Abstract. Burn injuries can trigger tissue changes that can explain the variation in the level of different biochemical markers that can be recorded both locally or systemically. Some events observed in burn wounds such as vascular hyperpermeability have been associated with the release of matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) after trauma. Because it is unknown whether the serum levels of MMP-9 and TIMP-1 are a consequence of these destructions or a local response to thermal damage, we decided to follow their dynamics. Twenty-five patients (mean age 49.40±17.55 years) with a total body surface area (TBSA) affected by a thermal burn of <25% and 30 healthy subjects (mean age 49.70±8.04 years) were enrolled in the present study. Enzyme immunoassays were used to measure the serum levels of MMP-9 and TIMP-1. Our results showed that MMP-9 was increased 6.25-fold immediately after injury compared to the controls and remained on a plateau throughout the 7-day monitoring period. TIMP-1 showed an upward trend with an increase of 49.52% on the seventh day after triggering insult. The time-course of the MMP-9/TIMP-1 ratio followed the inverse dynamics of TIMP-1 starting from a ratio value measured at admission 3.82-fold higher than the one observed in the healthy volunteers and a highly statistically significant correlation between the values measured at different time-points during the monitoring period (P<0.001). The results of this retrospective study indicate that the MMP-9/TIMP-1 ratio may provide information on local changes over time, starting from the triggering insult, and may be considered as a predictive biomarker of burn evolutivity.

Introduction
Thermal injury remains a challenging disease and a leading cause of death. The analysis of the pathological lesions found in burn wounds showed an increase in vascular permeability at the site of injury (1). The responsible mechanisms are not yet well understood and can involve numerous factors (2). Some authors have described a possible role for matrix metalloproteinases (MMPs) in endothelial hyperpermeability (1,3-5). The effects of MMPs are not necessarily limited to the wound site, thus it is difficult to assess their precise role in the dynamics of the burn wound (4).

Wound healing involves complex processes that have been carefully researched over time. Some studies have described time-dependent increases in proteinase concentrations in burn wound fluid (6). High levels of proteinases (MMP-2 and MMP-9) have been found in wound fluid from chronic wounds...
but not in those produced by other types of injuries (7,8). Several studies have shown that the plasmatic levels of MMP-9 are higher after burn injuries (7-10). MMP-9 appears early after burn injury, and its level rises after 48 h (9,11). MMP-2 can also show higher levels in burn wounds but to a lesser extent than in other injuries (7,9). In burn wounds, with a typical chronic evolution, degradation products can be found but it is not clear which of the tissue proteinases are responsible for local repair (10). Another possible explanation could be the degradation of the adhesion molecules and growth factors by the local proteinases (12-14). Moreover, the expression of different tissue proteases in burn wounds could influence the prognosis (15). As a confirmation, some authors have associated increased MMP-9 concentrations with delayed healing of burned skin (16).

MMPs cannot be separated from their natural inhibitors (tissue inhibitors of metalloproteinases or TIMPs) (17). These maintain a balance that contributes to local tissue homeostasis (18-20). Independent roles for TIMPs have also been described (21). The inhibitor effect of TIMP-2 on burn-induced vascular hyperpermeability was demonstrated on some tissues, even in the presence of high MMP-9 levels (22). Serum concentrations of TIMP-1 reach a peak 2 days after a severe burn (23). TIMP-1 is known to inhibit the catalytic activity of MMP-9 in a 1:1 stoichiometric relationship (24,25).

Since the role of MMP-9 and TIMP-1 in early inflammation associated with a burn injury is poorly understood, we aimed to investigate the dynamics of MMP-9, TIMP-1, and the MMP-9/TIMP-1 ratio in the early shock phase of burn-injured patients.

Patients and methods

Patients and study protocol. This study included 25 adult patients with thermal burns (16 males/9 females, mean age 49.40±17.55 years) admitted to the Clinical Emergency Hospital for Plastic, Reconstructive, and Burns Surgery in Bucharest, between 2018 and 2019. The study was conducted respecting the principles outlined in the Declaration of Helsinki and has been approved by the Clinical Emergency Hospital for Plastic, Reconstructive, and Burns Surgery Ethics Committee (approval no. 6627/04.10.2017).

The severity of the burn trauma is given by the burn depth and burn size. Burn size has been estimated by reference to the total body surface area (TBSA). Inclusion criteria were: i) Thermal burns with a TBSA affected by the burn of <25%; ii) deep second-degree and third-degree burns; iii) patient age over 18 years. All patients received routine treatment. They were investigated upon admission and after 2 and 7 days. Exclusion criteria were as follows: i) Patients with age under 18 years. All patients received routine treatment. They were then immediately aliquoted into labelled cryo-vials and frozen at -70°C until analysis.

