Non-ischemic scar underlines ventricular arrhythmias in Kearns-Sayre syndrome

Introduction

Kearns-Sayre syndrome (KSS) is a rare mitochondrial disease in which cardiac involvement has been associated with poor prognosis. Although the most common clinical manifestation is progressive conduction system impairment, patients can suffer from ventricular arrhythmias. Yet, they show a high prevalence of sudden cardiac death, whose etiopathological mechanism is not completely understood. Cardiac magnetic resonance is a rising tool to detect subclinical heart involvement in many heart diseases and was recently able to detect non-ischemic scar, which is an arrhythmogenic substrate, in patients affected by KSS.

Case Report

A 44-year old male with KSS was referred to our cardiology clinic four years before for palpitations. Serial 24-h ECG demonstrated frequent ventricular ectopic beats (VEBs) and non-sustained ventricular tachycardia that persisted despite beta-blockers therapy. There was no family history of cardiac disease and his medications were carvedilol, ramipril and coenzyme Q-10. Baseline electrocardiogram (ECG) (Figure 1, panel A) and transthoracic echocardiography were normal. A 12 lead 24-h ambulatory ECG monitoring recorded 2175 isolated VEBs, 35 couplets and a run of nonsustained ventricular tachycardia of 5 beats with a right bundle branch block/superior axis pattern of the ectopic QRS, suggesting left ventricular free-wall origin (Figure 1, panel B). Frequent atrial ectopic beats (1981 in 24 h) were also present, while there was no evidence of atrioventricular block. Contrast-enhanced cardiac magnetic resonance (CMR) revealed mid-wall late gadolinium enhancement (LGE) in the basal-mid anterolateral and inferolateral segments, consistent with a left ventricular non-ischemic scar (Figure 1, panels C and D) in the absence of morpho-functional abnormalities, myocardial edema or fatty infiltration. The regional distribution of the myocardial scar was consistent with the plausible site of origin of VEBs.

Discussion

Scar tissue is a well-known substrate for VEBs (which origin from surviving myocytes interspersed among fibrous tissue or the scar border-zone) and re-entrant sustained ventricular tachycardia in patients with cardiomyopathies. More recently, isolated left-ventricular myocardial scar with a non-ischemic distribution has been recognized as a substrate of apparently unexplained VAs in patients with otherwise structurally normal heart. Although these lesions are traditionally considered the sign of a healed myocarditis, left ventricular scar with a subepicardial/midmural (i.e. non-ischemic) distribution can be secondary to genetically-determined cardiac damage such as in case of desmoplakin, phospholamban or filamin-C gene-mutation. All those conditions are characterized by a high risk of SCD for ventricular tachyarrhythmias unrelated to the degree of ventricular systolic dysfunction.

A recent CMR study detected pathological findings in 10 out of 35 patients affected by KSS, despite normal ECG and negative biomarkers. Similar to our case, in 8 out of these 10 patients, myocardial involvement consisted of a mid-wall area of LGE in the basal-mid lateral segments. Interestingly, this LGE pattern was not found in other mitochondrial disorders with heart involvement. KSS is distinctively characterized by a high risk of SCD: although atrioventricular block due to progressive conduction system disease is traditionally believed to be the cause, a number of patients died suddenly despite pacemaker implantation. In these cases, myocardial scar-related VAs may be a potential mechanism. According to this perspective, CMR should be strongly considered for detection of cardiac involvement in KSS patients, particularly in those with ventricular arrhythmias, as it may help to identify concealed arrhythmogenic substrates.

Conclusions

Although the most common clinical manifestation of KSS is progressive conduction system impairment, patients can also suffer from VAs. Myocardial scar is an arrhythmogenic substrate that is frequently demonstrated by CMR in the absence of echocardiographic or ECG abnormalities. Consequently, CMR may provide an incremental value for cardiac involvement identification and risk stratification of patients with KSS. Prospective cohort studies are needed to evaluate the impact of myocardial scarring on indications to prophylactic ICD implantation even in the absence of myocardial involvement in patients with KSS.
dysfunction or intraventricular conduction defects.
