events. The elastic part generates the diffraction pattern of the atomic lattice structure. If the detected signal cannot distinguish the two spin components, the light provides almost no information about the AFM order. But with spin-specific imaging, the emerging AFM order and the period doubling can be identified as additional Bragg peaks.

Specifically, we find that the elastic component of the scattered light intensity is given by

$$I_{\alpha}(\Delta k) = \frac{\alpha_{\Delta k} B}{\alpha_{\Delta k} B} \left( \sqrt{M^{-1}_{\uparrow\uparrow} \langle \hat{\rho}_{\Delta k\uparrow\uparrow} \rangle} + \sqrt{M^{-1}_{\downarrow\downarrow} \langle \hat{\rho}_{\Delta k\downarrow\downarrow} \rangle} \right)^2. \quad (1)$$

In this expression the dependence on level structure, polarization, and scattering direction are coded in $\hat{M}\hat{M}_h$ [Eq. (63)], $\Delta k$ is the change in the momentum of the scattered photons [Eq. (53)] while $\Delta k$ is the same momentum projected into the lattice plane. Here the Debye-Waller factor $\alpha_{\Delta k}$ depends on the lattice site wave function and determines the overall envelope of the diffraction pattern [Eqs. (62) and (64)]. For the AFM state we find

$$\langle \hat{\rho}_{\Delta k\uparrow\uparrow} \rangle = u_{\Delta k} f_g + u_{\Delta k+Q} m \eta(g), \quad (2)$$

where $\hat{\rho}_{Qg}$ [Eq. (32)] is the density operator for the spin state $g, Q = (\pi/a, \pi/a)$ (a denotes the lattice spacing) is the magnetic ordering wavevector, $f_g = 1/2$ is the atomic filling factor of species $g$ at half-filling, and $\eta(\uparrow) = 1, \eta(\downarrow) = -1$. The staggered magnetization $m$ [Eq. (15)] represents the AFM order parameter and $|u_{\Delta k}|^2$ [Eq. (68)] generates the diffraction pattern from the periodic atom density [Eq. (75)]. The second term of Eq. (2), when substituted into Eq. (1), is responsible for the magnetic peaks due to the period doubling
in the AFM state. In the absence of true long-range AFM order the staggered magnetization, however, may vary in space, resulting in a significant suppression of the magnetic Bragg peaks when the correlation length is not much larger than the size of the lattice (Sec. VII B).

While elastically scattered light gives information about the AFM ordering of the system, the inelastic component directly probes the correlations of the spin \( S^z_i \) \((i = z,+,−)\) [Eqs. (30), (31)] or the density \( \hat{\rho}_q \) [Eq. (32)] operators. The basic MFT analysis (Sec. IV B) does not include quantum fluctuations and we calculate the correlations functions by a partial summation of the Feynman–Dyson perturbation series in RPA (Sec. IV D) that incorporates the correct spin wave physics at strong coupling. We explicitly show how the time-ordered many-body correlation functions obtained in RPA [Eqs. (44)-(48)] are mapped onto the inelastically scattered light intensity [Eq. (96)]

\[
\frac{I_q (\Delta k)}{a_\Delta k^2} = \frac{1}{4} \left( M_{\uparrow \uparrow} + M_{\downarrow \downarrow} \right) \sum_{q \neq 0}^{\text{RBZ}} u_{\Delta k-q}^\dagger \left[ \mathcal{S}_{\rho \rho} (q) + \mathcal{S}_{zz} (q) \right] u_{\Delta k-q}
\]

where the equal time 2 \( \times \) 2 matrix response function

\[
\mathcal{S}_{ij} (q) = \left( \begin{array}{c} \langle \hat{O}_q \hat{O}_{q+Q}^c \rangle \langle \hat{O}_q \hat{O}_{q+Q}^c \rangle \\ \langle \hat{O}_{q+Q} \hat{O}_q^c \rangle \langle \hat{O}_{q+Q} \hat{O}_q^c \rangle \end{array} \right) . \quad (4)
\]

\( \hat{O}_q \) can be any of the operators \( S^z_i \) \((i = z,+,−)\) [Eqs. (30), (31)] or \( \hat{\rho}_q \) [Eq. (32)]. We have also introduced the two-component vector [Eq. (95)] \( u_k = (u^\dagger_k, u_k, Q) \).

In Eq. (3), the scattering contributions in which spin is conserved are proportional to density and longitudinal spin correlations. The spin-exchanging transitions (Fig. 7) generate the term depending on the transverse spin correlations. The two processes exhibit very different angular distribution of the scattered light and can also be separated in frequency. Thus, another key result of this paper is that specific quantum correlations can be separated in the detected signal.

We estimate the minimum number of experimental measurements needed to obtain a given relative accuracy in the magnetization or temperature [26]. This is determined by two factors: photon shot noise that dictates a minimum difference in the number of photons detected for two close AFM magnetization values and the total number of photons collected that is set by the heating rate of the system due to inelastic scattering of atoms by light (Sec. VII B). In this analysis the best magnetization measurement accuracy can be achieved with spin-specific detection where the photons are collected near the perpendicular direction or around the direction of the magnetic Bragg peak, while the temperature of the atoms can be measured in the near-forward direction [Fig. 16(b)]. In the perpendicular direction [Fig. 16(c) and 20], it is preferable to detect only the light scattered from spin-exchanging transitions.

For the spectrum of the scattered light we obtain an expression similar to the scattered light intensity, with the static correlations replaced by dynamic ones \( \mathcal{S}_{ij} (q, \omega) \) (Sec. VIII). We find that at moderately large to large \( U/J \), the collective excitations generate a sharp peak in the low energy part of the spectrum, which is separated by an energy gap of order \( U \) from a more broad feature generated by single particle excitations. The location and width of these features can give a quantitative measure of the AFM order.

### III. OPTICAL LATTICES AND THE HUBBARD MODEL

We consider a tightly-confined 2D square lattice with the potential \( V (r) = s_x E_R \sin^2 \left( \frac{\pi x}{a} \right) + s_y E_R \sin^2 \left( \frac{\pi y}{a} \right) + \frac{1}{2} m \omega_z^2 z^2 . \) (5)

We choose the lattice depth \( s = s_x = s_y \) similar to the 2D lattice experiments with a disk-like lattice [14]. Here the frequency of the harmonic confinement in the \( z \) direction is denoted by \( \omega_z \) and the lattice light recoil energy

\[
E_R = \left( \frac{\hbar k^2}{2m} \right) . \quad (6)
\]

We define an effective wavenumber for the optical lattice in terms of the lattice spacing \( a \) by

\[
k_l = \frac{\pi}{a} . \quad (7)
\]

When the effective wavenumber coincides with the laser wavenumber, we have \( k_l = 2\pi/\lambda_l \) and \( a = \lambda_l/2 \), where \( \lambda_l \) denotes the wavelength of the laser beam generating the lattice. In the case of accordion lattices the lattice spacing is manipulated by optical components and can be considerably increased [44–46].

In typical experimental situations, the trapping potential is a superposition of the lattice and an external trap.
Here we will assume a weak external potential and ignore, for simplicity, any modulations of the uniform lattice. Experimentally, it is also possible to produce entirely homogeneous traps; a first step towards this has recently been demonstrated for a Bose-Einstein condensate [47]. The effects of the additional harmonic trap, e.g., in the context of the Mott insulator states has already been addressed by several studies [6, 7].

We expand the atomic field operators $\hat{\Psi}_g(\mathbf{r})$ for the hyperfine state $g$ in terms of Wannier functions $w_{n,j}(\mathbf{r}) = w_n(\mathbf{r} - \mathbf{r}_j)$ (at position $\mathbf{r}_j$ and band $n$ [48])

$$\hat{\Psi}_g(\mathbf{r}) = \sum_{n,j} w_{n,j}(\mathbf{r}) \hat{c}_{njg},$$

where $\hat{c}_{njg}$ denotes the annihilation operator for hyperfine state $g$ at site $j = (j_x, j_y)$. In the uniform lattice of this study the spatial variation of Eq. (8) between different lattice sites is entirely encapsulated in the phase factors of $\hat{c}_{njg}$.

We assume that the higher bands in the initial ground state are not populated ($U,T$ are much smaller than the bandgap), such that only the $n = 0$ state in Eq. (8) is included in the analysis of the ground-state properties, and we drop the band index for now. (Later, we will consider the effect of light scattering of atoms into higher bands in Sec. V C.) In order to describe the lattice system we introduce the one-band Hubbard Hamiltonian [49]

$$\mathcal{H} = -J \sum_{\langle j,j' \rangle} \left( \hat{c}_{jg}^{\dagger} \hat{c}_{j'g} + \text{H.c.} \right) + U \sum_j \hat{n}_{j\uparrow} \hat{n}_{j\downarrow} - \mu \sum_j \hat{n}_{jg}. \quad (9)$$

Here $\mu$ is the chemical potential and the hopping amplitude between the nearest-neighbor sites is $J$. The on-site interaction strength is denoted by $U$. It can be modified by changing the spatial confinement or via a Feshbach resonance of the $s$-wave scattering length $a_s$ [50]. The two hyperfine states are identified by “spin” labels $\uparrow$ and $\downarrow$, in analogy to electrons in solids.

For deep lattices, the lattice potential can be approximated locally close to the site minimum as a harmonic potential with frequencies

$$\omega_x = \omega_y = \frac{2E_R}{\hbar} \sqrt{s}. \quad (10)$$

Then, the ground state Wannier function becomes

$$w(\mathbf{r}) = \prod_{i=x,y,z} \frac{1}{(\pi l_i^2)^{1/4}} \exp \left( -\frac{r_i^2}{2l_i^2} \right), \quad (11)$$

$$l_i = (\hbar/m\omega_i)^{1/2}, \quad i = x, y, z, \quad (12)$$

With this approximation,

$$U = ka_s \sqrt{\frac{\hbar^2 \omega_x \omega_y \omega_z}{2E_R \pi}} = 2ka_s \sqrt{\frac{\hbar E_R \omega_z}{\pi}}. \quad (13)$$

In the limit $s \gg 1$, the hopping matrix element can be obtained from the 1D Mathieu equation as

$$J = \frac{4}{\sqrt{\pi}} E_R(s)^{3/4} \exp \left[ -2\sqrt{s} \right]. \quad (14)$$

Thus $J$ and $U$ are readily changed by tuning the laser intensity and magnetic fields in the experiment.

IV. APPROXIMATE SOLUTION OF THE HUBBARD MODEL AT HALF-FILLING

A. Low energy physics of the Hubbard model

In the experimentally relevant large $U/J$ limit, and at half-filling (i.e., on average one atom per site), the ground state of the Hubbard model is a Mott insulator. This is a state where the energy cost of a doubly occupied site ($\sim U$) is too large compared to both the hopping energy $J$ and the temperature $T$ when $k_BT \lesssim U$. In the Mott insulator state the on-site total atom number fluctuations are suppressed. Immediately below the onset of the Mott transition there is, however, very little energy cost in mixing the relative populations of the two spin states and the on-site relative atom number may still fluctuate. At even lower temperatures, below a new characteristic scale determined by the Néel temperature, the spins in a square lattice form into an AFM pattern. Classically, with equal numbers of $\uparrow$ and $\downarrow$ atoms, this represents a checkerboard pattern where spin $\uparrow$ and spin $\downarrow$ atoms occupy alternating sites. In the alternating density pattern, virtual hopping of atoms between nearest neighbor sites becomes energetically favorable. Second-order perturbation theory at large $U/J$ then leads to an effective spin exchange interaction $\sim 4J^2/U$ between the atoms in the neighboring sites, defining the Néel temperature scale. At such low energies, the system is described by the (spin only) Heisenberg model [51].

At zero temperature, it is known that the ground state of the 2D Hubbard model (or the effective Heisenberg model) has true long-range AFM order; for a review, see Ref. [52]. The order parameter for the AFM state is the staggered magnetization, defined as

$$m = \frac{1}{2} e^{iQ \cdot r_j} \langle \hat{S}_j^z \rangle, \quad (15)$$

where the spin operator in real space is $\hat{S}_j^z = (\hat{c}_j^{\dagger} \hat{c}_j - \hat{c}_j^{\dagger} \hat{c}_j)$ [cf. the momentum space version in Eq. (30)]. For the checkerboard pattern in a 2D square lattice, the ordering momentum is

$$Q = (\pi/a, \pi/a). \quad (16)$$

This in turn corresponds to the expectation value of the number operator for each spin component at half-filling

$$\langle \hat{n}_{jg} \rangle = \frac{1}{2} + m \eta(g) e^{iQ \cdot r_j}, \quad (17)$$
The AFM state breaks lattice translation symmetry such that the new unit cell in real space is doubled in size (to contain both spin components). Hence, in momentum space, the Brillouin zone is halved to become the RBZ. In Fig. 1, we show one choice of the RBZ, which is bounded by the four lines \( k_x \pm k_y = \pm \pi/a \). The filled circles denote the momentum states belonging to the RBZ, and the ordering vector \( \mathbf{Q} \) links a state within the RBZ to one outside (and vice versa). Note that in order to avoid double counting, half the states on the bounding lines belong to the RBZ and the other half are outside of the RBZ.

The AFM order can approximately be characterized by a MFT, and results so obtained can be used to calculate the effect of the ordering on off-resonant light scattering. However, MFT contains only single particle excitations (of order \( U \) at large \( U/J \)). Importantly, MFT does not include quantum fluctuations that give rise to collective excitations at low energies, the spin waves of the AFM state. Schrieffer et al. [38] and others [53–55] have demonstrated how the RPA can partially incorporate quantum fluctuations and describe both the spin wave excitations of the system, and the consequent suppression of the AFM order. Moreover, Ref. [38] and [53] showed that the spin wave spectrum and the AFM order suppression are given quantitatively by the RPA at large \( U/J \), despite the RPA being a priori a weak-coupling approach. Thus even though the formalism becomes strictly accurate in the limit \( U \ll J \), a qualitative description can also be obtained for \( U \gg J \). Hence, we will use the RPA at zero temperature to study how collective modes modify the scattered light.

On the other hand, at any non-zero temperatures, there is no true long-range AFM order in the thermodynamic limit in the Hubbard model or the Heisenberg model [56]. This loss of long-range order is due to the enhanced quantum and thermal fluctuations in 2D. Instead, there is at most quasi-long-range order; for a review, see [57]. For example, in the Heisenberg model, the spin correlation function \( \langle \mathbf{S}_i \mathbf{S}_j \rangle \) decays with the distance \( r = |r_i - r_j| \) as \( \exp(-r/\xi_{\text{AFM}}) \), for \( r \gg \xi_{\text{AFM}} \). \( \xi_{\text{AFM}} \) is the AFM correlation length in 2D given by

\[
\xi_{\text{AFM}}(T) \approx c_0 \exp \left( \frac{2 \pi b_0 J_H}{k_B T} \right),
\]

where \( c_0 \approx 0.26 \), \( b_0 \approx 0.2 \), \( J_H \) is the Heisenberg exchange coupling and \( a \) is the lattice spacing [51, 58]. In contrast, true long-range order is signaled by an additional constant term in the spin correlation function, which is just \( m^2 \). In the absence of true long-range order, the existence of the length scale \( \xi_{\text{AFM}} \) leads to the following physical picture: If the system size \( L \) is such that \( L \gg \xi_{\text{AFM}} \), the system is made up of small domains of size \( \sim \xi_{\text{AFM}} \) within which there exists AFM ordering. The order parameter \( m \) in different domains, however, are uncorrelated, so that there is no net AFM order overall. Such short-range order can be masked, if the system size is small compared to \( \xi_{\text{AFM}} \) and only consists of a single domain (see [57] for the actual form for the spin correlation function at \( r \lesssim \xi_{\text{AFM}} \)).