Detection of serum MMP-9 and TIMP-1 by ELISA. The quantitative determination of human MMP-9 (cat. no. DMP900) and TIMP-1 (cat. no. DTM100) was performed using ELISA kits purchased from R&D Systems Inc. Because contamination may lead to falsely elevated serum concentrations due to the MMP-9 and TIMP-1 presence in saliva, protective measures were required to prevent contamination during the test. Three samples of known concentration were tested 20 times on one plate to assess intra-assay precision and in 40 separate assays to assess inter-assay precision. The values of the inter-assay imprecision study were similar to those of the intra-assay study with CVs ranging from 2 to 6.9%. The within CVs for MMP-9 were 2.0% at a mean concentration of 83.3 ng/ml and 2.9% at a mean concentration of 1,100 ng/ml (for low- and high-concentration patient samples). CVs for the TIMP-1 were ~4.5%. The MMP-9/TIMP-1 ratio was calculated according to the following formula: MMP-9 (ng/ml)/TIMP-1 (ng/ml). All assays were performed in duplicate according to the manufacturers' recommendations and in such a way minimized any effects of repeated freeze-thaw cycles.

Statistical analysis. Patient data processing was performed using Microsoft Office Excel 2007 SP2 (including Data Analysis Tools). Statistical analysis was conducted using SPSS version 25 software (IBM Corp.). The difference between the serum concentrations measured in dynamics for MMP-9 and TIMP-1 was analyzed by one-way ANOVA test with Bonferroni correction, comparing their evolution during the 7-day monitoring period from the initial burn injury. The Anderson-Darling, Shapiro-Wilk, and Kolmogorov-Smirnov tests were also used to verify the data obtained after preliminary analysis and to check the consistency of the group. The correlation between investigated biomarkers was assessed using Spearman's correlation coefficient for TIMP-1 with data that did not have a normal distribution and Pearson's correlation coefficient for MMP-9 and MMP-9/TIMP-1 ratio with normally distributed data. For all tests, the significance level for statistical analysis was set at P-values <0.05.

Results

After a post-injury accelerated increase, MMP-9 remains at the same serum level. Data from the analysis of the sera collected from patients with burn injury, at different time intervals, compared to the healthy controls are summarized in Table 1. Highly significant differences in the levels of MMP-9, TIMP-1, and MMP-9/TIMP-1 ratios were observed among patients.
Pearson correlations between MMP-9/TIMP-1 ratios calculated in dynamics. Furthermore, comparing the ratio of the two biomarkers measured at different time post-injury, the Pearson's correlation coefficient was as follows: Admission vs. 2 days post-injury ($r_{P1-P2}=0.63$, $P=0.0006$) and 2 days post-injury vs. 7 days post-injury ($r_{P2-P3}=0.56$, $P=0.0035$) (Fig. 3A and B).

**Discussion**

The main findings of the present study are: i) MMP-9 increased immediately post-injury (a 6.25-fold increase compared to controls) and remained on a plateau throughout the monitoring period; ii) TIMP-1 showed a steady increase during the study period: 2 days post-injury by 30.04% and 7 days post-injury by 49.52%; iii) the MMP-9/TIMP-1 ratio followed the inverse dynamics of TIMP-1 with a steady decrease: 2 days post-injury by 15.38% and 7-days post-injury by 36.92%; iv) the dynamics of MMP-9, TIMP-1 and the MMP-9/TIMP-1 ratio was demonstrated by the correlation between the values measured at different time-points after burning injury.

The MMP-9 and TIMP-1 biomarkers were investigated in dynamics over 7 days. We considered that the study interval of 7 days is enough to detect both ascending and descending inflammatory responses, the 7-day period being the time interval during which the post-injury systemic inflammatory response syndrome usually occurs (11,12,26,27). It should be noted that none of the patients enrolled in our study had septic complications during the monitoring period.

Burn injuries can trigger tissue changes that can explain the variation in the level of different biochemical markers that can be recorded both locally or systemically. Some events observed in burn wounds such as vascular hyperpermeability have been associated with matrix metalloproteinase (MMP) release after trauma (1,3,6,7,9,27). Because it is unknown whether the serum level of MMP-9 is a consequence of these destructions or a local response to thermal damage, we decided to follow its dynamics.

Burn injuries can trigger tissue changes that can explain the variation in the level of different biochemical markers that can be recorded both locally or systemically. Because it is unknown whether the serum level of MMP-9 is a consequence of these destructions or a local response to thermal damage, we decided to follow its dynamics.

