Highlights of the Study

- Sarcoidosis is a systemic granulomatous disease with progressive fibrosis.
- Galectin-3 plays a crucial role in the stimulation of inflammation and autoimmune disorders.
- Levels of serum galectin-3 increase in the presence of diseases like sarcoidosis that progress with pulmonary fibrosis.
- Galectin-3 can be considered for use in determining the staging and severity of sarcoidosis.

Keywords
Sarcoidosis · Galectin-3 · Pulmonary fibrosis · Inflammation

Abstract

Introduction: Galectin-3 is a multifunctional protein, the levels of which increase in the presence of diseases that progress with pulmonary fibrosis. This study investigated the role of galectin-3 levels in the staging and assessing of the severity of sarcoidosis. Methods and Subjects: Seventy-three subjects were studied; 25 were healthy individuals and 48 patients had pathologically confirmed diagnosis of sarcoidosis in which other potential causes had been ruled out. Galectin-3 levels were measured and compared in terms of such parameters as hemogram, biochemistry, age, body mass index, and smoking status. Results: The mean galectin-3 levels of the sarcoidosis patients (14.87 ± 5.57) were significantly higher than those in the healthy subjects (11.81 ± 2.67), and the mean galectin-3 levels differed significantly among different stages of the disease (p < 0.05). The serum galectin-3 level in patients with stage 2, 3, and 4 sarcoidosis was found to be higher than in patients with stage 0 and 1 sarcoidosis and the control group. In addition, serum galectin-3 levels in the sarcoidosis patients had significant positive correlations with blood urea nitrogen, alkaline phosphatase, white blood cells, red blood cell, hemoglobin, and neutrophil levels (34.9% [p < 0.05]; 40.1% [p < 0.05]; 41.2% [p < 0.01]; 43.3% [p < 0.01]; 34.7% [p < 0.05]; and 40.6% [p < 0.01], respectively) and a significant negative correlation with the platelet distribution width levels (p < 0.05). Conclusion: Serum galectin-3 levels are significantly elevated in sarcoidosis patients with parenchymal involvement at stage 2 or higher, suggesting that serum galectin-3 levels can be used to estimate disease severity in sarcoidosis.

Introduction

Sarcoidosis is a systemic granulomatous disease with an unknown etiology that progresses with multi-systemic involvements. Its yearly incidence has been reported as...
Galectin-3 is a β-galactoside-binding animal lectin that has sites of carbohydrate recognition [8, 9]. Galectin-3 is released from the cytoplasm or nucleus of various cell types, including but not limited to, monocytes (MONs), macrophages, and endothelial, microglia, and epithelial cells [10]. Galectin-3 is a multifunctional protein that is involved in various physiological and pathologic processes, such as cell growth, angiogenesis, carcinogenesis, and inflammation. Extracellular galectin-3 mediates inflammation and leukocyte adhesion and plays roles in the retrieval and activation of neutrophils (NEUs) [11] and also has a crucial role in the stimulation of inflammation in a wide range of acute and chronic events, particularly neurologic degeneration, autoimmune disorders, atherosclerosis and heart failure, and response to infections or diseases of the lungs, kidney, and liver [12]. A recent study by Sun et al. [13] showed a relationship between galectin-3 level and prognosis of acute kidney injury. These observations suggest that galectin-3 may result in fibrosis in several systems.

Increased levels of serum galectin-3 in the presence of diseases progressing with pulmonary fibrosis have been reported [14]. Taking into account the limited number of studies investigating the relationship between galectin-3 levels and pulmonary diseases, some of which reported significant findings in the presence of pulmonary fibrosis, we hypothesized that serum galectin-3 may be used as a biomarker for the staging and assessment of severity of sarcoidosis. In the present study, we investigated the levels of galectin-3 in sarcoidosis patients and healthy controls.

**Subjects and Methods**

The present study included patients aged between 18 and 75 years who were followed in our hospital and diagnosed with pulmonary sarcoidosis after other potential causes were ruled out. The inducted patients had the following features: they had pathological evidence of granuloma without calcification necrosis; they did not have interstitial lung disease other than sarcoidosis, or organ malignancy or history of chronic disorders. They made regular outpatient clinic visits and agreed to participate in the study. Healthy subjects aged between 18 and 75 years with no history of chronic disease and who voluntarily agreed to participate in the study constituted the control group. The study was initiated after approval was granted by the Ethics Committee of our hospital (Research Protocol Number 4221). The patients were informed about the study, and all signed an informed consent form.

The following data were garnered and evaluated for the 48 patients who agreed to participate in the study: demographic characteristics (age, gender, height, weight, and smoking status), pulmonary function test results, methods of diagnosis, current treatments, presence of extrapulmonary involvement, galectin-3 levels, and results of hemogram and biochemistry investigations performed within the last 6 months, obtained from hospital records.