We can estimate roughly the temperature at which such a finite size effect can become significant in ultracold atom lattice systems. The crucial ingredient is the strong exponential dependence of \( \xi_{\text{AFM}} \) on \( T \) in Eq. (19). The Heisenberg exchange coupling \( J_H \) can be related to the Hubbard model parameters by \( J_H \approx 4 J^2/U \) in the large \( U/J \) limit. At \( U/J = 6 \), we find that \( \xi_{\text{AFM}} \approx 100a \) for \( k_B T/J \sim 0.1 \). On the other hand, at \( k_B T/J \sim 0.2 \) the correlation length \( \xi_{\text{AFM}} \approx 20a \) is already smaller than current typical optical lattice size of \( \sim 30 \) sites in each dimension.

\[c_{ij} = \frac{1}{N_s} \sum_{k} \exp(i \mathbf{k} \cdot \mathbf{r}_i) c_{kj}\]

The summation over momenta is defined for the whole Brillouin zone: \( \langle k_x, k_y \rangle = \frac{2\pi}{N_s} (j_x, j_y) \) with \(-N_s/2 \leq k_x, k_y \leq N_s/2\).
The last equation holds because $\Delta$ is invariant system with periodic boundary conditions, we split up the fermion operator $\hat{c}_{k,g}$ defined over the whole Brillouin zone, to two operators $\hat{c}_{k,g}$ and $\hat{c}_{k+Q,g}$, where $k$ is now defined only for the RBZ. They are then collected into a two-component Nambu spinor (in analogy to superconductivity)

$$\hat{\Psi}_{k,g} = \begin{pmatrix} \hat{c}_{k,g} \\ \hat{c}_{k+Q,g} \end{pmatrix}, \quad k \in \text{RBZ}. \quad (21)$$

Using the definition of the staggered order parameter [Eq. (17)] and substituting Eq. (20) and (21), the MFT Hamiltonian $H$ can be written as a $2 \times 2$ matrix

$$H = C_m + \sum_{k,g}^{\text{RBZ}} \hat{\psi}_{k,g}^\dagger \begin{pmatrix} \epsilon_k & \Delta_g \\ -\Delta_g^* & \epsilon_{k+Q} \end{pmatrix} \hat{\psi}_{k,g}, \quad (22)$$

where we have defined the coefficient $C_m \equiv U N^2 (m^2 - 1/4)$, single-particle dispersion

$$\epsilon_k = -2J(\cos k_x a + \cos k_y a), \quad (23)$$

and the order parameter (also called gap parameter)

$$\Delta_g = \eta(g) \Delta, \quad \Delta = m U. \quad (24)$$

Also, at half-filling we have used $\mu = U/2$ to simplify the equation. Note that the Hamiltonian factors into separate spin sectors due to the choice of ordering in the $z$ direction.

The MFT Hamiltonian (22) can be diagonalized by a canonical (Bogoliubov) transformation

$$\begin{pmatrix} \hat{c}_{k,g} \\ \hat{c}_{k+Q,g} \end{pmatrix} = \begin{pmatrix} v_{k,g} & u_{k,g} \\ -\eta(g) u_{k,g} & \eta(g) v_{k,g} \end{pmatrix} \begin{pmatrix} \hat{c}_{1k,g} \\ \hat{c}_{2k,g} \end{pmatrix}. \quad (25)$$

with appropriately chosen $v_{k,g}$ and $u_{k,g}$. The solution is

$$v_{k,g} = \sqrt{\frac{1}{2} \left( 1 - \frac{\epsilon_k}{E_{k+Q}} \right)}, \quad u_{k,g} = \sqrt{\frac{1}{2} \left( 1 + \frac{\epsilon_k}{E_{k+Q}} \right)},$$

$$E_{k+Q} = \sqrt{\Delta_g^2 + \epsilon_k}, \quad \Delta = m U. \quad (27)$$

The last equation holds because $\Delta_g = \eta(g) \Delta$ [see Eq. (18)]. The subscript of the new operators in Eq. (25) refers to the energy bands in RBZ. In the new basis, the Hamiltonian reads

$$H = C_m + \sum_{k,g}^{\text{RBZ}} \left( \hat{c}_{1k,g}^\dagger \hat{c}_{2k,g} \right) \begin{pmatrix} -E_{k+Q} & 0 \\ 0 & +E_{k} \end{pmatrix} \left( \hat{c}_{1k,g} \hat{c}_{2k,g}^\dagger \right). \quad (28)$$

In summary, the MFT ansatz [Eq. (15)] leads to the MFT Hamiltonian Eq. (22) that couples a particle at $k$ to a hole at $k + Q$. The Bogoliubov rotation then transforms the original one-band Hubbard model, defined over the full Brillouin zone, to a two-band model with energies $\pm E_{k+Q}$. To accommodate the same number of states, the momenta in the two-band model are defined over the RBZ only. At temperature $T = 0$, the ground state has all the negative energy modes filled at half-filling, i.e., band 1 is filled. At finite temperatures, the usual Fermi-Dirac distribution describes the occupation of the two bands.

The MFT is found by minimizing the total energy with respect to $m$ at a given temperature using the Hamiltonian (28). The resulting order parameter equation is

$$1 = \frac{1}{N^2} \sum_{k'} \frac{U}{E_{k'}} \tanh \left( \frac{E_{k'}}{2k_B T} \right). \quad (29)$$

At half-filling at $T = 0$ with $U \gg J$ the solution saturates towards $m = 1/2$. The MFT critical temperature $T_{C,MFT}$ can be obtained from solving Eq. (29) with $m = 0$. The value of staggered magnetization $m$ is shown in the $(U, T)$ space in Fig. 2.

As mentioned at the beginning of this Section, in 2D, there is strictly no true long-range order except at $T = 0$ [56]. However, one can define instead a cross-over temperature $T_X$ below which there is at least short-range order, see Borjesza and Dupuis [59, 60]. In the moderate to large $U$ regime, $T_X$ is defined as the temperature at which the AFM correlation length equals the lattice spacing $a$: $\xi_{AFM}(T_X) = a$. It turns out that [59] at large $U/J$, $k_B T_X \sim 4J^2/U$, the Néel temperature scale. On the other hand, at small $U/J$, $T_X \sim T_{C,MFT}$ where the critical temperature $T_{C,MFT}$ is exponentially small in $J/U$. A detailed analysis of the cross-over phase diagram can be found in Ref. [59]. Figure 3 (based on Fig. 2 of [60]) shows a schematic phase diagram for the Hubbard model in 2D at half-filling.
C. Mean-field susceptibilities at zero temperature

One key result of this paper is the explicit connection between the physical observables of inelastic scattered light intensity and spectrum (coded in static and dynamical structure factors), and susceptibilities calculated for the Hubbard model. We first indicate the chain of relations from structure factors to susceptibilities in Sec. IV C 1, and then proceed to give the MFT susceptibilities in Sec. IV C 2 and the RPA ones in Sec. IV D.

1. Time-ordered and retarded correlation functions

We shall show in Sec. V that the inelastic scattered intensity [Eq. (67)] and inelastic scattered spectrum [Eq. (79)] depends on the static and dynamic structure factors defined in Eqs. (69) and (80). For the specific system of two-species atomic gas of ^40K (see Sec. VI A), these general formulae can be reduced [Eqs. (96) and (116)] to involve static and dynamic response functions [Eqs. (71), (81) and (94)] for the spin operators (we follow the notation convention from Ref. [38])

\[ \tilde{S}_q^+ = \sum_k \left( \hat{c}_{k+q,\uparrow} \hat{c}_{k,\uparrow} - \hat{c}_{k+q,\downarrow} \hat{c}_{k,\downarrow} \right), \]

\[ \tilde{S}_q^- = \sqrt{2} \sum_k \hat{c}_{k+q,\uparrow} \hat{c}_{k,\downarrow}, \]

or for the density operator \( \hat{\rho}_q \),

\[ \hat{\rho}_q = \sum_g \hat{\rho}_{q g}, \quad \hat{\rho}_{q g} = \sum_j e^{i q \cdot r_j} \hat{n}_{j g} = \sum_k \hat{c}_{k+q, g} \hat{c}_{k, g}, \]

expressed in terms of the density operators \( \hat{\rho}_{q g} \) for species \( g \), where \( \hat{n}_{j g} = \hat{c}_{j g} \hat{c}_{j g}^\dagger \) and \( r_j \) is the coordinate of the center of the lattice site \( j \). On the other hand, anticipating the calculations of Sec. IV D, the RPA method involves a Feynman-Dyson perturbation series that requires the use of time-ordered correlation functions (often called susceptibilities). The Fourier transform in time of time-ordered correlation function is defined as

\[ \chi^{ij}(q, q'; \omega) = \int dt \frac{i}{2 \pi N_s} \langle T \hat{O}_q(0) \hat{O}_{q'}(t) \rangle e^{i \omega t}, \]

where \( T \) represents the time ordered product, and \( \hat{O}_q(t) \) can be \( \hat{\rho}_q(t) \) or \( \hat{S}_q(t) \).

Fortunately, linear response theory [61] allows to connect time-ordered correlation functions to the response functions needed for scattered intensity and spectrum, as follows. First, at temperature \( T = 0 \), the dynamic response function \( S^{ij}(q, q'; \omega) \) [Eq. (81)] is related to the retarded susceptibility \( \chi^{ij R} \) via

\[ S^{ij}(q, q'; \omega) = -\frac{2}{\pi N_s} \text{Im} \left[ \chi^{ij R}(q, q'; \omega) \right], \]

where the indices \( i, j = \rho, \sigma, \) or \( i, j = \rho, \sigma, \tau \). Note the factor of 2 in Eq. (34) there to compensate for the unconventional factor of 2 in Eq. (33). The superscript \( R \) in the susceptibility \( \chi^{ij R} \) denotes retarded correlation functions that corresponds to the normally ordered physical observables of the scattered light intensity or spectrum. Next, these retarded susceptibilities can be analytically continued from time-ordered susceptibilities, resulting in [61]

\[ \text{Re}[\chi^{ij}(q, q'; \omega)] = \text{Re}[\chi^{ij R}(q, q'; \omega)], \]

\[ \text{Im}[\chi^{ij}(q, q'; \omega)] = \text{sgn}(\omega) \text{Im}[\chi^{ij R}(q, q'; \omega)]. \]

For the MFT (Sec. IV C 2), and for the RPA, (Sec. IV D), all susceptibilities are time-ordered (and Fourier transformed in time).

For future reference, we also point out that the static response function [Eq. (71)] can be obtained from the dynamic response function by integrating over \( \omega \),

\[ S^{ij}(q, q') = \hbar \int_{-\infty}^{\infty} d\omega S^{ij}(q, q'; \omega). \]

2. Mean-field susceptibilities

Because of the RBZ structure of the AFM state, the MFT susceptibilities defined in Eq. (33) can also be written in a 2×2 matrix form,

\[ \chi^{ij}_{(0)}(q, \omega) = \begin{pmatrix} \chi^{ij}_{(0)}(q, q; \omega) & \chi^{ij}_{(0)}(q, q + Q; \omega) \\ \chi^{ij}_{(0)}(q + Q, q; \omega) & \chi^{ij}_{(0)}(q + Q, q + Q; \omega) \end{pmatrix}. \]

The subscript \( (0) \) in all the susceptibilities signifies that these correlation functions are calculated within MFT. A similar 2×2 structure can also be written for the RPA susceptibilities. We shall use a boldface \( \chi \) to denote the
susceptibility matrix. Here, and for the rest of the Section, unless it is explicitly indicated that this is not the case, we use the notation that the momentum $q$ belongs to the RBZ only. Schrieffer et al. [38] and others [53] have calculated the zero temperature susceptibilities using MFT. Here we will present the results; see Appendix A for an outline of the derivation.

\[
\chi_{(0)}^{\rho\rho}(q, \omega) = -\frac{1}{2 N_s^2} \sum_{k}^{\text{RBZ}} \left( 1 - \frac{\epsilon_{k} + k q + \Delta^2}{E_k E_{k+q}} \right) \left( \frac{1}{\hbar \omega - E_k - E_{k+q} + i\delta} + \frac{1}{-\hbar \omega - E_k - E_{k+q} + i\delta} \right). \tag{39}
\]

Here in Eq. (39) the momentum $q$ belongs to the full BZ for both sides of the equation. We have explicitly shown the convergence factor $+i\delta$ ($\delta > 0$) appropriate for time-ordered susceptibilities. For the calculations in this paper we set $\delta$ a small but finite value which determines the frequency resolution in calculated spectra. Since the total density does not distinguish between the spin components, there can be no component in the susceptibility matrix which transfers momentum $Q$ between atoms, hence the diagonal nature of the matrix in Eq. (38). The form of the susceptibility in Eq. (39) is similar in structure to susceptibilities for BCS superfluidity.

It turns out that at the MFT level, the longitudinal spin susceptibility is equal to the density susceptibility

\[
\chi_{(0)}^{\sigma\sigma}(q, \omega) = \chi_{(0)}^{\rho\rho}(q, \omega). \tag{40}
\]

For the 2D Hubbard model in a square lattice at half-filling in the AFM ground state, the MFT density susceptibility is

\[
\chi_{(0)}^{\rho\rho}(q, \omega) = \begin{pmatrix} \chi_{(0)}^{\rho\rho}(q, q; \omega) & 0 \\ 0 & \chi_{(0)}^{\rho\rho}(q + Q, q + Q; \omega) \end{pmatrix}, \tag{38}
\]

This however, is no longer true when RPA is used to compute the susceptibility, cf. Eqs. (44) and (45).

The transverse spin susceptibility, on the other hand, is sensitive to the coupling of atoms that differ in momentum by $Q$. This then leads to two distinct components in the transverse spin susceptibility matrix with nonzero off-diagonal components

\[
\begin{pmatrix}
\chi_{(0)}^{\sigma\sigma}(q, q; \omega) & \chi_{(0)}^{\rho\rho}(q + Q, q; \omega) \\
\chi_{(0)}^{\rho\rho}(q, q + Q; \omega) & \chi_{(0)}^{\sigma\sigma}(q + Q, q + Q; \omega)
\end{pmatrix}. \tag{41}
\]

We find

\[
\chi_{(0)}^{\pm\pm}(q, q; \omega) = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \end{pmatrix}, \tag{42}
\]

\[
\chi_{(0)}^{\pm\pm}(q, q + Q; \omega) = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \tag{43}
\]

Similarly to Eq. (39) the momentum label $q$ in Eqs. (42) and (43) is valid for the full BZ on both sides of the equation and $\chi_{(0)}^{\pm\pm}(q, q + Q; \omega) = \chi_{(0)}^{\pm\pm}(q + Q, q; \omega)$. Note that the transverse spin susceptibilities are different to the longitudinal one. This is due to isotropy in spin space being broken in our MFT: we have assumed in Eq. (15) that the AFM ordering occurs in a specific spin direction (along $z$ axis).

We also generalize these MFT susceptibilities to finite temperatures in Appendix B. At finite temperatures, there are more available scattering processes as the lower effective band (band 1) is no longer fully filled, leading to several additional terms in the expressions for the susceptibilities.

\section{RPA susceptibilities}

The MFT results of the previous subsection capture only the ground state order and single particle excitations. The latter have energies of order $U$ at $U/J \gg 1$, and hence only describe high energy excitations. However, the low energy physics is that for spin, coming from the effective Heisenberg exchange interaction at large $U/J$. In particular, there are low energy quantum fluctuations that lead to gapless collective excitations, cor-

responding to the spin waves of the Heisenberg antiferromagnet. The simplest approximate theory that can capture these collective modes is the RPA [38], which we will therefore employ here.

The basic idea behind the RPA is that certain terms in the perturbation expansion in \( U \) in the Dyson equation can be summed to infinite order as a geometric series (see Appendix A 2). Formally, at least for the non-magnetically ordered state, RPA can be justified as a series expansion in the small parameter \( k_F a_s \) where \( k_F \) is the Fermi wavevector, and \( a_s \) is the scattering length related to \( U \) [62]. However, it is interesting that the RPA for the AFM ordered state also captures the collective modes at large \( U/J \). These collective modes show up as bosonic \emph{gapless} modes in the transverse spin susceptibility \( \chi_{\text{RPA}} \). Furthermore, these collective modes (via \( \chi_{\text{RPA}} \)) can be incorporated into an RPA renormalisation of the AFM order parameter \( m \) [38].

In Appendix A 2, we outline the derivation of the RPA susceptibilities, here we only state the relevant results. For the density correlation, susceptibilities, here we only state the relevant results.

\[
\chi_{\text{RPA}}^{\rho}(q, \omega) = \chi_{(0)}^{\rho}(q, \omega) \left[ 1 + U \chi_{(0)}^{\rho}(q, \omega) \right]^{-1} \tag{44}
\]

and for the longitudinal spin correlation,

\[
\chi_{\text{RPA}}^{zz}(q, \omega) = \frac{\chi_{(0)}^{zz}(q, \omega)}{1 - U \chi_{(0)}^{zz}(q, \omega)} \tag{45}
\]

Note the only difference between these two is the sign of the term proportional to \( U \) in the denominator. Both have the form recognizable from summing a geometric series; indeed they have the same form as the more familiar RPA result for the non-ordered interacting Fermi gas.

The transverse spin susceptibility is more complicated: the AFM state doubles the unit cell and halves the Brillouin zone, coupling a spin \( g \) particle at \( k \) to a spin \( g \) hole at \( k + Q \) [see Eq. (22)]. This gives rise to the non-diagonal matrix form of Eq. (41) for the MFT susceptibility, which then feeds into the RPA one. The RBZ structure can be accommodated in a \( 2 \times 2 \) matrix version of Dyson’s equation to give (see Appendix A 2)

\[
\chi_{\text{RPA}}^{\pm}(q, \omega) = \frac{\chi_{(0)}^{\pm}(q, \omega)}{1 - U \chi_{(0)}^{\pm}(q, \omega)} \tag{46}
\]

Or in the explicit form given by [53],

\[
\chi_{\text{RPA}}^{\pm}(q, \omega) = \frac{\chi_{(0)}^{\pm}(q, \omega)[1 - U \chi_{(0)}^{\pm}(q, \omega)] + U[\chi_{(0)}^{\pm}(q, \omega)]^2}{[1 - U \chi_{(0)}^{\pm}(q, \omega)][1 - U \chi_{(0)}^{\pm}(q, \omega)] - U^2[\chi_{(0)}^{\pm}(q, \omega)]^2}
\]

Here in Eqs. (47) and (48), as in Eqs. (39), (42) and (43), the momentum \( q \) belongs to the full BZ on both sides of the equation and \( \chi_{\text{RPA}}^{\pm}(q, \omega) = \chi_{\text{RPA}}^{\pm}(q + Q, \omega) \).