**Table I. Serum biomarkers in patients with skin burn injury (N=25) and healthy controls (N=30).**

| Variables         | P1             | P2             | P3             | Control          | P-value<sup>b</sup> | P-value<sup>c</sup> | P-value<sup>d</sup> |
|-------------------|----------------|----------------|----------------|------------------|--------------------|--------------------|--------------------|
| MMP-9 (ng/ml)<sup>a</sup> | 1,744.2±811.9  | 1,659.6±521.4  | 1,744.9±677.1  | 279.3±72.4       | <0.001<sup>e</sup>| <0.001<sup>e</sup>| <0.001<sup>e</sup>|
| TIMP-1 (ng/ml)<sup>a</sup> | 269.9±93.6     | 386.8±334.9    | 534.7±381.2    | 166.7±45.5       | <0.001<sup>e</sup>| <0.001<sup>e</sup>| <0.001<sup>e</sup>|
| MMP-9/TIMP-1<sup>a</sup> | 6.5±2.6        | 5.5±2.6        | 4.1±2.2        | 1.7±0.3          | <0.001<sup>e</sup>| <0.001<sup>e</sup>| <0.001<sup>e</sup>|
the one calculated between the measured values after 2 and 7 days did not have the same statistical power ($r=0.407$, $P=0.04$). It is obvious, that MMP-9 does not occur as a simple local response to thermal damage. It is more than that. In burn trauma, the physiological balance is disturbed. The statistical power decrease after 7 days post-injury can be explained by the imbalance between MMP-9 and its tissue inhibitor, MMP-9 staying on a plateau, and TIMP-1 having an upward trend. Our results showing an increasing trend for TIMP-1 are in contrast to other studies (11,23) that have found significantly higher...
TIMP-1 concentrations in the plasma of patients with TBSA affected by a burn of <20% relative to healthy controls, with a median time to peak TIMP-1 concentration at 2.09 days. Given that a moderate increase in the MMP-9 serum concentration is beneficial, the epithelialization rate being partially dependent on the presence of collagen (13,16), MMP-9 levels remaining constant during the 7-day monitoring period could be associated with a better-quality scar. Because none of the patients enrolled in our study had septic complications during the 7-day monitoring period, the maintaining/decrease of MMP-9 serum levels may be an indicator for better survival.

Dynamic changes in circulating levels of MMP-9 and TIMP-1 demonstrate their involvement in the early response after thermal injury. As can be seen from Table I, at all-time points the differences between serum MMP-9 and its inhibitor TIMP-1 concentrations in the study group compared to the control group were statistically significant. The time-course of the MMP-9/TIMP-1 ratio followed the inverse dynamics of TIMP-1 starting from a ratio value measured at admission 3.82-fold higher than the one observed in the healthy volunteers. The constant linear decrease in the MMP-9/TIMP-1 ratio during the 7-day monitoring period (decrease by 14.28% in 2 days and decrease by 38.43% in 7 days from the measured value from admission) may represent an indicator of an effective healing process without hypertrophic scars and keloids for patients with a TBSA affected by the thermal burn <25%. As a confirmation, the comparison of the MMP-9/TIMP-1 ratio in dynamics showed a statistically significant correlation both between the values measured at hospitalization and those measured after 2 days \((r=0.63, P=0.0006)\) and between those measured after 2 and 7 days, respectively \((r=0.56, P=0.0035)\), much better than those obtained for MMP-9 and TIMP-1 individually.

Healing processes after thermal burn evolve, as evidenced by clinical practice. The factors that influence local changes are not fully known, but our results have shown that serum proteinases may be responsible for tissue remodeling. In this regard, monitoring of the MMP-9/TIMP-1 ratio may provide information concerning local changes over time, starting from the moment of the triggering insult, ultimately indicating the need for surgery or other therapeutic approaches.

The most apparent weakness of our study is related to the small number of patients included. Despite the small sample size, three aspects need to be mentioned: i) The study group matched the control group in terms of number, sex distribution, and age; ii) all the patients included in the study had a TBSA affected by the thermal burn <25%; and iii) none of the patients enrolled in our study had septic complications during the monitoring period.

In conclusion, the results of the present study demonstrated the MMP-9 and TIMP-1 involvement in the early response after thermal injury. Our findings suggest that the MMP-9/TIMP-1 ratio may provide information on local changes over time, starting from the triggering insult, and may be considered a predictive biomarker of burn evolutivity. Further investigations are needed to confirm these findings.

Funding

This research did not receive any specific grant from any funding agency in the public, commercial or not-for-profit sector.

Availability of data and materials

All data generated or analyzed during this study are included in the manuscript.

Authors' contributions

AES and AZCA conceived and planned the experiments. Experiments were performed by AES. AZCA, FLF, and MMS performed statistical analysis of the results. AES, AZCA, MMS, MG, RH, FLF and DCG contributed to the interpretation of the results. AES took the lead in writing the manuscript. All authors provided critical feedback and helped shape the research, analysis, and manuscript. All authors read and approved the final manuscript for publication.

Ethics approval and consent to participate

The study conformed to the principles outlined in the Declaration of Helsinki and was approved by the Clinical Emergency Hospital for Plastic, Reconstructive, and Burns Surgery ethics committee (approval no. 6627/04.10.2017). Written informed consent was obtained from enrolled patients or their legal representatives and volunteers.

Patient consent for publication

Not applicable.

Competing interests

The authors declare that they have no competing interests.