The following data were recorded and evaluated for the 25 healthy controls who agreed to participate in the study: demographic characteristics (age, gender, height, weight, and smoking status), serum galectin-3 levels, as well as hemogram and biochemistry investigations performed within the last 6 months, obtained from hospital records. Galectin-3 levels of all sarcoidosis patients (n = 48) were compared along with their demographic data, pulmonary function test results, current treatments (if any), presence of extrapulmonary involvement, and hemogram and biochemistry investigations performed within the last 6 months, which were obtained from hospital records. Galectin-3 levels of all the healthy controls (n = 25) were compared along with their demographical data, body mass index (BMI), smoking status, and hemogram and biochemistry investigations performed within the last 6 months, obtained from hospital records.

Blood samples were obtained from both groups and centrifuged at 8,000 rpm for 10 min at 4°C. Serum samples were stored in Eppendorf tubes at −21 to −40°C. Galectin-3 levels in the serum samples were measured using a commercial kit based on the ELISA method (eBioscience, catalog no: BMS279/4, lot no: 133218001).

Based on the hemogram results of the peripheral blood, the NEU lymphocyte (LYM) ratio was calculated by dividing the absolute NEU count by the absolute LYM count, and the thrombocyte LYM ratio was calculated by dividing the absolute thrombocyte count by the absolute LYM count. Radiological classification was carried out by two different blinded pulmonologists, following the Scadding stage system, and classification difference between the specialists was detected using the Kappa method.

Numerical data were evaluated using the IBM SPSS Statistics 23 program, and measures of central tendency were presented as mean, standard deviation, minimum, and maximum values. Frequency distribution of the categorical variables was presented. An independent samples t test was used to evaluate the differences between the 2 groups, and a one-way variance analysis (ANOVA) was used to assess the potential differences between more than 2 groups. Based on the results of the ANOVA, a Levene’s test was applied to assess the homogeneity of variances, and a multiple comparison test (Bonferroni or Tamhane’s T2) was carried out to identify the group(s) causing significant difference. The differences between the groups were investigated with a Bonferroni test for variables with homogeneous variances and with Tamhane’s T2 test for variables without homogeneous variances. The Pearson Correlation Coefficient was used to investigate the relationship between serum galectin-3 levels, clinical characteristics, and blood parameters.
Results

Seventy-three cases were included in this; 65.8% (n = 48) had been diagnosed with sarcoidosis and 34.2% (n = 25) were healthy controls; 58.9% (n = 43) of all subjects were female and 41.1% (n = 30) were male. Women and men accounted for 62.5% (n = 30) and 37.5% (n = 18) of the sarcoidosis patients, while in the control group 50% (n = 13) of the cases were male and 50% (n = 13) were female. The mean age of the entire study population was 42.11 ± 12.29 (20–67) years, while mean age of the patient and control groups was 45.21 ± 11.90 (23–67) and 36.16 ± 10.953 (20–64) years, respectively.

Of all subjects, 49.30% (n = 36) were smokers and 50.70% (n = 37) had never smoked; smokers and those who had never smoked constituted 41.10% (n = 20) and 58.30% (n = 28) of the patient group and 46.15% (n = 12) and 38.40% (n = 10) of the control group, respectively.

The staging of the patients according to Scadding staging was as follows: stage 0 patients 25% (n = 12), stage 1 patients 35.4% (n = 17), stage 2 patients 25% (n = 12), stage 3 patients 12.5% (n = 6), and stage 4 cases 2.1% (n = 1). Of all the patients with sarcoidosis, 58.3% (n = 28) had previously undergone steroid therapy, while 21.3% (n = 10) were actively using steroid therapy while participating in the study. In addition, 4.2% (n = 2) of patients were concomitantly receiving methotrexate treatment. Extrapulmonary involvement was present in 37.5% (n = 18) of sarcoidosis patients, and eye, skin, and kidney involvement was present in 6.25% (n = 3), 31.25% (n = 15), and 8.3% (n = 4) of the patients, respectively. Of all the patients, 2.08% (n = 1) had concomitant skin and eye involvement, whereas 4.16% (n = 2) had both skin and kidney involvement.

