(March 21, 2022)

We investigate the ground and low excited states of a rotating, weakly interacting Bose-Einstein condensed gas in a harmonic trap for a given angular momentum. Analytical results in various limits, as well as numerical results are presented, and these are compared with those of previous studies. Within the mean-field approximation and for repulsive interaction between the atoms, we find that for very low values of the total angular momentum per particle, $L/N \rightarrow 0$, where $L\hbar$ is the angular momentum and $N$ is the total number of particles, the angular momentum is carried by quadrupolar ($|m| = 2$) surface modes. For $L/N = 1$ a vortex-like state is formed and all the atoms occupy the $m = 1$ state. For small negative values of $L/N = 1$ the states with $m = 0$ and $m = 2$ become populated, and for small positive values of $L/N = 1$ atoms in the states with $m = 5$ and $m = 6$ carry the additional angular momentum. In the whole region $0 \leq L/N \leq 1$ we have strong analytic and numerical evidence that the interaction energy drops linearly as a function of $L/N$. We have also found that an array of singly quantized vortices is formed as $L/N$ increases. Finally we have gone beyond the mean-field approximation and have calculated the energy of the lowest state up to order $N$ for small negative values of $L/N = 1$, as well as the energy of the low-lying excited states.

I. INTRODUCTION

One of the basic questions about Bose-Einstein condensates in trapped alkali atom vapors is how they behave under rotation. A lot of theoretical work has been done on this subject, both analytical, and numerical, and the problem has been studied theoretically, both in the Thomas-Fermi limit of strong interactions and in the limit of weak interactions, which we consider in this paper.

In Ref. Wilkin et al. considered a weakly interacting Bose gas with attractive interactions and showed that in the lowest energy state of a given angular momentum, the angular momentum is carried by the center of mass motion. Butts and Rokhsar calculated numerically the moment of inertia of a weakly-interacting trapped Bose gas with effective repulsive interactions. One of us identified the elementary modes of excitation for small angular momentum and demonstrated in Ref. that a system of rotating weakly-interacting bosons exhibits two additional kinds of condensation associated with the nature of low-lying excitations. Finally Bertsch and Penbrock performed in Ref. exact numerical diagonalization within the subspace of states with a given angular momentum, which are degenerate in the absence of interactions.

Experimentally the detection of vortex states in a two-component system has been reported by Matthews et al., while Madison et al. have provided evidence for the formation of vortex states in a stirred one-component Bose-Einstein condensate.

Our basic goal in this study is to identify the lowest energy states of a harmonically trapped, weakly interacting Bose gas for a given angular momentum $L$. As we show below these states are selected by the interactions. In Sec. II we describe the model and discuss the degeneracy of the many-body states for a given angular momentum in the absence of interactions. In Sec. III we use the mean-field approximation to calculate the interaction energy, and derive numerical and analytical results under various conditions. In Sec. IV we describe how one can go beyond the mean-field approximation and study as an example the specific case of small negative $L/N - 1$. Finally in Sec. V we give our conclusions.

II. THE MODEL

Our starting point is the Hamiltonian $H$, given by

$$H = H_0 + V.$$ (1)

Here

$$H_0 = \sum_i -\frac{\hbar^2}{2M} \nabla_i^2 + \sum_i \frac{1}{2} M \omega^2 (x_i^2 + y_i^2) + f(z_i)$$ (2)

includes the kinetic energy of the particles and their potential energy due to the trapping potential. The axis of rotation is taken to be the $z$ axis, and the trapping potential is assumed to be that of an isotropic harmonic oscillator of frequency $\omega$ in the $x$-$y$ plane. Also $M$ is the mass of the atoms. Our results do not depend on the trapping potential $f(z)$ in the $z$ direction. The interaction $V$ between atoms is assumed to be of zero range,

$$V = \frac{1}{2} U_0 \sum_{i \neq j} \delta(r_i - r_j),$$ (3)
where $U_0 = 4\pi\hbar^2 a/M$ is the strength of the effective two-body interaction, with $a$ being the scattering length for atom-atom collisions. We assume that the interaction is repulsive, $a > 0$. Attractive interactions have been studied in Refs. \[3,6\].

Much theoretical work on rotating condensates has been done in the Thomas-Fermi limit of strong interactions, where the superfluid coherence length has been measured relative to that of the ground state is therefore non-interacting bosons with angular momentum. The energy of the lowest state of a system of zero or having the same sign as the total angular momentum $L$ is the particle density, is much less than the size of the cloud, and the situation is analogous to that for BCS pairing of nucleons in nuclei.