The appearance of new poles in \( \chi_{\text{RPA}}^{\pm} \) of Eq. (46) is displayed in Fig. 4. Figure 4(a) shows the individual poles originating from the MFT transverse susceptibility \( \chi_{(0)}^{\pm} \) [Eq. (42)]. These poles start from \( \hbar \omega \geq 2 \Delta \), and the width of the peaks is determined by \( \delta \) [see discussion after Eq. (38)]. Figure 4(b) shows the real and imaginary parts of the denominator of Eq. (47). When the real part of the denominator crosses zero, a new pole emerges. We can estimate the energy of this pole as follows. The Heisenberg model has the spin wave dispersion given by [51]

\[
\hbar \omega_{\mathbf{q}} = 2JH \sqrt{1 - \gamma_{\mathbf{q}}^2}, \tag{49}
\]

with \( \gamma_{\mathbf{q}} = (\cos q_x a + \cos q_y a)/2 \). The effective coupling constant \( J_H \) is related to the Hubbard model parameters via \( J_H = 4J^2/U \) in the large \( U/J \) limit. Then, in Fig. 4 with \( \mathbf{q} = (\pi/a, 0) \) and \( U = 5J \), the pole occurs at energy \( \hbar \omega_{\mathbf{q}} \sim 8J^2/U \sim 1.6J \). It can be seen that this is an overestimate, because we are not strictly in the \( U \gg J \) limit. The imaginary part of both MFT and RPA transverse spin susceptibilities are compared in Fig. 5(a) to illustrate how the RPA renormalizes the single particle excitations and induces collective modes. The RPA transverse susceptibility notably differs from the MFT result owing to the collective excitations.

In Fig. 5(b), we show the corresponding RPA renormalization of the MFT density and longitudinal spin susceptibilities. The different signs in the denominators in Eqs. (44) vs. (45) indicate that the RPA corrections have opposite effects on the MFT density and longitudinal spin susceptibilities, as shown in Fig. 5(b).

1. RPA correction to the AFM order parameter

One can also incorporate quantum fluctuations and the effect of collective excitations in the calculation of the AFM order parameter \( m \) [38], see Appendix A 3 for a sketch of the method. Indeed, quantum fluctuations are known to strongly suppress \( m \) (by about 40%) [51] in the
Here we show how these quantities are calculated for the AFM ordered fermionic atoms in an optical lattice. In this Section we study quantum correlations in AFM-ordered strongly-correlated phase of the ultracold atoms in the lattice. Moreover, it was shown in Ref. [26] that by collecting the scattered light into the forward direction by a lens with the diffraction maxima blocked, an experimentally feasible thermometer for fermionic atoms can be realized. The sensitivity of the thermometer was analyzed by comparing the shot noise of the scattered light with fluctuations in the far-field diffraction pattern that arise from thermal correlations of the atoms. In this paper we study quantum correlations in AFM-ordered strongly-correlated phase of fermionic atoms in an optical lattice. In this Section we introduce the formalism describing the relationship between optical signal (the intensity and spectrum of the scattered light) and the atomic correlations.

We assume that the atoms in the lattice are illuminated by light that can be approximated by a monochromatic plane wave with the frequency $\Omega_m$, propagating perpendicular to the lattice (in the positive $z$ direction). The setup is illustrated in Fig. 6. We write the positive frequency electric field component $E_{in}^+$ as

$$E_{in}^+(\mathbf{r}, t) = \frac{1}{2} \xi \mathbf{e}_m e^{i \mathbf{k}_1 \cdot \mathbf{r} - i \Omega_m t}, \quad (50)$$

where $\mathbf{e}_m$, $\mathbf{k}_1 = k \hat{\mathbf{e}}_z$ ($k = \Omega_m/c$), and $\xi$ denote the polarization, wavevector, and the amplitude, respectively, of the incoming light. In an optically thin sample, the dynamics of the electronically excited atomic state may be adiabatically eliminated and the scattered field amplitude $E_{sc}^+(\mathbf{r}, t)$ is proportional to the transition amplitude related to measurements on the light scattered from the atoms. In optical lattice systems the atoms can be confined by highly anisotropic trapping potentials in which the atom dynamics is restricted to 1D or 2D. This makes the atomic samples particularly suitable for imaging. For the incident light tuned off from the atomic transition resonance frequency, the sample is then optically thin and the quantum statistical correlations of the atoms can be mapped onto fluctuations of the scattered light [22–35]. Measurements on the scattered light therefore convey information about the many-body state of the atoms and can be employed in the diagnostics of the correlated phases of the ultracold atoms in the lattice. Moreover, we will use the RPA-corrected data of Ref. [38] for computing the elastic scattering intensity in Secs. VI B 1 and VII B.

V. OPTICAL DIAGNOSTICS

A. Scattered intensity

In the previous Section we showed how the time-ordered and normally-ordered correlation functions can be calculated for the AFM ordered fermionic atoms in an optical lattice. Here we show how these quantities are

FIG. 4. Transverse spin susceptibility for $U = 5J$ and $q = (\pi/a, 0)$ computed with a finite convergence factor $\delta = 0.1J$ in a 20×20 lattice. (a) We show for the MFT case the individual momentum terms $\chi_{(0)}^{(k)}(q, q; \omega)$ of Eq. (42) $\chi_{(0)}^{-}(q, q; \omega) = \sum_k \chi_{(0)}^{-}(q, q; \omega)$. Each term contributes with a Lorentzian shaped peak at $\omega = E_k - E_{k+q}$. (b) Imaginary (solid) and real (dashed) parts of the denominator in the RPA case $\chi_{RPA}^{-}(q, q; \omega)$ [Eq. (47)]. The inset in (b) zooms in close to the origin and shows the zero-crossing in the real part.

FIG. 5. Imaginary part of the MFT and RPA density, longitudinal spin and transverse spin susceptibilities for a lattice size of 40×40. Other parameters are as in Fig. 4. (a) Imaginary part of the transverse spin susceptibility for the MFT case $\chi_{(0)}^{(0)}(q, q; \omega)$ of Eq. (42) (dashed) and for the RPA case $\chi_{RPA}^{(0)}(q, q; \omega)$ of Eq. (47) (solid). (b) RPA density susceptibility $\chi_{RPA}(q, q; \omega)$ of Eq. (44) (dashed). RPA longitudinal spin susceptibility $\chi_{RPA}^{\rho \rho}(q, q; \omega)$ of Eq. (45) (dotted). Note that the in the MFT case $\chi_{(0)}^{\rho \rho}(q, q; \omega)$ (solid) coincides with the MFT $\chi_{(0)}^{(0)}(q, q; \omega)$, see Eqs. (39) and (40). However, the RPA renormalizes these two susceptibilities differently.

Heisenberg model. For the half-filled Hubbard model, Schrieffer et al. [38] have computed the RPA corrections to $m$ numerically (see their Fig. 7). Chubukov et al. have further shown that at large $U$ the RPA corrected $m$ indeed approaches the Heisenberg model result quantitatively. We will use the RPA-corrected data of Ref. [38] for computing the elastic scattering intensity in Secs. VI B 1 and VII B.
of atoms between the initial and final hyperfine electronic ground states $g$ and $g'$ [63],

$$ E_{sc}^g(r, t) = C \sum_{g'g} A_{g'g} \int d^3r' e^{-i\Delta k \cdot r'} \hat{\Psi}^\dagger_{g'}(r', t) \hat{\Psi}_{g}(r', t). \quad (51) $$

Here the scattered field at $r$ is evaluated in the far radiation zone, so that $|r - r'| \simeq r - \hat{n} \cdot r'$ with

$$ \hat{n} = \frac{(r - r')}{|r - r'|}, \quad (52) $$

and the origin is located inside the atomic sample. The integration is over all the radiating atomic dipole sources at the positions $r'$. The field is scattered in the direction $k_2$ and the change of the wavevector of light upon scattering is, see Fig. 6,

$$ \Delta k = k_2 - k_1 = k(\hat{n} - \hat{\epsilon}_z) = k(\sin \theta \sin \phi, \sin \theta \cos \phi, \cos \theta - 1). \quad (53) $$

In Eq. (51) the effects of the level structure are incorporated in $A_{g'g}$ defined by

$$ A_{g'g} = \frac{1}{\mathcal{D}} \sum_{\epsilon} \sum_{\sigma} \left(\hat{n} \cdot \mathbf{d}_{\epsilon'\sigma}(\hat{\epsilon}_\sigma \cdot \mathbf{d}_{\epsilon g})\right). \quad (54) $$

Here the atomic transition dipole matrix elements between the ground state $g$ and the excited state $\epsilon$ are

$$ \mathbf{d}_{\epsilon g} = (\mathbf{d}_{\epsilon g})^* = (\epsilon|d|g) = \mathcal{D} \sum_{\sigma} (\epsilon|\sigma g)\hat{\epsilon}_\sigma^*, \quad (55) $$

where $(\epsilon|\sigma g)$ denotes the corresponding Clebsch-Gordan coefficient. The summation runs over the circular polarization vectors $\hat{\epsilon}_\sigma$ ($\sigma = -1, 0, 1$),

$$ \hat{\epsilon}_z = -\frac{1}{\sqrt{2}} (\hat{\epsilon}_x + i\hat{\epsilon}_y), \quad \hat{\epsilon}_0 = \hat{\epsilon}_z, \quad \hat{\epsilon}_- = \frac{1}{\sqrt{2}} (\hat{\epsilon}_x - i\hat{\epsilon}_y), \quad (56) $$

and $\mathcal{D}$ is the reduced dipole matrix element. The latter is related to the Weisskopf-Wigner radiative resonance linewidth $\gamma$ by

$$ \gamma = \frac{\mathcal{D}^2 k^3}{\delta \pi \epsilon_0}, \quad (57) $$

where $\epsilon_0$ is the vacuum permittivity. In Eq. (51) we defined the prefactor $C$ by

$$ C = \frac{3\epsilon_0 e^{ikr\gamma}}{4\delta k r}, \quad (58) $$

Here $\delta$ denotes the detuning of the incident light frequency $\Omega_\text{in}$ from the atomic resonance frequency $\omega_0$.

Typically the wavenumber for the probe light is not the same as the effective wavenumber of the optical lattice potential. In order to suppress the spontaneous emission due to the lattice light lasers, the lattice lasers are considerably more off resonant. The probe and the lattice lasers may also be tuned to different transitions and the lattice spacing can be modulated by optical components, resulting, e.g., in the accordion lattices where the lattice spacing may vary for a given lattice light laser frequency [44–46]. We investigate the effect of different ratios $\kappa$ between the probe light wavenumber $k$ and the effective lattice light wavenumber $k_1$ [Eq. (7)], so that

$$ \kappa = \frac{k}{k_1} = \frac{ka}{\pi}, \quad (59) $$

The intensity of the scattered light is given by

$$ I = 2\epsilon_0 c \langle E_{sc}^g(r, t) E_{sc}^{g*}(r, t) \rangle \quad (60) $$

where $c$ denotes the speed of light in vacuum. By substituting the field amplitudes from Eq. (51) in the expression for the light intensity, we obtain the intensity in terms of the atomic correlation functions. The atoms are initially assumed to occupy the ground state in the lowest energy band. In the tight-binding regime the atomic field operators in the correlation function may be expanded in the series of the Wannier functions [Eq. (8)] where $\hat{c}_g$ denotes the annihilation operator for the atoms in the electronic ground state $g$ and the lattice site $j = (j_x, j_y)$. We obtain for the scattered light intensity

$$ \frac{I}{B} = \alpha_{\Delta k} \mathcal{M}_{g_1g_4} \mathcal{M}_{g_2g_1} e^{i\Delta k \cdot (r_j - r_i)} \langle \hat{c}_i^\dagger \hat{c}_{g_4} \hat{c}_{g_3}^\dagger \hat{c}_{g_2} \rangle \quad (61) $$

Here we have defined

$$ B \equiv I_{\text{in}} \left(\frac{3\gamma}{2\delta k r}\right)^2, \quad I_{\text{in}} = \frac{1}{2} f_0 e^2, \quad (62) $$

where $I_{\text{in}}$ denotes the intensity of the incoming light, and

$$ \mathcal{M}_{g_1g_4} \mathcal{M}_{g_2g_1} = \Lambda_{g_1g_4}^* \Lambda_{g_2g_1}^* \quad (63) $$

In deriving Eq. (61) we have assumed that the spatial overlap between different sites is negligible. If the lattice potential is approximately independent of the different ground state labels $g$, the Debye-Waller factor $\alpha_{\Delta k}$ exhibits a simple format of the Fourier transform of the lattice site density that can be evaluated by means of the Wannier functions [Eq. (11)],

$$ \alpha_{\Delta k} = \left| \int d^3r e^{-i\Delta k \cdot r} w_0(r) \right|^2 \quad (64) $$

where the oscillator length $l_i$ is defined by Eq. (12).

In the expression (61) for the scattered light intensity, the spatial variation of atomic correlations is encapsulated in the operators $\hat{c}_g$. The result is general and also includes the cases where the translational invariance of the lattice is broken owing to finite-size effects. In this work, we neglect any additional potential superposed
with the lattice that would lead to a nonuniform density distribution, so that \( (c^\dagger_\alpha y_g) \) is here constant. The spatial profile in Eq. (61) is therefore solely determined by the phase factors of \( \tilde{\alpha}_g \)'s. The simple relationship (61) between the scattered light intensity and the atomic correlation functions is a consequence of the weak off-resonant coupling of light. For near-resonant light the coupling is strong even in a 2D lattice and results in excitations of collective polarization modes [64].

We will consider the scattering processes of the atoms to higher energy bands in Sec. V C. Although such processes result in the photon frequencies that are shifted by the energy difference between the bands and can be filtered from the signal, they can contribute to the heating rate of the atoms in the lattice.

In the specific analysis of the optical signatures of the atomic correlations it is beneficial to separate in the scattered intensity the contributions from the elastic and inelastic scattering events. In the following study we define the elastic scattering processes as those in which the atom scatters back to its original momentum state. We evaluate Eq. (61) in terms of the elastically and inelastically scattered light intensities \( I_e(\Delta k) \) and \( I_i(\Delta k) \), respectively,

\[
I_e(\Delta k) = I_e(\Delta k) + I_i(\Delta k) \\
I_e(\Delta k) = B_0 \Delta k \left| \sum_\alpha N_\alpha \langle \tilde{\rho}_{\Delta k g} \rangle \right|^2 \\
I_i(\Delta k) = B_0 \Delta k \sum_{g, g_1, q_1} M_{g g_1}^{\text{RPA}} \langle \tilde{\rho}_{\Delta k g} \rangle \langle \tilde{\rho}_{-\Delta k g_1} \rangle,
\]

Here \( \Delta k \) denotes the change of wave vector of light on the \( xy \) plane and the density operator \( \tilde{\rho}_{k g} \) for the spin state \( g \) is given by Eq. (32). We have defined

\[
u_k = \sum_j e^{-ik \cdot r_j},
\]

and the static structure factor

\[
S_{g g_1}^{xg_1}(\Delta k) = \sum_{q, q', \neq 0} \langle \tilde{u}_k + q - q' \rangle^2 \langle \tilde{c}_k + q_g \tilde{c}_{k'} - q_{g_2} \tilde{c}_{k' g_1} \rangle_c.
\]

All the \( q = q' = 0 \) terms in the previous equation are included in the elastic part. This corresponds to incorporating only the connected Feynman diagrams in the correlation function of the static structure factor (indicated by the subscript \( c \)) and the disconnected ones in the relevant expansion are precisely those that go into the elastic part, see Ch. 13.4 of [65].

The finite-size effects of the lattice contribute in Eq. (69) via the \( u_k \) factors. In the limit of a large lattice, we may approximate \( S_{g g_1}^{xg_1} \) by translationally invariant atomic mode functions, so that the summation over the sites approaches a delta function \( u_k \to N_k \delta_{k,0} \) and

\[
S_{g g_1}^{xg_1}(\Delta k) \simeq \sum_{k, k'} \langle \tilde{c}_k + \Delta k_{g_1} \tilde{c}_{k'} \rangle \langle \tilde{c}_{k} - \Delta k_{g_2} \tilde{c}_{k' g_1} \rangle_c.
\]

In a typical 40x40 lattice we are investigating, taking the continuum limit changes the integrated inelastically scattered light intensity by less than 2%.