### Table 1. Investigation of differences in parameters (independent samples t test)

| Parameters          | N   | Mean   | SD   | t     | p value |

LDH, lactate dehydrogenase; CRP, C-reactive protein. *p < 0.05. **p < 0.01.
An independent samples t test showed that mean galectin-3 levels, age, BMI, blood urea nitrogen (BUN), uric acid, lactate dehydrogenase, and sedimentation values were significantly higher in the sarcoidosis patients than in the healthy controls (shown in Table 1). One-way ANOVA revealed a statistically significant difference in serum levels of galectin-3 between sarcoidosis disease stages \((p < 0.05)\) (Table 2). The mean levels of serum galectin-3 in the sarcoidosis patients at stage 2 or higher were significantly higher than those in patients at stage 0 or 1. The independent samples t test revealed no statistically significant differences in the mean levels of serum galectin-3 between the patients with and without a concomitant disease, between smokers and nonsmokers, between patients receiving and not receiving active treatment, and between patients with and without extrapulmonary involvement.

### Table 2. Investigation of the differences in serum galectin-3 levels according to stages of sarcoidosis (independent samples t test)

| Stage of sarcoidosis | N  | Mean  | SD   | F    | p value | Difference |
|----------------------|----|-------|------|------|---------|------------|
| Stage 0              | 12 | 10.70 | 2.834|      |         |            |
| Stage 1              | 17 | 12.75 | 3.176| 19.385| 0.000***| 0.1–2      |

monary involvement ($p > 0.05$). Compared to the healthy controls, a significantly stronger relationship was observed between the mean serum galectin-3 levels and the serum BUN, MON, and NEU count, leukocyte and erythrocyte count, and hemoglobin (HGB) and hematocrit values in the sarcoidosis patients (Table 3).

**Discussion**

Sarcoidosis is a systemic granulomatous disease with unknown etiology and progresses with multi-systemic involvement. With a devious onset from asymptomatic bilateral hilar adenopathy to multiple extrapulmonary lesions, the disease may result in progressive fibrosis of the lungs and other organs. Prognosis and disease course may be associated with its mode of onset and its extent [1–3].

In the present study, we found that serum levels of galectin-3 were significantly higher in the sarcoidosis patients than in the healthy controls and that the levels were particularly elevated in patients at stage 2 or higher (characterized by parenchymal involvement), when compared to patients at stage 0 and 1. On the other hand, extrapulmonary involvement, smoking, age, or BMI was not significantly associated with serum galectin-3 levels.

In vitro studies investigating galectin-3 have demonstrated that the absence of galectin-3 may improve fibrotic response in the kidneys, liver, and lungs [15, 16]. Previous studies have also reported increased levels of galectin-3 in diseases progressing with fibrosis, such as cirrhosis and idiopathic pulmonary fibrosis [13–17]. A previous study reported that galectin-3 levels were elevated in sarcoidosis patients with cardiac involvement when compared to the controls [18]. Another study reported that serum galectin-3 levels were similar in sarcoidosis patients and control groups [19]. These data indicate that galectin-3 may result in fibrosis in several organs. In the present study, we investigate the role of galectin-3 in the staging and severity of sarcoidosis that progresses with fibrosis.

Consistent with the findings of previous studies [14–18], galectin-3 levels were found to be significantly higher in sarcoidosis patients than in the healthy controls. While galectin-3 levels were compared based on the radiological stages of sarcoidosis, the levels were found to be significantly higher in patients at stage 2 or higher, progressing with parenchymal involvement, when compared to the healthy controls, as well as patients with stage 0 or 1 sarcoidosis who were in remission, and who were being followed without treatment. This increase in galectin-3 levels indicates that fibrosis developed as soon as parenchymal involvement occurred. The detection of high levels of galectin-3 prior to a radiological diagnosis of stage 2 can indicate disease progression before radiology and may help with early diagnosis, and the consideration of alternative treatments before the full development of pulmonary fibrosis.

We also observed that extrapulmonary involvements in such organs as the eye, kidney, and skin did not significantly affect galectin-3 levels in sarcoidosis patients. Similarly, a previous study reported elevated serum galectin-3 levels in patients with pulmonary sarcoidosis when compared to the control group but did not point to a significant difference in galectin-3 levels between patients with and without cardiac involvement [18]. The present study showed that galectin-3 levels in the sarcoidosis patients were not significantly affected by smoking status, age, gender, BMI, creatinine, serum calcium, lactate dehydrogenase, sedimentation, angiotensin-converting enzyme, FEV1%, FVC%, 24-h urine calcium, NEU, LYM ratio, or thrombocyte LYM ratio. A previous study identified a significant relationship between serum levels of galectin-3 and age and gender, found the levels to be higher in women than men, and were observed to increase with age, whereas we identified no such relationships in the present study [20]. The same study also reported significant relationships between galectin-3 levels and BMI, kidney function tests, DM, C-reactive protein, and smoking status, while no such relationships were identified to any significant degree between galectin-3 levels and these parameters in the present study [20]. Similarly, a study performed in 2007 reported significantly elevated levels of serum galectin-3 in bronchoalveolar lavage samples obtained from patients with diseases progressing with pulmonary fibrosis, particularly in patients with idiopathic pulmonary fibrosis and interstitial lung disease associated with connective tissue disorders. Furthermore, the galectin-3 levels in patients with interstitial lung diseases associated with connective tissue disorders who underwent steroid treatment were also found to be mildly decreased, although this decrease was not statistically significant in that study, contradicting the findings of the present study [14]. This may be attributed to the inclusion of a healthy control group and sarcoidosis patients with normal renal functions in the present study.