In the lowest energy state of the many boson system along the $z$ axis. Therefore the coherence length is larger than the size of the cloud, and the situation is analogous to that for BCS pairing of nucleons in nuclei.

Since we consider rotation around the $z$ axis, the condition $nU_0 \ll \Delta E_z$ implies that the motion along this axis is frozen out and the problem is essentially two-dimensional. It is well known that for the harmonic oscillator potential in two dimensions the single-particle energies $\epsilon$ are given in the absence of interactions by

$$\epsilon = (2n_r + |m| + 1)\hbar \omega,$$

where $n_r$ is the radial quantum number, and $m$ is the quantum number corresponding to the angular momentum. In the lowest energy state of the many boson system all particles are in states with $n_r = 0$, and with $m$ being zero or having the same sign as the total angular momentum. The energy of the lowest state of a system of non-interacting bosons with angular momentum $L$ measured relative to that of the ground state is therefore

$$E = L\hbar \omega.$$

There is a huge degeneracy corresponding to the many different ways of distributing $L$ quanta of angular momentum among $N$ atoms. Interactions between the atoms lift the degeneracy. We incorporate the effect of the interactions in both the mean-field approximation, as well as by diagonalization within some appropriately chosen truncated space of degenerate states. We describe the two methods separately below.

III. MEAN-FIELD APPROXIMATION

We start with the mean-field Gross-Pitaevskii approach. Butts and Rokhsar have used this method to derive numerical results for the moment of inertia of a Bose gas. In this scheme the many-body condensate wavefunction with $N$ particles and $L$ units of angular momentum $Ψ_{L,N}(r_1, r_2, . . . , r_N)$ is taken to be the product of the single-particle states $Ψ(r_i)$:

$$Ψ_{L,N}(r_1, r_2, . . . , r_N) = Ψ(r_1) × Ψ(r_2) . . . Ψ(r_N).$$

The single-particle states $Ψ(r_i)$ can be expanded in terms of the harmonic-oscillator eigenstates $Φ_m(r_i)$:
\[
\Psi(\mathbf{r}) = \sum_{m=0}^{\infty} c_m \Phi_m(\mathbf{r}),
\]

where the \(c_m\) are variational parameters, which are complex in general and are functions of \(L\). The summation in Eq. (9) is restricted to positive \(m\), since states with negative \(m\) do not belong to the space of degenerate states. The quantity \(|c_m|^2\) gives the occupation probability for state \(\Phi_m\). Also
\[
\Phi_m(\mathbf{r}) = \frac{1}{(m! \pi a_{osc}^2)^{1/2}} g(z) \left( \frac{\rho}{a_{osc}} \right)^{|m|} e^{i m \phi} e^{-\rho^2/2 a_{osc}^2}.
\]

Here \(\rho, z, \phi\) are cylindrical polar coordinates. In the above expression we have assumed that the bosons are in their ground state \(g(z)\) along the axis of rotation. The expectation value of the interaction energy \(V\) in the state given by Eq. (8) is
\[
\langle V \rangle = \frac{1}{2} N(N-1) U_0 \int |\Psi|^4 \, d\mathbf{r}.
\]

To find the lowest energy state we calculate \(\langle V \rangle\) as a function of the variational parameters \(c_m\), and minimize it with respect to them under the following two constraints: the normalization condition,
\[
\sum_m |c_m|^2 = 1,
\]
and the condition that the expectation value of the angular momentum per particle be fixed,
\[
\sum_m m|c_m|^2 = L/N.
\]

The parameters \(c_m\) are complex in general, and therefore both their magnitudes, and their phases need to be determined. However Eqs. (12) and (13) impose two constraints on the magnitudes of the \(c_m\). Furthermore, the overall phase of the wavefunction is arbitrary. Finally the rotational symmetry of the confining potential implies that the origin of the angular coordinate is arbitrary, which corresponds to the condition for conservation of angular momentum, which holds even in the presence of interactions. Therefore if the expansion (9) is truncated at a value \(m_{\text{max}}\), the number of independent variables is \(2 \times (m_{\text{max}} + 1) - 4 = 2(m_{\text{max}} - 1)\).

**A. Numerical results**

We have examined the problem numerically with \(m_{\text{max}}\) up to 9. The total number of terms in the expression for \(\langle V \rangle\) is 125 in this case. The result of such a calculation with \(m_{\text{max}} = 6\) is shown in Fig. 1 for \(0 \leq L/N \leq 2\).