In order to calculate the intensity of the scattered light [Eq. (67)] and the corresponding static structure factor [Eq. (69)] it is useful to define a static response function as

\[
S_{g g_1}^{xg_1}(q, q') = \frac{1}{N_s} \sum_{g, g_2} \langle \tilde{c}_k + q_{g_2} \tilde{c}_{k'} - q_{g_2} \tilde{c}_{k' g_1} \rangle_c.
\]

In Sec. IV C 2 and IV D we showed how both the RPA correlations based on the Feynman-Dyson perturbation series as well as the MFT correlations for the AFM state in the large lattice limit can then be efficiently calculated in a compact form by evaluating the diagonal components \( S_{g g_1}^{xg_1}(q, q) \). In this paper we approximate the inelastically scattered light intensity by these diagonal expressions, while still including finite-size contribution from the diffraction pattern via \( |u_k_{\Delta k - q}|^2 \). The corresponding intensity expression reads

\[
I_e(\Delta k) \approx \sum_{q, \neq 0} \langle \tilde{u}_k - q \rangle^2 M_{g g_1}^{\text{RPA}} S_{g g_1}^{xg_1}(\Delta k).
\]

In Sec. VI B we will show how \( S_{g g_1}^{xg_1}(q, q) \) can be related to the density as well as longitudinal and transverse spin correlation functions [Eq. (64)].

The general Eqs. (65)-(67) give the scattered light intensity for an arbitrary lattice system. The scattered light carries information about the atomic correlation functions. The lattice structure generates the diffraction pattern and the overall envelope of the pattern is produced by the Debye-Waller factors that depend on the profile of the atomic wave functions on individual sites. The dependence of the scattered light on the polarization, atomic level structure, and the scattering direction is incorporated in \( M_{g g_1}^{\text{RPA}} \).

The elastic scattering produces a diffraction pattern from a non-fluctuating atom density in the lattice where the Wannier site wave functions play the role of the diffraction slit profile [26]. The inelastic scattering processes are those in which an atom scatters from one quasimomentum state to another different state. The inelastic scattering is sensitive to the fluctuations of the atoms and reflects the underlying statistical correlations between the atoms. It produces scattered light into angles outside the diffraction orders, generating fluctuating shifts in the diffraction pattern that result from the atomic-lattice system absorbing recoil kicks from the scattered photons [26].
The elastic component corresponds to a peak at \( \omega \equiv 0 \), revealing the excitations of the system [see Sec. VIII]. We then find that the elastically scattered light intensity,

\[
I_\omega(\Delta k) = B \alpha_{\Delta k} |u_{\Delta k}|^2 \sum_g \Lambda_{gg} f_g^2 ,
\]

is determined by the Bragg diffraction pattern of the lattice \(|u_{\Delta k}|^2\), weighted by the contributions from the atomic level structure via \( \Lambda_{gg} \), and modulated by the Debye-Waller factor \( \alpha_{\Delta k} \). In the specific case of a 2D square lattice we obtain the familiar diffraction pattern of a 2D square array of \( N_x \times N_y \)分布在四分之一处的

\[
|u_{\Delta k}|^2 = \prod_{\alpha=x,y} \sin^2 \left( \frac{N_x \Delta k_\alpha}{2} \right) .
\]

For uniformly filled lattice the elastic part contains no information about the elastic light before the measurement [26]. We will explain this procedure in detail in Sec. VI B 1. For the AFM state studied in Sec. IV B, lattice translation symmetry is broken, resulting in the Brillouin Zone being halved in size. We shall show in Sec. VI B 1 that in this case, there are new diffraction peaks that correspond to this new lattice periodicity, and is therefore a key signature of the AFM order. This effect was first analyzed in Ref. [36].

### B. Scattered spectrum

In the previous Section we established the relation between the scattered light intensity with the equal time atomic correlations [Eqs. (65)-(67)]. We now analyze the spectrum of the scattered light and show how it conveys information about the excitation spectrum of the atoms in the lattice. The scattered light spectrum may be obtained as a Fourier transform of the two-time correlation function of the scattered electric field [63]

\[
S(\Delta k, \omega) = A \int dt e^{i \omega t} (E^-(r, 0) E^+(r, t)) ,
\]

where \( A \) denotes the normalization factor. We can then write the scattered spectrum in terms of the two-time correlation functions of the atoms in the optical lattice. The spectrum can be separated into an elastic and inelastic component and we obtain

\[
S(\Delta k, \omega) = S_\omega(\Delta k, \omega) + S_1(\Delta k, \omega) ,
\]

\[
S_\omega(\Delta k, \omega) = A' \delta(\omega) \sum_g \Lambda_{gg} \langle \hat{\rho}_{\Delta k} \rangle^2 ,
\]

\[
S_1(\Delta k, \omega) = A' \delta(\omega) \sum_{g_1, g_2, g_3} M_{g_1 g_2 g_3} S_{g_1 g_2 g_3}(\Delta k, \omega) .
\]

where \( A' \equiv AB/(2c_0) \). In the last equation we have introduced the dynamic structure factor, which is analogous to the static case of Eq. (69)

\[
S_{g_1 g_2 g_3}(\Delta k, \omega) = \frac{1}{N^4} \sum_{q_1, q_2, q_3} u_{\Delta k - q_1}^* u_{\Delta k - q_2} u_{\Delta k - q_3} \sum_{k,k'} \int dt e^{i \omega t} \langle \hat{c}_{k+q_1}^\dagger(0) \hat{c}_{k+q_2}(0) \hat{c}_{k'+q_3}^\dagger(t) \hat{c}_{k'}(t) \rangle .
\]

The elastic component corresponds to a peak at \( \omega = 0 \). The subscript \( c \) indicates the connected diagrams for which \( \omega \neq 0 \), revealing the excitations of the system [see Sec. VIII]. Analogously to Eq. (71) we define the dynamical response functions as

\[
S_{g_1 g_2 g_3}(\Delta k, \omega) = \frac{1}{N^4} \sum_{k,k'} \int dt e^{i \omega t} \langle \hat{c}_{k+q_1}^\dagger(0) \hat{c}_{k+q_2}(0) \hat{c}_{k'+q_3}^\dagger(t) \hat{c}_{k'}(t) \rangle .
\]

We approximate Eq. (79) in a similar fashion as Eq. (72)

\[
\frac{S_1(\Delta k, \omega)}{\alpha_{\Delta k} A'} \approx \sum_{q \neq 0} |u_{\Delta k - q}|^2 \sum_{g_1, g_2, g_3} M_{g_1 g_2 g_3} S_{g_1 g_2 g_3}(q, q; \omega) .
\]

### C. Atom losses to higher bands

In Sec. VA we calculated the optical intensity signal for probing the atoms in an optical lattice. This consists of the elastic scattering processes in which the final state of the atoms is the same as the initial state as
well as the inelastic scattering processes within the lowest energy band where the quasimomentum state of the atoms changes. The atoms that initially occupy the lowest energy band may also undergo scattering to higher bands. Owing to the energy splitting between the adjacent bands, which is of the order of \( 2s^{1/2}E_R \) [\( E_R \) was defined in Eq. (6)], the photons that scatter to higher bands are frequency-shifted from the optical signal and could be filtered out. This is because the maximum recoil kick absorbed by the atom within the lowest band on the \( xy \) plane is \( \kappa \) [the recoil component on the lattice plane satisfies \( |\Delta q| = k\sin(\theta) \), see Eq. (53)], corresponding to the energy shift of \( s^2E_R \) [Eqs. (6) and (59)], which is less than the energy difference between the bands \[66\]. The scattering to higher bands, however, provides a loss mechanism which we will estimate when calculating the measurement accuracy of AFM correlations of the atoms.

Here we extend the analysis of the loss rates of Ref. [30] to our multi-level formalism. In the evaluation of the scattered intensity the following correlation functions involving states in higher energy bands yield nonvanishing contributions

\[
\mathcal{G}_{m,j,0,j_0}^{\tilde{g}+}\mathcal{G}_{n,j_0,j}^{\tilde{g}+} = \int d^3r d^3r' w^{\tilde{g}}_{m,j}(r) w^{\tilde{g}}_{m,j}(r') w^g_{n,j_0}(r) w^g_{n,j_0}(r') e^{i\Delta k(r-r')}. \tag{84}
\]

The mode functions in each site form a complete basis and we have

\[
\sum_{\tilde{g},g,\tilde{g},g} w^{\tilde{g}}_{m,j}(r) w^{\tilde{g}}_{m,j}(r') = \delta(r-r') - \sum_j w^{g}_{n,j_0}(r) w^{g}_{n,j_0}(r'). \tag{85}
\]

This can be used to simplify Eqs. (83) and (84). We find that the contribution to the scattered intensity of this process reads

\[
I_{hb} = BN_s^2 \left[ 1 - \alpha_{\Delta k} \right] \sum_{g,g'} M^{g'}_{g} \delta_{g,g'}, \tag{86}
\]

where \( I_{hb} \) refers to the scattered light intensity resulting from the scattering events where the atoms end up in the higher energy bands. Here \( N = N_s^2 \) is the total number of atoms in the lattice. This result remains valid for both fermions and bosons as long as the assumption of unpopulated higher bands is valid.

VI. OPTICAL SIGNATURES OF MAGNETIC ORDERING IN SCATTERED INTENSITY

A. Two-species atomic gas of \(^{40}\)K

In the previous Section we presented the general expressions for the dependence of the scattered light on the atomic correlation functions in an optical lattice system. Next we analyze the 2D square lattice system of two-species fermionic atoms introduced in Sec. III, with equal population of \( N_s^2/2 \) atoms of both species. As a specific example we consider \(^{40}\)K, which has been used in an experimental realization of fermionic Mott insulator states in lattices [6–8] and recently AFM ordering [8]. We consider the two electronic ground states

\[
\begin{align*}
| \downarrow \rangle &= |4S_{1/2}, F_g = 9/2, m_F = -9/2 \rangle, \\
| \uparrow \rangle &= |4S_{1/2}, F_g = 9/2, m_F = -7/2 \rangle.
\end{align*}
\]

The incident field is assumed to be \( \sigma^- \) polarized, so that the two ground states are coupled to the electronically excited states

\[
\begin{align*}
|1\rangle &= |4P_{3/2}, F_e = 11/2, m_F = -11/2 \rangle, \\
|2\rangle &= |4P_{3/2}, F_e = 11/2, m_F = -9/2 \rangle.
\end{align*}
\]

The level scheme and the transitions are illustrated in Fig. 7. The atoms in | \downarrow \rangle undergo a cycling transition in which case they are only excited to |1\rangle, decaying back...
to the original state $|↓\rangle$. The atoms in $|↑\rangle$ are excited to $|2\rangle$ from where they can decay either back to $|↑\rangle$ or to $|↓\rangle$. The latter represents a spin-exchanging transition. We will find that the transitions in which the spin is changed convey information about transverse spin correlation functions, while those associated with the scattering processes in which the spin is conserved are proportional to density and longitudinal spin correlation functions. Specifically, the different transitions can be identified with the different RPA susceptibilities in Eqs. (44), (45) and (46), respectively.

In our system we vary the lattice size between $N_s = 16$ and $40$ sites along each direction. We consider two lattice heights, $7.8E_R$ and $25E_R$. The trap frequency perpendicular to the lattice is chosen as $\omega_z = 10E_R/h$. For $^{40}\text{K}$ we take experimentally realistic [6-8] values for the incoming light $\lambda = 766.5\text{nm}$ and $I_{in} = 5W/m^2$, and assume it to be detuned from the atomic resonance $\delta = 20\gamma$ [Eq. (58)]. This yields in Eq. (62) $B\tau^2 \approx 1615$ photons/s. We vary the ratio between the lattice spacing and the wavelength of the incident light by changing $\kappa$ [Eq. (59)] and take $\kappa = 0.66$, $1.05$ and $1.5$. All these correspond to subwavelength lattice spacing, but the additional magnetic peak due to period doubling may only be observed for $\kappa = 1.5 > \sqrt{2}$.

B. Scattered intensity

In Sec. V A the total scattered intensity was separated into the elastic component $I_{e}(\Delta k)$ and an intraband inelastic component $I_{i}(\Delta k)$, see Eqs. (66) and (67). Furthermore, in Sec. V C we have taken into account the inelastic scattering of atoms to higher bands in Eq. (86), $I_{hh}(\Delta k)$, that is not assumed to contribute to the detected signal but affects the heating rate of the atoms. The total scattered intensity is thus

$$ I = I_{e} + I_{i} + I_{hh}. \quad (89) $$

We now analyze each of these components for the specific case of a two-species $^{40}\text{K}$. Applying the level structure of Fig. 7 we find the explicit expressions for all the scattered elastic and inter-band intensity components

\[
\frac{I_{e}(\Delta k)}{\alpha_{\Delta k}B} = \left( \sqrt{M_{↑↓}^{↑↓}}(\hat{\rho}_{\Delta k \downarrow}) + \sqrt{M_{↓↑}^{↓↑}}(\hat{\rho}_{\Delta k \uparrow}) \right)^2, \quad (90)
\]

\[
I_{hh}(\Delta k) = B\eta^2 (1 - \alpha_{\Delta k}) \left( M_{↑↓}^{↑↓} + M_{↓↑}^{↓↑} \right). \quad (91)
\]

Here the Debye-Waller factor $\alpha_{\Delta k}$ is given in Eq. (64) and the coefficient $B$ in Eq. (62). In the elastically scattered intensity, Eq. (90), the Fourier transform of the density operator is defined in Eq. (99). The components of $M_{gg'g''}^{\alpha\beta\gamma\delta}$ in Eq. (63) read [see Eqs. (87) and (88)]

\[
M_{↓↓}^{↑↓} = \frac{1}{4} (3 + \cos 2\theta), \quad M_{↑↓}^{↑↓} = M_{↓↑}^{↓↑} = \frac{9}{44} (3 + \cos 2\theta), \quad M_{↓↑}^{↑↓} = \frac{81}{484} (3 + \cos 2\theta), \quad M_{↑↑}^{↓↓} = \frac{18}{121} \sin^2 \theta. \quad (92)
\]

We now consider the scattered inelastic intraband intensity component $I_{i}$. Due to the broken translation symmetry in the AFM state, the RPA susceptibilities of Eqs. (44), (45) and (46) have a matrix structure [cf. the MFT susceptibility matrix Eq. (37)]. To exhibit clearly this RBZ structure, the inelastic intensity component of Eq. (72) can be written by generalizing the static response functions of Eq. (71) to a $2 \times 2$ matrix with a RBZ momentum structure analogous to that of Eq. (37) as

\[
S_{gg'g''}(q) = \left( \begin{array}{cc} S_{gg'g''}^{\alpha\beta\gamma\delta}(q, q) & S_{gg'g''}^{\alpha\beta\gamma\delta}(q, q + Q) \\ S_{gg'g''}^{\alpha\beta\gamma\delta}(q + Q, q) & S_{gg'g''}^{\alpha\beta\gamma\delta}(q + Q, q + Q) \end{array} \right). \quad (93)
\]

The static response functions that appear in each element of the previous matrix are defined in Eq. (71). To relate to the RPA density and spin susceptibilities [Eqs. (44), (45), and (46)] we first note that using Eqs. (32), (31) and (30), we can define the matrix of static response functions for the density, longitudinal and transverse spin operators

\[
S_{gg'}^{\alpha\beta\gamma\delta}(q) = \sum_{g'g''} \eta(g) \eta(g') S_{gg'}^{\alpha\beta\gamma\delta}(q) \quad (94)
\]

where $\eta(g)$ is defined in Eq. (18). These static response functions can in turn be related to the time-ordered correlation functions (susceptibilities) of Eqs. (44), (45) and (46) of Sec. IV, using the relationship in Eqs. (35) and (34) together with frequency integration from Eq. (36).

The diffraction factors $u_k$ defined in Eq. (68) can also be accommodated into the RBZ structure by defining

\[
u_k = \left( \begin{array}{cc} u_k \\ u_{k+Q} \end{array} \right), \quad k \in \text{RBZ}. \quad (95)
\]

Hence, the inelastic component of the intensity of light scattering off atoms in the AFM state of Eq. (72) can be written as
\[
\frac{I_c(\Delta k)}{\alpha_{\Delta k} B} = \frac{1}{4} \left( M_{\uparrow \uparrow} + M_{\downarrow \downarrow} \right) \sum_{q \neq 0}^\text{RBZ} u^\dagger_{\Delta k-q} \left[ S^{\uparrow \uparrow}(q) + S^{\downarrow \downarrow}(q) \right] u_{\Delta k-q} + \frac{1}{4} \left( M_{\uparrow \uparrow} + M_{\downarrow \downarrow} \right) \sum_{q \neq 0}^\text{RBZ} u^\dagger_{\Delta k-q} \left[ S^{\uparrow \downarrow}(q) - S^{\downarrow \uparrow}(q) \right] u_{\Delta k-q} + \frac{1}{2} M_{\uparrow \downarrow} \sum_{q \neq 0}^\text{RBZ} u^\dagger_{\Delta k-q} S^{\uparrow \downarrow}(q) u_{\Delta k-q} .
\]  

(96)

In the following we will analyze the different scattering contributions. The spectrum and the excitations will be studied in Sec. VIII.