Previous studies have also reported a relationship between high serum levels of galectin-3 and prognoses of acute and chronic heart failure, pulmonary hypertension, and acute coronary syndrome [20, 21]. This suggests that serum galectin-3 may also be used as a marker of prognosis.
in sarcoidosis patients. The short duration of our study prevented the collection of a sufficient amount of data for the investigation of the relationship between serum galectin-3 levels and prognosis in sarcoidosis patients. We believe that future prospective studies will better establish the relationship between serum galectin-3 levels and disease prognosis.

The results of the present study reveal that HGB, hematocrit, red blood cell, white blood cells, MON and NEU values, and BUN levels have a positive effect on serum galectin-3 levels in sarcoidosis patients, although contrary to our findings, a previous study involving patients with heart failure found no significant relationship between HGB and serum galectin-3 levels [22]. Previous studies have identified a negative relationship between HGB and inflammation [23]. We believe that the differences between our findings and those of previous studies may be attributed to the fact that the majority of patients in the present study were in a stable phase of the disease or were in regression.

Elevated alkaline phosphatase (ALP) levels are detected in up to 33 percent of sarcoidosis patients, and ALP is superior to gamma-glutamyl transferase in terms of showing liver involvement. In this study, ALP levels were not significantly different between the healthy control group and the sarcoidosis patients, although ALP levels were found to be associated with galectin-3 levels in the sarcoidosis patients. Galectin-3 levels increase in the presence of acute and chronic inflammation. Like galectin-3, ALP is a biomarker that is used as a marker of inflammation [24]. The relationship between galectin-3 and ALP levels can be explained by the fact that the levels of both markers increase in the presence of inflammation.

Platelet distribution width (PDW) is associated with thrombocyte activation and has been shown to play a role in thrombosis, and to be elevated in the presence of bone marrow involvement and inflammation [25, 26]. In the present study, PDW was significantly higher in the sarcoidosis patients when compared to the healthy controls. Moreover, a negative relationship was identified between PDW and galectin-3 levels in sarcoidosis patients, whereas a positive association was found between these 2 parameters in the control group. In the light of these data, it may be argued that pulmonary fibrosis may develop in sarcoidosis patients with low PDW values, although further studies are required to confirm this hypothesis.

We aimed to use galectin-3 in the prognosis or staging of sarcoidosis but not in the diagnosis of sarcoidosis fibrosis and fibrotic process is seen in advanced stages of sarcoidosis and fibrosis is not a specific condition of the disease. Our findings demonstrating that galectin-3 levels were significantly elevated in sarcoidosis patients at stage 2 or higher with parenchymal involvement suggest that serum galectin-3 can be used to assess the staging and severity of sarcoidosis. While several parameters have been investigated for the assessment of response to treatment and progression of sarcoidosis, there is currently no universally accepted and routinely used parameter for either of these purposes. Despite being a benign disease in general, sarcoidosis is still a matter of concern due to the challenges faced in its diagnosis, its economic burden on health expenditure, and its consequences in terms of loss of workforce. We suggest that serum galectin-3 could be a useful parameter in sarcoidosis for several reasons, including its ease of use, its amenability for rapid testing and its ability to identify fibrosis earlier than radiology, and the consequent avoidance of radiation exposure. That said, there are several limitations to our study, including the low number of patients at stage 3 and 4. Furthermore, this study was not designed as a controlled progressive study for the monitoring of patients with diseases progressing with pulmonary fibrosis. In addition, only a snapshot of galectin-3 levels was obtained in the study, and therefore, serum galectin-3 levels during the course of disease were not compared in sarcoidosis patients taking into account progression status. Accordingly, there is a need for prospective studies involving larger patient groups to investigate the routine use of serum galectin-3 in sarcoidosis patients and clarify its relationship with other parameters affecting disease course.

Conclusion

There are currently no parameters that can be used as a marker of progression and disease activity in sarcoidosis. In the present study, we found that serum levels of galectin-3 were significantly elevated in sarcoidosis patients when compared to healthy controls and that levels were significantly increased particularly in patients at stage 2 or higher, associated with parenchymal involvement. Serum galectin-3 levels may be used in the monitoring of sarcoidosis, being a simple and rapid approach that avoids radiation exposure and reveals pulmonary fibrosis prior to radiological staging.