![Figure 3](image-url)

**FIG. 3.** Lines of constant density for \(L/N = 0.1, 0.6, 0.8,\) and 1.0 in a plane perpendicular to the \(z\) axis. On the darker curves \(|\Psi|^2 = 0.3 n_0\), and on the lighter curves \(|\Psi|^2 = 0.1 n_0\), where \(n_0 = g(z)^2/\pi a_{osc}^2\). The unit of length is the oscillator length \(a_{osc}\). These pictures show how a vortex enters the cloud of bosons as the angular momentum per particle increases.

We show the results with \(m_{\text{max}} = 6\), since the occupancy of states with higher \(m\) is very low, and therefore including such states would not alter the results on this scale. Figure 2 shows the corresponding interaction energy. Also Fig. 3 shows the lines of constant density, \(|\Psi|^2 = \text{constant}\) for \(L/N = 0.1, 0.6, 0.8,\) and 1.0. Figure 3 shows the gradual transition from mostly quadrupole and to a less extent octupole excitations, which are present at low angular momentum, to vortex-like structures as \(L\) approaches \(N\). We should also mention that the structures in Fig. 3, as well as those in Figs. 4, 5 and 6, rotate with an angular frequency \(\Omega\) given by
\[
\Omega = \frac{1}{\hbar} \frac{\partial E_{\text{tot}}}{\partial L} = \omega - \frac{1}{N \hbar} \frac{\partial \langle V \rangle}{\partial l},
\]

which is lower than the trap frequency \(\omega\). Here \(E_{\text{tot}}\) is the total energy of the system. When \(L\) increases beyond \(N\), the rotational invariance for \(L/N = 1\) is lost. Density contours for various values of \(L\) between \(N\) and \(2N\) are shown in Fig. 4. These were calculated including the states up to \(m = 6\). For \(L \gtrsim 1.75 N\) the optimal wavefunction has a two-fold axis of symmetry, and the odd-\(m\) coefficients in the wavefunction vanish smoothly as the transition is approached, as shown in Fig. 1. In Figs. 5 and 6 we show contours for \(L = 2N\) and \(L = 2.1N\). There is a first-order transition from a state with two-fold symmetry to one with three-fold symmetry for \(L \approx 2.03 N\). The solution for \(L/N = 2.0\) with the states \(m = 0, 2, 4, 6,\) and 8 considered has an energy of \(\approx 0.1757 N^2 v_0\), whereas the one with the three-fold symmetry, with \(m = 0, 3, 6,\) and 9, has \(0.1761 N^2 v_0\). In contrast for \(L/N = 2.1\), the state with the three-fold symmetry has an energy \(0.1691 N^2 v_0\).
The difference in the energies of two states, as well as for the occupancy of the states, as follows:

\[ \langle V \rangle = \frac{1}{2} |c_0|^4 + \frac{1}{2} |c_0|^2 |c_2|^2 + \frac{1}{4} |c_0|^2 |c_3|^2 + \frac{3}{16} |c_2|^4 + \frac{5}{32} |c_3|^4 + \frac{5}{8} |c_2|^2 |c_3|^2 + |c_0|^2 |c_1|^2 - \frac{\sqrt{3}}{2} |c_0||c_1||c_2||c_3| + \frac{1}{8} |c_0|^2 |c_4|^2 - \frac{\sqrt{6}}{8} |c_0||c_2|^2 |c_4| + \frac{1}{16} |c_0|^2 |c_3|^2 - \frac{\sqrt{10}}{8} |c_0||c_2||c_3||c_5| + \frac{1}{32} |c_0|^2 |c_6|^2 - \frac{\sqrt{5}}{16} |c_0||c_3|^2 |c_6| \right) N v_0 + O(v_0). \tag{18} \]

In the above expression we have chosen the phases of the variational coefficients $c_m$ in such a way as to minimize $\langle V \rangle$, and in the specific example we can arrange them so that all the off-diagonal matrix elements are negative. One of the phases can have any value, and
we make the choice $\phi_0 = 0$. The rest of them can be expressed in terms of, say, $\phi_1$. We have found that up to $m = 6 \ [m \neq 0]$ the expression

$$\phi_m = m \phi_1 + (m + 1) \pi$$

(19)
gives the lowest energy.