1. Elastic scattering

This Section is devoted to studying the elastic component of the scattered light. We show that the emergence of AFM ordering in the system is directly observable in the elastically scattered light intensity as this results in magnetic Bragg peaks in the scattered light signal. For the two-species system studied here (Fig. 7) the total scattered light intensity can be computed from Eqs. (90) and (92). This results in

\[
I_c(\Delta k) = \frac{1}{4} (3 + \cos 2\theta) \left( \hat{\rho}_{\Delta k} + \frac{9}{11} \rho_{\Delta k} \right)^2 .
\]  

(97)

Note that the two spin terms contribute unequally because the Fourier transform has a new term. It can be written as

\[
\langle \hat{\rho}_{\Delta k} \rangle = \sum_j e^{i\Delta k \cdot r_j} \hat{n}_j = \sum_j e^{i\Delta k \cdot r_1} (f_g + mn\eta(g)e^{iQ \cdot r_1})
\]

(98)

\[
= u_{\Delta k} f_g + u_{\Delta k+Q} m n \eta(g) ,
\]  

(99)

where \( f_g = 1/2 \) is the atomic filling factor of species \( g \) at half-filling and \( \eta(g) \) is defined in Eq. (18). Comparing to Eq. (73), the new term is proportional to the AFM order parameter \( m \), Eq. (15), and is centered at the ordering vector \( Q = (\pi/a, \pi/a) \). The order parameter \( m \) can be obtained by solving the implicit MFT [Eq. (29)]. The MFT phase diagram of Fig. 2 shows its dependence on \( T \) and \( U \). However, as discussed in Sec. IV D and Appendix A 3, quantum fluctuations around the MFT solution have significant effects not only on susceptibilities, but also on the AFM order parameter \( m \): the ordering can decrease by up to \( \sim 40\% \) at large \( U \). Thus, we shall use the RPA-corrected \( m \) values as computed by Schrieffer et al. [38].

Substituting Eq. (99) into Eq. (97), we see that in addition to the usual diffraction term \( u_{\Delta k} \) \( u_{\Delta k} \) centered at \( \Delta k = 0 \), there is a new magnetic Bragg peak centered at \( \Delta k = Q \), proportional to \( m^2 \) (see Fig. 8). This new peak can be detected by collecting scattered light around \( \Delta k \sim Q \), which, according to the definition of \( \Delta k \) in Eq. (53), corresponds to \( \theta_B = \arcsin \frac{\pi}{\Lambda} \) and \( \phi_B = \pi/4 \).
(see Sec. VII A). The position of the magnetic peak depends on the ratio \( \kappa \) [Eq.(59)] between the probe light wavevector and the effective wavevector of the lattice light, see Eqs. (53). Hence it will only be observable if \( \kappa \geq \sqrt{2} \). Magnetic Bragg peaks were first studied in optical lattices in Ref. [36] and experimentally observed for an artificially prepared density pattern in Ref. [37].

The dependence of the magnetic Bragg peak on the staggered magnetization \( m \) is illustrated in Fig. 8(a) that shows the elastically scattered intensity from a lattice populated by both atomic species for different values of \( m \) [Eq. (97)]. The different values of \( m \) may correspond, e.g., to different values of temperature or the on-site interaction strength \( U \).

On the other hand, if for example only the \( \downarrow \) species is imaged, according to Eq. (97), the elastic part of the intensity becomes
\[
\frac{I^\downarrow(\Delta k)}{B^\downarrow} = \frac{(3 + \cos 2\theta)}{4} (\bar{\rho}_{\Delta k})^2 \tag{100}
\]
\[
= \frac{(3 + \cos 2\theta)}{4} \left( \frac{\mu_{\Delta k}}{2} - \nu_{\Delta k+Q}\right)^2. \tag{101}
\]

The resulting magnetic Bragg peak is now strongly enhanced, see Fig. 8(b). We show two different cases: the case when both species are present in the system [Eq. (97)] and the case when imaging is done with only a single species present in the lattice [Eq. (101)]. In the first case, without spin-specific detection, the total signal is very weak because of destructive interference between the scattered light from the two species. In fact, the magnetic Bragg peak is observable only because the dipole transition matrix elements between the two species are not equal and, according to Eqs. (97) and (99), is weaker than the single species response by the factor of \((2/11)^2\). If the transition matrix elements were the same, the spin-independent imaging would only probe the total density without revealing the AFM order.

Alternatively, if the Zeeman splitting between the two spin states can be sufficiently increased by magnetic fields, such that the incident laser is tuned in between the resonances of the two states while simultaneously being far-detuned from both of them, the optical signatures of the staggered magnetization order parameter can be further enhanced. This is because the light scattered from the two species can then be \( \pi \) phase-shifted with respect to each other. This changes the sign of one of the density terms originating from Eq. (99). By appropriately adjusting the detuning it is therefore possible to have the elastically scattered light intensity proportional to \( m^2 \)
\[
\frac{I^\downarrow(\Delta k)}{B^\downarrow} = \frac{1}{4} \left(3 + \cos 2\theta \right) \left( \frac{18}{11} \bar{\rho}_{\Delta k+Q} \right)^2, \tag{102}
\]
where the detuning \( \delta \) in the parameter \( B \) [Eq. (62)] is now the detuning of the incident light from the resonance of the atomic species \( | \downarrow \rangle \). For \( ^{87}\text{Rb} \) the necessary splitting would require very strong magnetic fields. The hyperfine levels \( m_F = 7/2 \) and \( m_F = 9/2 \) can exhibit a more significant splitting than \( m_F = -7/2 \) and \( m_F = -9/2 \). For strong fields the nuclear spin \( I \) can also decouple from the optical transitions, such that the atomic levels needed in the imaging could, e.g., be \( |J = 1/2, m_J = \pm 1/2\rangle, |J = 3/2, m_J = -1/2\rangle, \) and \( |J = 3/2, m_J = -3/2\rangle \) (all with the same \( I, m_I \)).

2. Elastic scattering in the presence of short-range correlations

So far we have considered long-range AFM order where the staggered magnetization \( m \) is constant throughout the lattice. In Sec. IV A, we discussed how there is no genuine long range AFM order in the Hubbard model (or its strong coupling limit, the Heisenberg model), at any finite temperature in the thermodynamic limit. Moreover, to avoid heating and atom losses (see Sec. VII B) due to scattering, the probe laser can only be turned on for a time about two orders of magnitude shorter than the hopping time \((\sim h/J)\) of an atom. This means that in a single experimental realization, the light is scattered off a specific frozen configuration of the atoms in the lattice. Therefore the measurements of the scattered light intensity necessitate a simulation of a specific stochastic atom configuration, and not an ensemble-averaged atom distribution. It is beyond the scope of this paper to calculate the finite temperature short-range effects, but we can present an example how a reduced correlation length would qualitatively influence the optical signal by simulating short-range ordering effects in a phenomenological manner, as follows: At finite temperatures, the spins are correlated up to the AFM correlation length \( \xi_{\text{AFM}} \) which leads to domains of size \( \sim \xi_{\text{AFM}} \). We introduce the spatial variation of the AFM order parameter by letting \( m_i \) to depend on the site index \( i \), with the amplitude fixed at the \( T = 0 \) magnetization value \( m_{\text{RPA}} \). For simplicity, we assume that \( m_i \)'s in different domains are not oriented in random directions, but that there exists a preferred axis, generated, e.g., by a small imbalance in the Fermi levels of the two species. We therefore introduce a sign \( s_i = \pm 1 \) (Ising variable) for \( m_i \)'s that fluctuates from site to site
\[
m_i = m_{\text{RPA}} s_i. \tag{103}
\]

The configuration of \( s_i \) is modelled using the nearest-neighbor Ising Hamiltonian
\[
\frac{H_i}{k_B T} = J_{\text{Ising}} \sum_{(i,j)} s_i s_j = -K \sum_{(i,j)} s_i s_j. \tag{104}
\]

For \( J_{\text{Ising}} < 0 \), the ground state of the system at \( T = 0 \) is an AFM Neél state. In contrast to the Heisenberg model, the Ising model has a nonzero critical temperature. The transition temperature for a finite system with periodic boundary conditions can be estimated as \([67]\]
\[
K_c(N_s = 40) \approx -0.437. \tag{105}
\]
We approximate the correlation length $\xi_{\text{Ising}}(K)$ for a finite-size system ($N_s = 40$) and for $T > T_c(40)$ [$K_c(40) < K$] by [68]

$$\xi_{\text{Ising}}(K) \approx \frac{1}{4|K_c(40) - K|}.$$  \hspace{1cm} (106)

Using the Wolff algorithm [69], we can numerically generate a specific configuration for the Ising variable $s_i$, with a correlation length determined by the temperature in the Ising model. To ensure that the number of up and down spins is equal, we impose a constraint $|m_F| = |\sum_i s_i| < 0.01$ on the ferromagnetic Ising order parameter. Figure 9 shows two of the generated configurations at different temperatures. A specific configuration of $m$ is then used in Eq. (98) to calculate the single-species ($\downarrow$ atom only) elastic part of the scattered intensity of Eq. (100) as

$$I^\downarrow_\Delta(\Delta k) = B\alpha m^3 F_{\text{RPA}} \left| \sum_j e^{i\Delta k \cdot r_j} s_j \right|^2.$$ \hspace{1cm} (107)

Note that this expression does not contain the diffraction peak in the forward direction, as we are only interested in the magnetic Bragg peaks whose contribution is significant around the perpendicular direction. The numerically calculated scattered light intensity at different temperatures is shown in Fig. 10(a)-(c). The average value of the order parameter $m$ is smaller than 0.02 in all the cases. The average scattered light intensity grows at temperatures close to the transition [Fig. 10(d)], and the magnetic Bragg peaks emerge as the correlation length increases. The large fluctuations between different realizations in the simplified model (Fig. 10) are likely to significantly overestimate the fluctuations of the true AFM state.

3. Inelastic intraband scattering

As was demonstrated in the previous Section, the elastic part of the scattered light intensity conveys information about the atom density in the lattice and generates the diffraction pattern of the atomic lattice structure. If the detected signal cannot distinguish the two spin components, the light provides almost no information about the AFM order. On the other hand, when the contributions of the two spin components can be separated in the scattered light, the emerging AFM order and the period doubling can be identified as additional Bragg peaks. In addition to the elastic signal, one may also study the inelastically scattered light intensity [Eq. (67)]. The inelastic scattering processes are proportional to static structure factors $S^{(22)}_g(\Delta k)$ [Eq. (69)] that represent scattering events in which an atom is excited from a quasimomentum state $q$ and scatters to a different quasimomentum state $q'$. Atoms absorb recoil kicks from the scattered photons. The recoil events depend on the statistical correlations between the atoms, generating fluctuating shifts in the diffraction pattern and significant scattering outside the diffraction orders. In the process, the atomic correlations are mapped onto the properties of the emitted light. Inelastically scattered light in a single-component fermionic gas in a lattice can reveal thermal correlations [26] and has in a two-component case previously been proposed as a detection method for topological order of the atoms [22].

The inelastically scattered light intensity for the two-
The lattice height is \( w \) based on MFT. Here the number of sites is 40. The scattered intensity decreases with increasing magnetization because of the changes in the density and longitudinal spin susceptibilities. The spin-exchanging transitions (see Fig. 7) generate the scattered light as shown in Eq. (92). In the spin-conserving processes the two approaches yield almost identical intensity distributions. The scattered light intensity based on MFT (solid) and RPA (dashed) at \( T = 0 \) along the direction \( \phi = \pi/4 \), with \( \kappa = 1.5 \). The difference between the two approaches in the scattered intensity distribution is illustrated in Fig. 12. The angular distribution of the different scattering contributions is clearly visible in Fig. 11. We find that in MFT the density and longitudinal spin susceptibilities are more sensitive to the variation of \( U \) than the transverse susceptibility.

The intensity calculations based on MFT fail to capture the effects of collective excitations. We showed in Sec. IV D how the collective modes emerge in RPA. (See Figs. 4 and 5 for comparisons of the RPA and MFT.) The difference between the two approaches in the scattered intensity distribution is illustrated in Fig. 12. The low-energy collective modes are notable in the transverse spin correlations, corresponding to the spin-flip transitions, but in the case of the spin-conserving scattering processes the two approaches yield almost identical intensity distributions. The scattered light intensity distributions based on the calculation of the atomic correlations within RPA at \( T = 0 \) for different \( U \) are shown in Fig. 13. The variation of the signal as a function of \( U \) and the AFM order are most notable in the perpendicular direction, compared with the MFT case of Fig. 11.

Finally, to produce an example how the scattered signal also depends on the temperature of the system, we show the calculated light intensity distributions for different \( U \) based on the MFT Eq. (67) [the finite temperature factors are presented in Eq. (B1) in Appendix B]. Although the collective excitations in this example are ignored, the comparison between the MFT and RPA at \( T = 0 \) results suggests that the scattered intensity is less sensitive to low-energy collective excitations in the near-forward direction where the spin-conserving transitions are dominant. A more accurate description of the temperature dependence would require a finite-temperature version of RPA which is beyond the scope.

component \(^{40}\)K gas is given by Eq. (96). The scattering contributions in which the spin is conserved are proportional to density and longitudinal spin susceptibilities. The spin-exchanging transitions (see Fig. 7) generate the term depending on the transverse spin susceptibility. The two processes exhibit very different angular distribution of the scattered light as shown in Eq. (92). In the spin-conserving processes the emitted photons are generated by the \( \sigma^+ \) transition in which case the intensity in the forward direction is twice the intensity in the perpendicular direction. The spin-exchanging process, on the other hand, produces scattered photons via the \( \pi \) transition which is oriented parallel to the propagation direction of the incident field. Therefore the scattering reaches its maximum in the perpendicular direction (\( \theta = \pi/2 \)) and entirely vanishes in the forward direction.

We have calculated the angular distribution of the inelastically scattered light for different values of the on-site interaction strength \( U \), and hence the staggered magnetization \( m \) of the AFM ordering. In Fig. 11 we show the results based on MFT at \( T = 0 \). In this case the intensity is obtained using the MFT static structure factor [Eqs. (B1) and (B2)] in Eq. (67). The corresponding MFT susceptibilities required in the calculation are provided by Eqs. (39)-(43), (34), (35), and (36). The different angular distribution of the different scattering contributions is clearly visible in Fig. 11. The MFT and the RPA results notably differ, owing to the collective modes that significantly modify the transverse spin component. The magnitude of the order parameter [Eq. (15)] is \( m = 0.19 \) \((m_{\text{RPA}} \approx 0.15)\) for \( U = 2J \) and \( m = 0.4 \) \((m_{\text{RPA}} \approx 0.28)\) for \( U = 5.3J \).
FIG. 13. Angular distribution of the inelastically scattered light intensity for different values of the interaction strength $U$ at $T = 0$ along the direction $\phi = \pi/4$. The calculations are based on RPA. We use the same parameters as in Fig. 11. Intensity contributions from (a) the density and longitudinal spin components; (b) transverse spin component; (c) total scattered light intensity. The scattered intensity increases with increasing magnetization near the perpendicular direction $\theta \sim \pi/2$ because, due to the collective modes, the transverse spin component dominates the scattered light.

FIG. 14. Angular distribution of the inelastically scattered light intensity at different temperatures along the direction $\phi = \pi/4$. The calculations are based on MFT. Here the on-site interaction is fixed at $U = 5.3J$. This means that lower $T$ corresponds to higher values of $m$. We use the same parameters as in Fig. 11. The intensity contributions from (a) the density and longitudinal spin components; (b) transverse spin component; (c) total scattered light intensity. An increase in temperature enhances scattering in the near-forward direction.

of the present study.

We find in Fig. 14(a) a significant dependence of the light intensity on the temperature $T$ of the atoms in the near-forward direction that is analogous to the temperature sensitivity of a single-component noninteracting fermionic gas [26]. (Note that in this figure, lower $T$ is represented by increased staggered magnetization $m$, for a given fixed value of $U = 5.3J$.) The suppression of small-angle scattering at low $T$ can be understood in terms of the Fermi blocking: the scattering events in which an atom would recoil to an already occupied state are forbidden and in MFT the small-momentum recoil events can take atoms out of the Fermi sea only near the Fermi surface. Owing to the sensitivity of the signal to temperature, optical diagnostics could be used as a thermometer of the atoms also for an interacting two-component case. We study the detection accuracy of this method in Sec. VII B.