It is convenient to introduce the variable $X = |c_2|^2 + |c_3|^2$, which is linear in $l$ to leading order, and make use of the constraints given by Eqs. (12) and (13) to get

$$|c_0|^2 = 1 - X - |c_1|^2 - |c_2|^2 - |c_5|^2 - |c_6|^2,$$

$$|c_2|^2 = 3X - l + |c_1|^2 + 4|c_4|^2 + 5|c_5|^2 + 6|c_6|^2,$$

$$|c_3|^2 = l - 2X - |c_1|^2 - 4|c_4|^2 - 5|c_5|^2 - 6|c_6|^2.$$  

(20)

Then Eq. (18) takes the form

$$\langle V \rangle = \left( \frac{1}{2} - \frac{l}{4} - \frac{31}{16} X^2 + \frac{13}{8} X - \frac{9}{32} l^2 \right. $$

$$+ \frac{1}{4} |c_1|^2 - \frac{\sqrt{3}}{2} |c_1||c_2||c_3|$$

$$+ \frac{1}{8} |c_4|^2 - \frac{\sqrt{6}}{8} |c_2|^2|c_4|$$

$$+ \frac{5}{16} |c_5|^2 - \frac{\sqrt{10}}{8} |c_2||c_3||c_5|$$

$$\left. + \frac{17}{32} |c_6|^2 - \frac{\sqrt{5}}{16} |c_3|^2|c_6| \right) N^2v_0 + \mathcal{O}(Nv_0).$$

(21)

The last four terms in the above equation can lower the energy to order $l^2$. For $c_4$, for example, the energy is minimized if [see the third line of Eq. (21)]

$$\frac{\partial}{\partial l} |c_4|^2 = \frac{\partial}{\partial l} \frac{\sqrt{6}}{8} |c_2|^2|c_4|,$$

(22)
or

$$|c_4| = \frac{\sqrt{6}}{2} |c_2|^2 \propto l.$$  

(23)

Due to the non zero value of $c_4$ the energy is lowered by an amount

$$\Delta \mathcal{E} = \left( \frac{1}{8} |c_1|^2 - \frac{\sqrt{6}}{8} |c_2|^2|c_4| \right) N^2v_0$$

$$= -\frac{3}{16} |c_2|^4 N^2v_0 \propto l^2 N^2v_0.$$  

(24)

It is remarkable that the term $\Delta \mathcal{E}$ exactly cancels the term $3|c_4|^4/16$ in the second line of Eq. (18). In a similar way $c_1$, $c_3$, and $c_6$ can be expressed in terms of $c_2$ and $c_3$ (and thus $X$), and Eq. (18) takes the form of the effective Hamiltonian

$$\langle V \rangle = \left( \frac{1}{2} |c_0|^4 + \frac{1}{4} |c_0|^2|c_2|^2 + \frac{1}{4} |c_0|^2|c_3|^2 \right.$$  

$$+ \frac{5}{34} |c_3|^4 - \frac{4}{4} |c_2|^2|c_3|^2 \right) N^2v_0 + \mathcal{O}(Nv_0),$$

(25)
or equivalently

$$\langle V \rangle = \left[ \frac{1}{2} - \frac{l}{4} + \frac{27}{17} \left( X - \frac{l}{2} \right)^2 \right] N^2v_0 + \mathcal{O}(Nv_0).$$

(26)

Minimizing the above expression with respect to $X$ we find that $X = l/2$ and thus the angular momentum has to be carried by the $m = 2$ state alone, since $|c_2|^2 = l/2$ and $|c_3|^2 = 0$ up to terms linear in $l$. Also the quadratic correction to $\langle V \rangle$ vanishes. Therefore for $L/N \to 0$, the quadrupole ($\lambda = 2$) excitations are dominant. This is one of the important conclusions of our study. We show in the Appendix that a diagrammatic perturbative expansion which assumes that only the states with $m = 0, 2,$ and $3$ are occupied by a macroscopic number of particles, while all the other states are not, [but still contribute to the energy] gives the same result. If one goes to higher order in $l$ the interaction energy has within the perturbative scheme a term of the form $|c_3|^4|c_2|^2$, which includes all the processes that convert three $\lambda = 2$ excitations to two $\lambda = 3$ excitations. This term can combine with the term $|c_3|^4$, which implies that it is possible that $|c_3|^2 \propto |c_2|^3 \propto l^{5/2}$, which actually turns out to be the case. Then $c_1$, for example, is given according to the second line of Eq. (21), by

$$|c_1| = \sqrt{3} |c_2||c_3| \propto l^{5/4}.$$  

(27)

Using similar arguments we find that

$$|c_m|^2 \propto l^{m/2} \text{ for } m \neq 1, \text{ and } |c_1|^2 \propto l^{5/2}.$$  

(28)

The leading terms in $|c_m|^2$ are given by

$$|c_0|^2 = 1 - \frac{1}{2} l + \frac{1}{3} l^{3/2},$$

$$|c_1|^2 = l^{5/2} + 2 l^3,$$

$$|c_2|^2 = \frac{1}{2} l - l^{3/2},$$

$$|c_3|^2 = \frac{2}{3} l^{3/2},$$

$$|c_4|^2 = \frac{3}{8} l^2 - \frac{3}{2} l^{5/2} - \frac{1173}{816} l^3,$$

$$|c_5|^2 = \frac{2}{15} l^{5/2} - \frac{4}{15} l^3,$$

and

$$|c_6|^2 = \frac{1}{144} l^3.$$  

(29)

and the corresponding interaction energy is

$$\langle V \rangle = \left[ \frac{1}{2} - \frac{l}{4} + \mathcal{O}(l^4) \right] N^2v_0 + \mathcal{O}(Nv_0).$$

(30)

The above equation is another basic result of our study, namely that the interaction energy drops linearly with the angular momentum up to the order we have examined, for $L/N \to 0$, in agreement with our numerical simulations and with those of Refs. [14].
C. Analytical results for \( l \approx 1 \)

We now turn to the region \( L/N \approx 1 \). When the angular momentum per particle is exactly equal to 1, the lowest-energy state is the one where \( |c_1|^2 = 1 \), and corresponds to a vortex state. We consider the two cases \( l < 1 \) and \( l > 1 \) separately, starting with \( l < 1 \).

a. Analytical results for \( l < 1 \)

The simplest way to create a state with \( l < 1 \) from that with \( l = 1 \) is to transfer particles from the \( m = 1 \) state to the ground state. However, the energy can be even lower if also the \( m = 2 \) state is populated, because of the off-diagonal term \(|c_0||c_1|^2|c_2|\). The interaction energy up to order \( l = 1 - L/N \) is found by minimizing the potential energy, retaining only the coefficients \( c_0, c_1, \) and \( c_2 \). This is

\[
\langle V \rangle = \left( \frac{1}{4}|c_1|^4 + |c_0|^2|c_1|^2 + \frac{3}{4}|c_1|^2|c_2|^2 - \frac{\sqrt{3}}{2}|c_0||c_1|^2|c_2| \right) N^2v_0 + \mathcal{O}(Nv_0),
\]

(31)

where we have used the fact that for this case too the phases may be shown to be given by Eq. (13). Equation (31) is valid for small negative \( L/N - 1 \) at least up to \( m = 4 \). Thus in this limit

\[
|c_0|^2 \propto |c_2|^2 \propto l.
\]

(32)

To obtain the coefficients of proportionality it is convenient to use the following parametrization:

\[
|c_0|^2 = (1 + \alpha)l,
|c_1|^2 = 1 - (1 + 2\alpha)l,
|c_2|^2 = \alpha l,
\]

(33)

where \( \alpha \) is a variational parameter. Minimizing the interaction energy in Eq. (31) with respect to \( \alpha \) we find that \( \alpha = 1 \). More generally using similar arguments we find that to leading order

\[
|c_m|^2 \propto l^{m-1},
\]

(34)

and the explicit expressions for the coefficients are

\[
|c_0|^2 = 2l - \frac{3}{2}l^2,
|c_1|^2 = 1 - 3l + \frac{27}{8}l^2,
|c_2|^2 = l - \frac{9}{4}l^2,
|c_3|^2 = \frac{3}{8}l^2,
\]

and

\[
|c_4|^2 = \frac{l^2}{12},
\]

(35)

and the interaction energy to order \( l^3 \) is,

\[
\langle V \rangle = \left[ \frac{1}{4} + \frac{l}{4} + \mathcal{O}(l^2) \right] N^2v_0 + \mathcal{O}(Nv_0).
\]

(36)

The above equation implies that also in the region \( l < 1 \) the interaction energy varies linearly with the angular momentum to the order we have examined, which is also in agreement with the numerical simulations. The coefficient of the linear term is the same as the one we found for small values of the angular momentum.