4. Inelastic losses to higher bands

The detected light intensity consists of the elastic and inelastic intraband components that were calculated for $^{40}$K in Secs. VI B 1 and VI B 3. In addition, the atoms can scatter to higher bands as demonstrated in Sec. V C. The interband scattering can be separated from the detected signal (owing to the different frequency of the photons), but still contributes to the heating rate of the atoms. For the level structure of $^{40}$K we can write the intensity of the scattered light corresponding to the interband transitions, Eq. (86), as

$$I_{\text{hb}}(\Delta k) = BN_s^2 (1 - \alpha_{\Delta k}) \frac{192 + 10 \cos 2\theta}{121}. \quad (108)$$

We show the angular distribution in Fig. 15. The inelastic interband scattering is proportional to $1 - \alpha_{\Delta k}$, where $\alpha_{\Delta k}$ denotes the Debye-Waller factor [Eq. (64)]. On the other hand, the intraband inelastic scattering is proportional to $\alpha_{\Delta k}$. Consequently, in deep lattices atoms are more strongly confined and the loss rate to higher bands can be suppressed, while the inelastic intraband scattering, that provides information on correlations, can be enhanced.
VII. DETECTION OF SCATTERED LIGHT

A. Optical components for light detection

As discussed in Sec. VI, the elastically and inelastically scattered light from the atoms can provide different information on the AFM order parameter \( m \), the temperature of the system, and collective and single particle excitations. Here in this subsection, we discuss in sequence how one might optimize the experimental configurations for i) detection of the extra intensity peak due to AFM order parameter \( m \), ii) temperature measurement, and iii) measuring the effects of atomic correlations on inelastically scattered light.

The elastically scattered light intensity in the presence of the AFM ordering contains extra peaks that result from the period doubling of the atom density when atoms in only one of the two spin states are measured [Eqs. (97) and (99)], or when the light is detuned in between the resonances of the spin components [Eq. (102)]. We consider detection of this emerging peak by a small optical lens that shows both the elastic and inelastic contributions (see Fig. 15). Since near-forward scattering is more strongly elastic, a lens placed near the forward direction will also capture the much stronger elastic scattering signal, see, e.g., Fig. 14. However, a lens placed near the forward direction will also capture the much stronger elastic scattering signal, see, e.g., Fig. 15. The elastically scattered light generates a diffraction pattern [Eq. (75)] and, for the subwavelength lattice spacing we consider, only the zeroth order Bragg peak is collected by the lens. Thus, in order to maximize the detection of inelastically scattered light in the measurement, we can block the high-intensity regions of the elastically scattered light by placing an appropriately designed block on the focal plane of the lens, see Fig. 16(b). For the case of atomic species for which the light can be tuned in between the resonances of the spin states, the elastically scattered light peaks could be suppressed by destructive interference. This setup is similar to the one proposed in Ref. [26] to measure the temperature of an ideal single-species fermionic gas in a lattice. In that case the elastically scattered light varied as a function of the temperature in the near-forward direction resulting from the enhancement of the Pauli blocking effect at low temperatures. In the two-species interacting case within the MFT we observe the same behavior as shown in Fig. 14. We correspondingly achieve the optimized detection efficiency by selecting a narrow cross-shaped block that covers the Bragg peak and high-intensity regions along the principal axis of the lattice, analogously to Ref. [26], as shown in Figs. 19(a) and (b).

We now consider how to optimize the detection of AFM correlations in the inelastically scattered light. At zero temperature, the effect of the AFM ordering on the angular distribution of the scattered light calculated with RPA is displayed in Fig. 13. The staggered magnetization most noticeably changes the signal away from the forward direction. Optimal shape and size of the block can be estimated from the angular distribution of scattered light that shows both the elastic and inelastic contributions (see Fig. 15). Since near-forward scattering provides only limited information on magnetization in this case, it is beneficial to consider a block that combines a narrow cross-shaped block with a circular block located at the center. The light can then be collected with a lens of large NA. For a lattice of 40×40 sites the block sizes used are listed in Table I. In Fig. 16(b) we show an example circular block with the angular size \( \Theta_{\text{Circ-Block}} \approx 0.20 \) rad.

As has been discussed in Sec. VI, spin-exchanging scat-
scattering processes dominate the inelastic signal near the perpendicular direction [Fig. 16(c)]. For \( \kappa < \sqrt{2} \), the elastic scattering contribution to the collected signal is negligible (Fig. 15) and no block is needed. On the other hand, for \( \kappa \geq \sqrt{2} \), the elastic component near the perpendicular direction strongly depends on the AFM order parameter \( m \) [see Fig. 8, and Sec. VI B, in particular Eqs. (97) and (101)]. As we will show in next subsection, this enhances the sensitivity of the signal to changes in

\[
\kappa \geq \sqrt{2}, \quad \eta(m) = \frac{\mathcal{I}^+_{\text{tot}}(m) + \mathcal{I}^+_{\text{tot}}}{\mathcal{I}^+_{\text{tot}}},
\]

where \( \mathcal{I}^+_{\text{tot}} \) and \( \mathcal{I}^+_{\text{tot}} \) denote the total rate of inelastic intraband and interband scattering events, respectively. We assume that the scattered light corresponding to interband transitions is filtered out of the signal so the corresponding rate is excluded from the numerator. If, for simplicity, we assume a 100% photon detector efficiency, the number of detected inelastically scattered photons in each experimental realization of the lattice system is given by \( N^e_i(m) = \eta(m)W \). If the lattice system is prepared and the experiment is repeated \( \tau \) times, we find that the total number of detected photons is

\[
\tau N^e_i(m) = \tau(N^i_i(m) + N^e_i(m)), \quad \text{and} \quad N^e_i(m) = \frac{\tau \mathcal{I}^+_{\text{tot}}(m)}{\mathcal{I}^+_{\text{tot}}(m)} N^i_i(m)
\]

where \( N^e_i(m) \) denotes the total number of detected elastically scattered photons in a single experimental realization of the lattice system and \( \mathcal{I}^+_{\text{tot}}(m) \) is the scattering

\[
\begin{array}{c|c|c}
\kappa & \text{Cross width (rad)} & \text{Circular radius (rad)} \\
\hline
0.66 & 0.08 & 0.22 \\
1.05 & 0.05 & 0.14 \\
1.5 & 0.03 & 0.10 \\
\end{array}
\]

### Table I. Parameters of the block used to estimate the measurement accuracy estimates shown in Fig. 18.

---

FIG. 16. Schematic illustration of the experimental configurations to detect AFM ordering of fermionic atoms in an optical lattice. The atoms are confined in the 2D optical lattice close to the \( z = 0 \) plane and the incident light propagates towards the positive \( z \) direction. In (a) the elastically scattered light corresponding to the emerging additional Bragg peak generated by the AFM ordering is collected by a small lens. In (b) the setup is closely related to that of Ref. [26]. The two lenses have focal lengths \( f_1 \) and \( f_2 \). The light scattered in the near-forward direction is first collected by lens 1. In the focal plane the scattered light is selectively stopped by a block in order to suppress the intensity of the elastically scattered light at the detector. The shape and the size of the block can be optimized for different measurements of collective excitations or of temperature. In (c) the scattered light is collected near the perpendicular scattering direction of \( \theta = \pi/2 \), to measure transverse spin correlations.
rate of elastically scattered photons that are collected by the lens. In optical diagnostics of AFM ordering one would need to distinguish in the scattered light signal two fermionic states in the lattice that exhibit different magnetic orderings \( m_1 \) and \( m_2 \). After \( \tau \) experimental realizations the difference in the total number of detected photons between the two ordered states is \( \tau[N_c(m_2) - N_c(m_1)] \). The minimum requirement for the two states to be distinguishable is that this difference is at least equal to the photon shot-noise \( \sqrt{\tau N_c(m_2)} \), so that \( \tau[N_c(m_2) - N_c(m_1)] \geq \sqrt{\tau N_c(m_2)} \). Thus the minimum number of experimental realizations \( \tau_{\text{min}} \) required to distinguish between the optical signal from two magnetization states \( m_1 \) and \( m_2 \) approximately satisfies

\[
\tau_{\text{min}} \simeq \frac{N_c(m_2)}{[N_c(m_2) - N_c(m_1)]^2}. \tag{113}
\]

In the rest of this Section, we present results for the rate of detected photons as a function of the staggered magnetization \( m \) and the number of experimental realizations \( \tau \) required to determine changes in the AFM order parameter \( m \). The changes are calculated with respect to a reference value, \( m_{\text{ref}} \), and for a given relative accuracy \( \Delta m/m_{\text{ref}} \) [Eq. (113)]. At \( T = 0 \), the inelastic scattering is calculated using the RPA susceptibilities. In Figs. 17, 18 and 20 \( m_{\text{ref}} \) is the RPA corrected order parameter (Sec. IV D 1) and also the elastic component of the scattered light [Eqs. (97) and (101)] has been computed using the RPA corrected order parameter \( m_{\text{RPA}} \) (Sec. IV D 1). At finite temperature we use only the MFT results. For the temperature dependent MFT results of Fig. 19 the \( m_{\text{ref}} \) is the MFT order parameter obtained from the solution of Eq. (15). Except the scaling analysis of \( \tau \) with lattice size, all the results in this Section are for a lattice of size 40 \( \times \) 40.

We first study the AFM order parameter measurement accuracy when a lens (NA= 0.2) is used to collect the light along the direction of the emerging magnetic Bragg peak [Fig. 16(a)]. We also study the configuration in which a lens (NA= 0.4) is placed perpendicular to the propagation direction of the incident probe laser [Fig. 16(c)]. In both cases, the ratio between the wavenumber of probe light and the effective lattice light \( \kappa = 1.5 > \sqrt{2} \) [Eq. (59)]. This allows the NA= 0.4 lens to collect the signal also from two magnetic Bragg peaks [Eq. (99)]. In Sec. VI B 1, we have shown that the elastic signal is strongly enhanced when only the \( \downarrow \) atoms are detected. Figure 17 compares this case [Fig. 17(c),(d)] to the case when both species are detected [Fig. 17(a),(b)]. In both lens configurations the number of experimental realizations \( \tau \) needed to achieve a given accuracy drops dramatically when only \( \downarrow \) atoms are detected. Some specific values of \( \tau \) for single species detection are presented in Table II. These values are (much) lower than all other experimental configurations to be presented later [see Table III]. We conclude that the single-species detection scheme provides the most accurate determination of the AFM order. (This could be improved for atomic species for which far-detuned light can be tuned in between the two resonances.) Experimentally, the single-species imaging can be realized by transferring the other spin component to a different hyperfine state [37].

In Fig. 18 we show the effect of lattice depth \( s \) [Eq. (5)] and \( \kappa \) on the detection accuracy of \( m \). The scattered light is collected by a lens of NA=0.8 in the forward direction, corresponding to the experimental arrangement of Fig. 16(b). We find that a deeper lattice generally en-

---

**TABLE II. Specific values of the estimated number of experimental realizations, \( \tau(m_{\text{ref}}) \) for single species detection** [Fig. 17(d)] with \( \kappa = 1.5 \). The two lenses with NA= 0.2 and NA= 0.4 are pointing in the direction of the magnetic Bragg peak [Fig. 16(a)] and in the direction perpendicular to the incident field[Fig. 16(c)], respectively. These values are for a relative accuracy of 10%. Here \( m_{\text{ref}} \) is the RPA corrected order parameter (Sec. IV D 1).

| NA   | \( \tau(0.08) \) | \( \tau(0.12) \) | \( \tau(0.19) \) |
|------|----------------|----------------|----------------|
| 0.2  | 210            | 60             | 10             |
| 0.4  | 200            | 50             | 10             |

**FIG. 17. Measurement accuracy at \( \kappa = 1.5 \) when light along the direction of the emerging magnetic Bragg peak is detected. The calculations are based on RPA susceptibilities at \( T = 0 \) with an RPA corrected order parameter \( m_{\text{RPA}} \) for the elastic component. We show the collected photon rates vs. the RPA corrected AFM order parameter \( m_{\text{RPA}} \) (left column) and the number of experimental realizations \( \tau \) to achieve a relative accuracy \( \Delta m/m_{\text{ref}} \) (right column). In all the plots (a)-(d), dashed curves correspond to the configuration of a lens with NA= 0.4 pointing in the perpendicular direction [Fig. 16(c)], and solid curves are for a small lens with NA= 0.2 pointing in the direction of the emerging magnetic Bragg peak [Fig. 16(a)]. Note that the lens in the perpendicular direction also collects the signal from two magnetic Bragg peaks.** (c), (d) show the case when only one spin species are detected. (c), (d) show the case when only the \( \downarrow \) atoms are detected. Far fewer experimental realizations are needed for a given accuracy when only one species is detected. In (b) and (d) we show the \( \tau \) values for two different reference states: \( m_{\text{ref}} \approx 0.12 \) in black (top two curves) and \( m_{\text{ref}} \approx 0.19 \) in green (bottom two curves).
FIG. 18. \( T = 0 \) collected photon rates vs. the RPA corrected AFM order parameter \( m_{\text{RPA}} \) with a lens of NA = 0.8 in the forward direction (top row) and the corresponding estimated number of experimental realizations to achieve a relative accuracy \( \Delta m/m_{\text{ref}} \) (bottom row). The calculations are computed with RPA susceptibilities at \( T = 0 \) and with an RPA corrected order parameter \( m_{\text{RPA}} \) for the elastic component. In both (a) and (b), we show a fixed value of \( \kappa = 1.05 \) and compare two different lattice depths \( s = 7.8 \) (dotted) and \( s = 25 \) (solid). In (b), the top two curves (in black) are for \( m_{\text{ref}} \approx 0.12 \) and the bottom two curves (in green) are for \( m_{\text{ref}} \approx 0.19 \). The top two curves are essentially on top of one another, similarly for the bottom two curves. In both (c) and (d) we show a fixed lattice depth \( s = 25 \) and compare three different values of the parameter \( \kappa = 0.6 \) (dotted line), \( \kappa = 1.05 \) (solid) and \( \kappa = 1.5 \) (dashed). Note that varying \( \kappa \) changes the width of the elastic diffraction peak. Thus, to block out the main elastic diffraction peaks, a different block width is required for each \( \kappa \) value, see Table I. In (d), the top three curves (in black) are for \( m_{\text{ref}} \approx 0.12 \) and the bottom three curves (in green) are for \( m_{\text{ref}} \approx 0.19 \). The top three curves are close together, and even more so for the bottom three curves.

FIG. 19. Finite temperature plots of (a) collected photon rates vs. the MFT AFM order parameter \( m \) with a lens of NA = 0.8 in the forward direction, and (b) the corresponding estimated number of experimental realizations to achieve a relative accuracy \( \Delta m/m_{\text{ref}} \). Results are obtained with MFT at finite \( T \) with fixed \( U = 5.3J \), and with \( s = 25 \) and \( \kappa = 1.05 \). The cross block width is 0.048 rad. At fixed \( U \), increasing \( T \) leads to decreasing \( m \), and in (b), we show from top to bottom (corresponding to lowering \( T \)), \( m_{\text{ref}} = 0.13, 0.18, 0.22, 0.26, 0.31, 0.35, 0.4 \). In (b) the data points are joined with straight lines.

TABLE III. Specific values of the estimated number of experimental realizations, \( \tau(m_{\text{ref}}) \), for two lattice depths with \( \kappa = 1.05 \) presented in Fig. 18(b). The parameters of the block are given in Table I. Here \( m_{\text{ref}} \) is the RPA corrected order parameter (Sec. IVD 1).

| \( s \) | \( \tau(0.12) \) | \( \tau(0.19) \) | \( \tau(0.12) \) | \( \tau(0.19) \) |
|-------|----------|----------|----------|----------|
| 7.8   | 410      | 50       | 90       | 10       |
| 25    | 390      | 50       | 90       | 10       |

enhances the scattering rate, but the effect of \( s \) on \( \tau \) in the studied cases is negligible [Fig. 18(a),(b)]. Some example values are shown in Table III. The number of required experimental realizations for a 40×40 lattice drops rapidly when the desired accuracy is reduced and the staggered magnetization is increased.

Similarly, increasing \( \kappa \) enhances the rate of detected photons [Figs. 18(c),(d)]. Generally however, the detection accuracy is lower for larger values of \( \kappa \). This is so because for larger \( \kappa \), there are more inelastic scattering events particularly near the ordering wavevector. Such inelastic signal contributes to inelastic scattering losses and heating, but is not captured by the forward direction lens considered here.

As explained previously (Sec. VI B 3), we only provide a qualitative analysis of finite temperature effects using MFT, without taking into account the collective excitations included in RPA. Using a narrow cross-shaped block of width 0.048 rad, the light can be collected near the forward direction where the temperature strongly affects the scattering rate (Fig. 14). Lower \( T \) corresponds to stronger magnetization values and fewer collected photons, as shown in Fig. 19(a), and the temperature changes in \( m \) can be accurately detected [Fig. 19(b)]. For example, \( m_{\text{ref}} = 0.18 \) can be measured with the accuracy of 10% with 100 realizations.

Finally in Fig. 20, we show the RPA results for the accuracy in \( m_{\text{RPA}} \) when the scattered light is collected perpendicular to the propagation direction of the incident laser [Fig. 16(c)]. The light scattered from the spin-conserving and spin-exchanging transitions may be separated owing to the different frequency of the scattered photons (or the polarization, see the next Section). If the transitions are not separated, the measurement accuracy in the perpendicular direction is significantly lower than, e.g., for forward direction measurements. There is a notable improvement in the detection accuracy in the perpendicular direction when only the spin-exchanging scattering processes (representing the transverse spin correlations) are selected (for the angular distribution of the scattered light for the different components, see Fig. 13). For instance, for \( \kappa = 1.5 \), 10% accuracy for \( m_{\text{ref}} \approx 0.19 \) can now be achieved after 50 realizations for NA = 0.4. By increasing the size of the lens to NA = 0.5 this can be further improved to 40 realizations. In general, for
FIG. 20. Collected photon rates vs. the AFM order parameter $m$ with a lens pointing in the perpendicular direction (left column) and the corresponding estimated number of experimental realizations $\tau$ to achieve a relative accuracy $\Delta m/m_{\text{ref}}$ (right column). The calculations are computed with RPA susceptibilities at $T = 0$ and with an RPA corrected order parameter $m_{\text{RPA}}$ for the elastic component. We compare the case when [(a) and (b)] all the density and spin components are collected by a lens with $\text{NA}= 0.4$, to the case when [(c) and (d)] only the transverse spin component of the scattered light is collected by a lens with $\text{NA}= 0.5$. In both (a) and (b), solid lines are for $\kappa = 1.05$ and dashed lines for $\kappa = 1.5$. In (b), the top two curves (in black) are for $m_{\text{ref}} \simeq 0.12$ and bottom two curves (in green) are for $m_{\text{ref}} \simeq 0.19$. Note that the bottom black dashed curve almost overlaps the top green solid curve. In both (c) and (d), dotted lines are for $\kappa = 0.66$, solid lines for $\kappa = 1.05$ and dashed lines for $\kappa = 1.5$. In (d), the top three curves (in black) are for $m_{\text{ref}} \simeq 0.12$ and bottom three curves (in green) are for $m_{\text{ref}} \simeq 0.19$.

the perpendicular direction the large $\kappa = 1.5$ case gives the highest number of scattered photons because of the strong enhancement of spin-exchanging scattering processes [cf. Fig. 21(a) vs Fig. 13(c)]. Also the $\tau$ values are substantially lower for the $\kappa = 1.5$ case [Fig. 20(b),(d)].

Our example calculations are for a 40×40 lattice. Smaller values of $\tau$ can be obtained for larger lattices. The number of required experimental realizations of the lattice system $\tau$ is approximately inversely proportional to the number of sites $\tau \propto N_s^{-2}$. We have simulated lattices sizes between $N_s = 16$ and $N_s = 40$, and our results confirm this scaling to be qualitatively accurate for reasonably large lattice systems $N_s \gtrsim 25$ for both forward and perpendicular directions measurements. For smaller systems the choice of the block size and shape can result in larger variations owing to the dependence of the width of the diffraction peak on the lattice size.

C. Distinguishability of transitions by light polarization

In general the scattered light corresponding to different transitions are separated in frequency space and could be

FIG. 21. Angular distribution of the inelastically scattered light intensity along the direction $\phi = \pi/4$ when the scattered light is projected along specific polarization directions. We show different values of the interaction strength $U$ at $T = 0$. The calculations are based on RPA, $\kappa = 1.5$ and the other parameters are as in Fig. 11. (a) The total scattered light intensity; (b) the total scattered intensity from the spin-conserving transition; (c) the total scattered intensity from the spin-exchanging transition; In (d) and (e) the light has been projected along the direction of the scattered light from the spin-conserving transition. (d) projected component of the scattered intensity from the spin-conserving transition which in this case equals to (b); (e) projected component of the scattered intensity from the spin-exchanging transition. In (f) and (g) the light has been projected along the direction of the scattered light from the spin-exchanging transition. (f) projected component of the scattered intensity from the spin-conserving transition; (g) projected component of the scattered intensity from the spin-exchanging transition which in this case equals to (c).
identified by filtering the relevant frequencies. If the sufficient frequency resolution is not achievable the transitions could still be partially distinguished by the polarization of the scattered light. The polarization of the scattered light from the spin-conserving and spin-exchanging transitions depend on the scattering direction and generally they are not orthogonal. For any given scattering direction we may project, e.g., the light scattered from the spin-exchanging transition to the direction of the polarization of the scattered light from the spin-conserving transitions. This provides the optimum value how much for the given scattering direction the light from the spin-conserving transition can be distinguished from the total scattered intensity. In order to analyze this we modify the polarization vector of Eq. (54) \( \Lambda_{g'g} \) by

\[
\Lambda_{g'g} \rightarrow \Lambda_{g'g} |\hat{\epsilon}_{g_{1}g_{2}}^{\dagger} \hat{\epsilon}_{g_{1}g_{2}}^{\star} ,
\]

where the polarization of the scattered is given by

\[
\hat{\epsilon}_{g'g} = \frac{\Lambda_{g'g}}{|\Lambda_{g'g}|}.
\]

In a studied example case of Fig. 21 we show the angular dependence of the scattered light intensity and compare this with the projected intensities along the polarization of the scattered light from either of the two transitions. The relative part of the signal from the density and longitudinal spin correlations is enhanced in Figs. 21(d) and (e), while the contribution of the transverse spin correlations is particularly strong in Figs. 21(f) and (g) in the direction around \( \theta \approx \pi/2 \).

VIII. DIAGNOSTICS OF EXCITATIONS FROM SCATTERED SPECTRUM

In this Section we calculate the spectrum of scattered light and show how intraband inelastic scattering can reveal the single-particle and collective excitations in an AFM ordered lattice system. In Sec. V B, the scattered spectrum is split up into an elastic [Eq. (78)] and an inelastic part [Eq. (79)]. The elastically scattered light has no nontrivial spectral structure, consisting of only the zero frequency part, by definition. Inelastic losses due to scattering to higher bands occur at high frequency (on the order of the band gap) and can therefore be filtered out and ignored, as this part does not contain information about the state probed.

The inelastic spectrum of Eq. (79), or the more specific form of Eq. (82), contains useful information about the excitation spectrum of the system being probed. In Sec. IV D, we show how the MFT contains only single particle excitations in the density, longitudinal and transverse spin susceptibilities. The RPA partially takes into account quantum fluctuations around the AFM ordered state and can capture the collective excitations (spin waves) emerging in the transverse spin susceptibility. RPA also renormalizes the single particle excitations. (See Figs. 4 and 5 for comparisons of the RPA and MFT.) Via linear response theory (see Sec. IV C 1), the various RPA susceptibilities can be related to the dynamic structure factor Eq. (80), or the dynamic response function Eq. (81). The spectrum of inelastically scattered light reads

\[
\frac{\tilde{S}_{i}(\Delta k, \omega)}{\tilde{\alpha} \Delta k B} = \frac{1}{4} (M_{i,i}^{\uparrow} + M_{i,i}^{\downarrow}) \sum_{q \neq 0}^{RBZ} u_{\Delta k - q}^{\dagger} \left[ \mathbf{S}^{\rho \rho}(q, \omega) + \mathbf{S}^{\sigma \sigma}(q, \omega) \right] u_{\Delta k - q} + \frac{1}{4} (M_{i,j}^{\uparrow} + M_{i,j}^{\downarrow}) \sum_{q \neq 0}^{RBZ} u_{\Delta k - q}^{\dagger} \left[ \mathbf{S}^{\rho \rho}(q, \omega) - \mathbf{S}^{\sigma \sigma}(q, \omega) \right] u_{\Delta k - q} + \frac{1}{2} M_{i,i}^{\uparrow} \sum_{q \neq 0}^{RBZ} u_{\Delta k - q}^{\dagger} S_{i}^{\star -}(q, \omega) u_{\Delta k - q}^{\star -}.
\]

This spectrum has been derived using the same procedures as the analogous expression for the intensity in Sec. VI B, generalizing the definitions of Eq. (94) to the frequency-dependent case here. We can translate the dynamical response function of Eq. (81) to the density, longitudinal and transverse spin dynamical response functions \( \mathbf{S}^{ij}(q, \omega) \) \( (i,j = \rho, z, +, -) \) using a frequency dependent version of Eq. (94). In turn, these dynamical response functions are related via Eq. (34) to the various RPA spin and density susceptibilities Eqs. (44), (45) and (46) of Sec. IV, which are then used to compute the scattered spectrum.

We first compare in Sec. VIII 1 the physical quantities of interest, the angle-resolved spectrum [Eq. (116)] and susceptibilities [Eqs. (44), (45) and (46)], with the angle-integrated spectra [Eq. (117)] that corresponds to a measurement of the spectrum by a lens over a range of scattering angles. We then analyze in Sec. VIII 2 the features corresponding to single particle excitations and in Sec. VIII 3, the collective mode peak.
FIG. 22. Comparison between the RPA susceptibilities, angle-resolved spectrum, and the spectrum collected by a lens over a range of scattering angles. The ratio between the wavenumber of the probe light to the effective wavenumber of the optical lattice light is \( \kappa = 1.5 \) [Eq. (50)] and \( U = 5J \). Each line shown has been normalized to its maximum value for comparison. We show \( \chi^{S}_{0} (\omega) \) [solid (black)], \( \chi^{S}_{0} (\omega) \) [dotted (blue)], \( S(\Delta k, \omega) \) [dashed (green)] and \( \chi(\Delta k, \Delta k; \omega) \) [dotted-dashed (red)]. (a) shows the configuration with a lens in the forward direction [Fig.16(b)]. The angle-resolved quantities, the spectrum \( S(\Delta k, \omega) \) and total susceptibility \( \chi(\Delta k, \Delta k; \omega) \) are computed at a wavevector close to the axis of the lens \( (\theta \sim 0, \phi \sim 0) \). (b) shows the case for a lens in the perpendicular direction [Fig. 16(c)]. \( S(\Delta k, \omega) \) and \( \chi(\Delta k, \Delta k; \omega) \) are computed at a wavevector \( \Delta k \) close to the axis of the lens at \( (\theta \sim \pi/2, \phi \sim \pi/4) \). (b) shows the collective mode at low energies and the inset shows the single-particle excitations at energies above the gap.

1. Comparison between angle-resolved spectrum and angle-integrated spectrum

The scattering rate of off-resonantly illuminated atoms is generally low. Experimentally, the number of measured photons can be increased by collecting the inelastically scattered photons over a range of scattering angles using a lens (see Sec. VII A). The spectrum, however, changes with the scattering angle, since each \( \Delta k \) represents a different argument of the dynamical structure factor. In this Section we analyze how much of the spectral structure can be extracted when the measured light is integrated over the corresponding range of scattering angles. We therefore define

\[
\chi^{L}_{\text{NA}} (\omega) = \int_{L, \text{NA}} d\phi \sin \theta d\theta \left. S(\Delta k(\theta, \phi), \omega) \right.,
\]

where \( L = F, P \) indicates the experimental configuration: \( F \) for the lens with a given NA pointing in the forward direction [Fig. 16(b)] and \( P \) for the perpendicular direction [Fig. 16(c)].

In Fig. 22, we compare the angular integrated spectrum [Eq. (117)] for two different lens sizes with the physical quantities of interest. These are the angle-resolved spectrum \( S(\Delta k, \omega) \) and the total susceptibility \( \chi(\Delta k, \Delta k; \omega) \), which is the sum of all the longitudinal and transverse susceptibilities. Here \( S(\Delta k, \omega) \) and \( \chi(\Delta k, \Delta k; \omega) \) are computed at a wavevector \( \Delta k \) close to the axis of each corresponding lens. In Fig. 22(a) the lens is pointing in the forward direction \( (\theta \sim 0, \phi \sim 0) \) and in}

Fig. 22(b) in the perpendicular direction \( (\theta \sim \pi/2, \phi \sim \pi/4) \).

It can be seen that the small lens measurement reproduces quite closely the spectrum \( S(\Delta k, \omega) \), in both forward and perpendicular directions. However, compared with the large lens, the small lens leads to the absolute magnitude of the signal being down by nearly a factor of 200 in the forward direction and about a factor of 10 in the perpendicular direction. But even the large lens captures well at least the position of the collective mode peak (at low energies) and single particle peak (at high energies). The collective mode peak is somewhat broadened by the large lens. (These peaks are analyzed in detail in the next subsections.)

Note that unlike the total susceptibility \( \chi(\Delta k, \Delta k; \omega) \), the spectrum \( S(\Delta k, \omega) \) contains the dipole matrix elements \( M^{\alpha \beta}_{g g} \), Eq. (92), that skews the signal towards the forward direction for spin-preserving transitions, and towards the perpendicular direction for spin-exchanging transitions (see Sec. VI B 3). Hence one key finding here is that different lens positions can be used to select for different types of transitions, to separate out the collective modes versus the single particle excitations.

2. Single particle excitations

In Fig. 23, we plot the RPA spectrum collected by a lens for different values of the on-site interaction strength \( U \) at \( T = 0 \). Here the number of sites is \( 40 \times 40 \). The lattice height is \( s = 25 \) and \( \kappa = 1.5 \). Light is collected with a lens of NA = 0.5 pointing in (a) the forward direction [Fig. 16(b)]; (b) the perpendicular direction [Fig. 16(c)]. From left to right, black (solid) is \( m_{\text{RPA}} \approx 0.19 \) \( (U \approx 2.6J) \), blue (dashed) is \( m_{\text{RPA}} \approx 0.25 \) \( (U \approx 4.0J) \), and green (dot-dashed) is \( m_{\text{RPA}} \approx 0.30 \) \( (U \approx 8.3J) \). Inset in (b) shows the renormalized single-particle excitations starting at \( \omega \approx U/J \). All the curves have been normalized to the maximum of the \( m_{\text{RPA}} \approx 0.30 \) case.
the gap opens up progressively and more sharply with larger $U$, and there is signal only between the aforementioned bounds. To compute numerical values, we give a finite value to the infinitesimal imaginary part using $\delta = 0.07J$, in the denominators of the susceptibilities of Eqs. (39), (42) and (43). Thus, individual delta functions coming from the susceptibilities are then spread out into Lorentzian functions, representing the finite frequency resolution of spectral measurements.

3. Collective modes

The other main feature in Fig. 23(a) and (b) is the sharp peak at low energies. This originates from light scattering off the spin-exchanging transitions that dominate the transverse spin susceptibility $\chi_{\text{RPA}}(q, q, \omega)$. In turn, such transitions can be induced by the excitation of gapless collective modes, the spin wave excitations above the AFM ground state (see Sec. IV D and Fig. 5). Notice that the sharp collective mode at low energy separates cleanly in frequency from the single particle excitations only from moderately large $U/J$ onwards. A rough criterion for this separation is that the collective mode bandwidth $\sim 2J_H$, see Eq. (49) and the text after should be smaller than the single particle gap $2\Delta$. At small $U/J$, the single particle gap is small and the collective mode peak merges with the single particle broad peak, as can be seen for the case of $U \approx 2.6J$ in Fig. 23.

As discussed in Sec. IV, for large $U/J$, the Hubbard model reduces to the Heisenberg model at low energies. In Fig. 24 we show the angular and frequency dependence of the scattered light along the $\phi = \pi/4$ line for $U = 8.3J$ ($m_{\text{RPA}} \simeq 0.30$) and compare it with the spin wave dispersion relation of the Heisenberg model, Eq. (49). As a visual aid, the line connecting the maximum of the spectrum for each $\theta$ point is also drawn. It is indeed similar to the dispersion relation curve. Such measurement could in principle be realized with a small NA lens scanning the $\theta$ direction. Note that this figure only shows the low energy spectrum, cutting off the higher energy single particle excitations shown in Figs. 22 and 23. Despite the similar shape, the RPA derived dispersion occurs for smaller frequencies compared with the Heisenberg model dispersion. This mismatch disappears for values of $U \gtrsim 25J$.

IX. CONCLUDING REMARKS

We have studied off-resonant imaging of AFM correlations in a two-species fermionic atomic gas in a tightly-confined 2D optical lattice. The AFM ordering represents a checkerboardlike alternating density pattern of the two species that effectively doubles the lattice periodicity of each spin component. This can be revealed in emerging magnetic Bragg peaks of elastically scattered light when only one spin component is detected, or via a destructive interference of the scattered light from the two components. The density correlations as well as the longitudinal and transverse spin correlations of the atoms are mapped onto the fluctuations of the scattered light where they can be detected in the inelastically scattered light. We have shown how the standard Feynman-Dyson perturbation theory of interacting many-body systems can then be related to the experimental observables of the intensity and the spectrum of the scattered light. Our specific example concerned RPA of the AFM ordering that corresponds to a partial summation of the diagrammatic perturbation series. The general principle could be adapted to other strongly-correlated states, indicating how off-resonant imaging can provide a powerful diagnostic tool in interacting ultracold atom systems.

Appendix A: Susceptibilities from Mean-field theory and RPA for the AFM via Feynman diagrams

In this Appendix, we outline the calculation of the MFT and RPA susceptibilities for density $\rho$ Eq. (44), longitudinal spin $\hat{S}^z$ Eq. (45) and transverse spin $\hat{S}^+, \hat{S}^-$ [Eqs. (47) and (48)] using the diagrammatic method. MFT susceptibilities (at $T = 0$ or finite $T$) can also be calculated directly from the MFT Hamiltonian [Eq. (28)] and the Bogoliubov transformation [Eq. (25)]. Here we

FIG. 24. RPA scattered spectrum at zero temperature along $\phi = \pi/4$ for $U = 8.3J$ ($m_{\text{RPA}} \simeq 0.30$). This figure only shows the low energy part of the spectrum that includes the collective modes. Single particle excitations occur at much higher energies and are not shown. The gray scale on the left gives the magnitude of the spectrum plotted. (a) shows $\kappa = 1.05$ and (b) $\kappa = 1.5$. $\omega_{\Delta k}$ (solid line) given by Eq. (49) is the spin wave dispersion relation of the Heisenberg model. The green (step-like) line connects the maximum values of the collective mode peak of the RPA spectrum for each $\theta$ point evaluated.
FIG. 25. Diagrammatic representation of the interaction vertices, spin densities, and Green’s function needed for the RPA calculation of the susceptibilities. (a) and (b) interaction vertices [Eq. (A1)], (c) density operator [Eq. (32)], (d) spin projection on the z direction [Eq. (30)], (e) spin raising operator [Eq. (31)] and (f) MFT Green’s function [Eq. (A3)].

derive the $T = 0$ MFT susceptibilities first to show briefly how the diagrammatic method works and how to generalize it to RPA.

As mentioned in Sec. IV B, we have dropped second order fluctuations to arrive at the MFT Hamiltonian of Eq. (22). The diagrammatic method in the AFM ordered state then approximately reinstates quantum fluctuations as follows: The full Hamiltonian is a sum of the MFT one $H$ [Eq. (22)] and the fluctuations (the interaction part), using the compact Nambu notation [Eq. (21)],

$$H_{\text{tot}} = H + V_0 + V_Q,$$

$$V_0 = \frac{U}{N^2} \sum_{q,k,k'} \bar{\Psi}_{k+q} \Psi_{k} \bar{\Psi}_{k+q} \Psi_{k'},$$

$$V_Q = \frac{U}{N^2} \sum_{q,k,k'} \bar{\Psi}_{k+q} \tau_z \Psi_{k} \bar{\Psi}_{k+q} \tau_z \Psi_{k'}, \quad \text{(A1)}$$

Here $V_0$ corresponds to the interaction with momentum transfer $q \in RBZ$, while $V_Q$ has momentum transfer $q + Q$ that is represented by the Pauli matrix $\tau_z$ acting in the Nambu spinor space.

The elements of the diagram technique can now be defined; see Fig. 25. The interaction vertices $V_0$ and $V_Q$ are defined in Fig. 25(a) and (b). The interaction is represented by a dashed line, with an associated factor of $-iU/N^2$. The various density operators (total density, longitudinal and transverse spin) can be written using the Nambu spinors, as shown in Fig. 25(c)-(e). Diagrammatically, a creation (annihilation) spinor operator $\hat{\Psi}^\dagger$ ($\hat{\Psi}$) is represented by an outgoing (incoming) arrow, with its momentum and spin label near the arrow. The momentum transfer is represented by a wavy line. Whenever the momentum transfer $q$ is shifted by $Q$, a Pauli matrix in Nambu space $\tau_x$ is needed in between $\hat{\Psi}^\dagger$ and $\hat{\Psi}$, and is represented as a open square. When there is no such shift, a unit matrix 1 is represented by a filled circle.

In the spin density wave ground state $|\Phi_{\text{sdw}}\rangle$, we can write the bare Green’s function at zero temperature as a $2 \times 2$ matrix, using the Nambu spinor defined in Eq. (21),

$$G^0_{\Phi}(k, t' - t) = -i \langle \Phi_{\text{sdw}}| T\hat{\Psi}_{k,q}(t')\hat{\Psi}^\dagger_{k,q}(t)|\Phi_{\text{sdw}}\rangle. \quad \text{(A2)}$$

From now on, we will drop the explicit ground state bra and ket. All expectation values are understood to be for this ground state. A matrix Green’s function $iG_\Phi^0$ is represented as a straight line with momentum and spin labels shown in Fig. 25(f). The arrow starts from a creation operator to end in an annihilation operator. $G_\Phi^0$ can be calculated via a Fourier transform in time, directly from the MFT Hamiltonian [Eq. (28)] and the Bogoliubov transformation [Eq. (25)] to give

$$G_\Phi^0(k, \omega) = \int_{-\infty}^{\infty} dt e^{i\omega t} G_\Phi^0(k, t) = \frac{1}{(\hbar \omega)^2 - E_k^2 + i\delta} \left( \begin{array}{cc} \hbar \omega + \epsilon_k & \Delta_g \\ \Delta_g & \hbar \omega - \epsilon_k \end{array} \right). \quad \text{(A3)}$$

We will not derive the diagram rules here, as this matrix formalism is a direct generalization of a similar matrix...
formalism in the well-documented BCS superconductivity case, which in turn is a matrix generalization of the usual diagram technique [70, 71]. We will just illustrate the rules with a few examples in the next subsections.

1. Mean-field susceptibilities

The MFT susceptibilities correspond to computing Eq. (33) in the matrix form Eq. (37) without any interaction vertices $V_0$ and $V_Q$. As an example, we calculate the first diagram of the diagonal element of the susceptibility matrix shown in Fig. 26,

$$
\chi^{\rho\rho}_{(0)}(q, \nu) = \begin{pmatrix}
    k, \nu, g & 0 \\
    k + q, \nu + g & k, \nu, g \\
    0 & k + q, \nu + g
\end{pmatrix}
$$

FIG. 26. Diagrammatic representation of the MFT transverse spin susceptibility matrix, see Eq. (37). The sums over internal momentum $k$, frequency $\nu$ have not been written explicitly.

The density susceptibility one [Eq. (40)] the only nonzero MFT susceptibilities for these quantities, as we shall see next. The overall minus sign comes from anticommuting the Nambu spinors, and is an example of the diagram rule for a fermion loop leading to a $(-1)$ factor. In frequency space, this becomes

$$
\chi^{\rho\rho}_{(0)}(q, \nu) = \frac{2i}{N_s^2} \sum_{k,k'} \langle T \hat{\Psi}_{k+q,\nu}(t) \hat{\Psi}_{k',\nu}(0) \hat{\Psi}_{k',\nu}(0) \rangle_c
$$

The two momenta in the left-hand side of Eq. (A4) are a consequence of the translation invariance with periodic boundary conditions that we have imposed on the system (Sec. VA) and $\text{Tr}$ denotes the trace of the matrix.

$$
\chi^{\rho\rho}_{(0)}(q, \nu) = \frac{2i}{N_s^2} \sum_{k} \text{Tr} G_0^0(k, \nu) G_0^0(k + q, \nu) .
$$

FIG. 27. Diagrammatic representation of the MFT density-density susceptibility matrix, see Eq. (37). The sums over internal momentum $k$, frequency $\nu$, and spin have not been written explicitly.

Substituting Eq. A3 into this and evaluating the frequency integral then leads to Eq. (42). Given that the MFT longitudinal spin susceptibility is equal to the density one [Eq. (40)] the only nonzero MFT susceptibilities are those shown in Figs. 27 and 26; in particular,

$$
\chi^{\rho\rho}_{(0)}(q, q + Q; \omega) = \chi^{\rho\rho}_{(0)}(q, q + Q; \omega) = 0 .
$$

This leads to a simple diagonal structure for the RPA susceptibilities for these quantities, as we shall see next. However, the matrix structure of $\chi^{\rho\rho}_{(0)}$ does lead to a full matrix equation for its RPA susceptibility.

2. RPA susceptibilities

For the RPA susceptibilities, the interaction vertices need to be inserted $n$ times for the $n$th order diagram.
FIG. 29. Diagrammatic representation of the alternative form of the interaction vertices suited to computing the transverse spin susceptibility for (a) Eq. (A11); (b) Eq. (A12). In (c), we show the RPA series for the transverse spin susceptibility. The sums over internal momenta $k$, $k'$, $k''$, and frequencies $\nu, \nu', \nu''$ have not been written explicitly.

We first look at the first order diagrams depicted in the second diagram of Fig. 28. For example, for the density susceptibility, the first order correction $\chi^{(1)}_{\rho\rho}$ reads

\[
\chi^{(1)}_{\rho \rho}(q, q; t) = 2 \left( \frac{i}{2N_s^2} \right) \left( \frac{-iU}{N_s^2} \right) \sum_{k, k'} \int_{-\infty}^{\infty} dt' \left[ \text{Tr} G_0^0(k, t - t') G_0^0(k + q, t' - t) \text{Tr} G_0^0(k', t') G_0^0(k' + q, -t') \right.
+ \left. \text{Tr} G_0^0(k, t - t') \tau_z G_0^0(k + q, t' - t) \text{Tr} G_0^0(k', t') G_0^0(k' + q, -t') \tau_z \right]
\]

(A7)

\[
\chi^{(1)}_{\rho \rho}(q, q; t) = -U \int_{-\infty}^{\infty} dt' \chi^{(0)}_{(0)}(q, q; t - t') \chi^{(0)}_{(0)}(q, q; t').
\]

(A8)

In Eq. (A7), the extra factor of 2 comes from the spin sum in Fig. 28, and using the fact that each bubble of a specific spin is spin independent. Importantly, the second line of Eq. (A7) does not contribute because this is proportional to $\int dt' \chi^{(0)}_{(0)}(q, q + Q; t - t') \chi^{(0)}_{(0)}(q, q + Q; t')$, which is zero by Eq. (A6). Hence, $\chi^{(0)}_{\rho \rho}$ is a diagonal matrix in Nambu space: effectively, there is no matrix structure needed.

This example can be generalized to higher order contributions and we find in the frequency domain, in the full matrix form,

\[
\chi^{(0)}_{\rho \rho}(q, \omega) = \chi^{(0)}_{(0)}(q, \omega) - \chi^{(0)}_{(0)}(q, \omega) U \chi^{(0)}_{(0)}(q, \omega)
+ \chi^{(0)}_{(0)}(q, \omega) U \chi^{(0)}_{(0)}(q, \omega) U \chi^{(0)}_{(0)}(q, \omega) + \ldots
+ \chi^{(0)}_{(0)}(q, \omega) \left[ 1 + U \chi^{(0)}_{(0)}(q, \omega) \right]^{-1}.
\]

(A9)

For $\hat{S}^z$, we sum the same set of diagrams in Fig. 28, except that each of the spin density operator $\hat{S}^z$ has a spin-dependence [Eq. (30)], which leads to a ($-1$) extra factor. Thus, we obtain

\[
\chi^{\hat{S}^z}_{\text{RPA}}(q, \omega) = \chi^{\hat{S}^z}_{(0)}(q, \omega) \left[ 1 - U \chi^{\hat{S}^z}_{(0)}(q, \omega) \right]^{-1}.
\]

(A10)

For the transverse spin susceptibility, the computation can be simplified in the following way: instead of writing the interaction term as $\sim U \hat{\rho}_1 \hat{\rho}_1$ as for Eq. (A1), we can...
instead write it as \( -U \tilde{S}^+ \tilde{S}^- \). More precisely, we write

\[
\tilde{V}_0 = - \frac{U}{N^2} \sum_{q,k,k'}^{\text{RBZ}} \tilde{\Psi}_{k+q,k}^{\dagger} \tilde{\Psi}_{k,k'}^{\dagger} \tilde{\Psi}_{k',q-k} \tilde{\Psi}_{k,q} .
\]

\[
\tilde{V}_Q = - \frac{U}{N^2} \sum_{q,k,k'}^{\text{RBZ}} \tilde{\Psi}_{k+q,k}^{\dagger} \tau_x \tilde{\Psi}_{k,k'}^{\dagger} \tilde{\Psi}_{k',q-k} \tau_x \tilde{\Psi}_{k,q} .
\]

The new forms of the interaction vertices are depicted in Fig. 29(a), (b). Using this new interaction form, the RPA series of diagrams, depicted in Fig. 29(c), have the same structure as for the longitudinal spin or density susceptibility cases. In particular, in the frequency domain the summation of the series yields

\[
\chi_{\text{RPA}}(q, \omega) = \chi_{(0)}^{\dagger}(q, \omega) \left[ 1 - U \chi_{(0)}^{\dagger}(q, \omega) \right]^{-1} .
\]

This is the matrix form for Eq. (46).

3. RPA renormalisation of the AFM order parameter

A more general method to calculate \( m \), from the definitions of \( m \) (Eq. (15)) and \( \tilde{S}^z \) (Eq. (30)), is to rewrite Eq. (15) using the single-particle Green’s functions of Eqs. (A2), (A3), following Schrieffer et. al [38]

\[
\langle \tilde{S}^z_Q \rangle = -i \sum_g \sum_k \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \eta(\omega) \left\{ G_g(k, k + Q; \omega) \right\} .
\]

We can define in analogy to the bare Green’s function of Eq. A2, a renormalised matrix Green’s function \( G_g(k, \omega) \), where \( G_g(k, k + Q; \omega) \) is the off-diagonal component. Note that using the bare Green’s function in Eq. (A14) gives back the MFT gap equation Eq. (29) at \( T = 0 \).

The renormalised matrix Green’s function satisfies a matrix Dyson equation

\[
G_g(k, \omega)^{-1} = G_g^{(0)}(k, \omega)^{-1} - \Sigma_g(k, \omega) .
\]

The self-energy \( \Sigma_g(k, \omega) \) can be approximated within the RPA as follows [38]. We can take a \( \chi_{\text{RPA}} \) diagram from Figs. 28 or 29, replace an external wavy line by an interaction vertex, and contract two external legs from these external interaction vertices by putting a relevant bare Green’s function between the legs. This results in a term that renormalises the Green’s function and the self-energy can be identified in the usual manner by removing the remaining two external legs. In general, order parameter suppression comes from low energy excitations, and Schrieffer et. al [38] have shown that only \( \chi_{\text{RPA}} \) diagrams need to be taken into account. They have thus computed \( m_{\text{RPA}} \) numerically for general values of \( U \) (see their Fig. 7), which we use in this paper.

Appendix B: Mean-field finite temperature susceptibilities

In this Appendix we give the full finite temperature MFT result for the correlation function needed in the structure factor of Eq. (69) that goes into the inelastic spectrum Eq. (67). Instead of using the imaginary time Matsubara formalism, we evaluate to the correlation function in Eq. (69), the original fermions belonging to the Brillouin Zone are transformed into the two-band fermions of the RBZ via the Bogoliubov transformation Eq. (25). Next, the resulting correlation function can be simplified because of the simple quadratic form of the MFT Hamiltonian of Eq. (28): any given term \( \langle \hat{c}_{\alpha,k+q,\omega+\Sigma}^\dagger \hat{c}_{\alpha,k,\omega} \rangle \) will be zero unless the effective band index \( \alpha \), the spin index \( \hat{\gamma} = \{ u, d \} \), and the momenta all match up pairwise. Now, we have \( \langle \hat{c}_{\alpha,k}^\dagger \hat{c}_{\alpha,k,G} \rangle = n_{\alpha,k} \), where \( n_{\alpha,k} = f(E_{\alpha,k}) \) and \( n_{2kG} = 1 - f(E_{2kG}) \), and \( f(E) = \left[ \exp(E/k_B T) + 1 \right]^{-1} \) denotes the Fermi-Dirac distribution. Hence, collecting all the factors, we get the MFT static structure factor [see Eq. (69)]
and $\alpha$ and $\beta$ are the effective band indices. The product of the occupation numbers $n_{qg,\alpha} (1 - n_{qg,\beta})$ indicates the Pauli blocking where the scattering from the initial state $n_{qg,\alpha}$ to an already occupied final state $n_{qg,\beta}$ is forbidden. At $T = 0$, only the scattering from the filled lower band to the empty upper band is allowed, while at the finite temperature also other processes are possible.

We present results for a lattice size $40 \times 40$, and finite-size effects shift the transition point from $K_c(N_s = \infty)$ to the finite-size critical point $K_c(N_s)$. The finite-size critical temperature can be estimated from the the infinite system using the scaling arguments of [72], along with the numerical fit to the finite-size scaling hypothesis from [73]. The finite-size shifted value of the critical temperature can be estimated as $K_c(N_s) \approx \frac{N_s K_c(\infty)}{N_s - \alpha}$. For a system with periodic boundary conditions $\alpha \approx -0.36$ [73].