Equations (30) and (36) as well as the numerical results [see Fig. 2] strongly suggest that the interaction energy \( \langle V \rangle \) drops linearly as a function of \( L/N \) in the whole region \( 0 \leq L/N \leq 1 \). The same result was derived by Butts and Rokhsar [4] numerically within the mean-field approximation. In Ref. [7] Bertsch and Papenbrock performed exact diagonalizations of degenerate states of a given \( L \) and found that up to machine accuracy the energy of the lowest state for a given \( L \) varies linearly with \( L \) in the range \( 2 \leq L \leq N \), in agreement with our analytic expansions. This result is specific to the contact form of the effective interaction, and is probably connected to a hidden symmetry in our Hamiltonian \( H \), as discussed by Pitaevskii and Rosch [13], where the same Hamiltonian was considered in the context of breathing modes.

b. Analytical results for \( l > 1 \)

We turn now to the case \( l > 1 \). We calculate the difference in energy between the states \( |1^N \rangle \), and \( |1^{N-1}, \lambda + 1 \rangle \), by a method similar to that which for small \( l \) led to Eqs. (13) and (16). The energy \( \epsilon_\lambda \) of this \( 2^\lambda \)-pole excitation with \( L = N + \lambda \), with \( \lambda \ll N \) is given by

\[
\epsilon_\lambda = \lambda \hbar \omega - \frac{1}{2} \left( 1 - \frac{\lambda + 2}{2\lambda} \right) Nv_0 + \mathcal{O}(v_0).
\]

(37)

This formula implies that for \( l > 1 \), the single-particle excitations with the lowest energy per unit of angular momentum are those with \( \lambda = 4 \) or 5, which means that the actual angular momentum carried by the particles is \( m = 5 \) or 6. In contrast to the low-angular momentum case, here both \( |c_5|^2 \) and \( |c_6|^2 \) vary linearly with \( l \), \( |c_5|^2 \propto |c_6|^2 \propto l \), where \( l = L/N - 1 \). In addition, in this regime we find that the energy has corrections of higher order than linear. Using similar arguments to those given before for small \( l \), we find, to order \( l^2 \),

\[
|c_0|^2 = 0.1213 l^2,
|c_1|^2 = 1 - 0.2241 l,
|c_2|^2 = 0.1934 l^2,
|c_3|^2 = 0.1205 l,
|c_4|^2 = 0.1036 l,
|c_5|^2 = 1.7 \times 10^{-3} l^2,
|c_6|^2 = 1.3 \times 10^{-3} l^2,
|c_7|^2 = 8.6 \times 10^{-3} l^2,
\]

(38)
and the interaction energy is
\[
\langle V \rangle = \left[ \frac{1}{4} - \frac{5\bar{l}}{64} + 6.7 \times 10^{-3} \bar{l}^2 + \mathcal{O}(\bar{l}^3) \right] N^2 v_0 + \mathcal{O}(N v_0).
\]

(39)

If we compare the expressions (36) and (39) for the interaction energy we see that there is a change in its slope, \(\partial \langle V \rangle / \partial L\), as \(L\) passes \(N\), from \(-Nv_0/4\) for \(L < N\) to \(-5Nv_0/64\) for \(L > N\).

D. Results for higher values of \(L/N\)

We mentioned earlier that as the angular momentum per particle increases even further, there are certain ranges of values of \(L/N\) over which the state with the lowest energy has a specific symmetry. The lowest value of \(L/N\) for which this occurs is \(\approx 1.75\) and the symmetry of the state is two-fold, i.e., only \(c_{2m} \neq 0\). We have examined analytically as an example the case \(L/N = 2\). Keeping only the first three non-zero coefficients, which are the dominant ones, we find to order \(l = L/N - 2\) that

\[
\begin{align*}
|c_0|^2 &= \beta(\bar{l}) - \bar{l}/4, \\
|c_2|^2 &= 1 - 2\beta(\bar{l}), \\
|c_4|^2 &= \beta(\bar{l}) + \bar{l}/4,
\end{align*}
\]

(40)

where

\[
\beta(\bar{l}) = \frac{3092 - 48\sqrt{6}}{12695} + \frac{17(64\sqrt{6} + 109)}{10156} \bar{l}
\]

\[
\approx 0.2343 + 0.4449\bar{l},
\]

(41)

or

\[
\begin{align*}
|c_0|^2 &\approx 0.2343 + 0.1949\bar{l}, \\
|c_2|^2 &\approx 0.5314 - 0.8897\bar{l}, \\
|c_4|^2 &\approx 0.2343 + 0.6949\bar{l},
\end{align*}
\]

(42)

and the corresponding interaction energy is:

\[
\langle V \rangle = \left[ A - B\bar{l} + \mathcal{O}(\bar{l}^2) + \mathcal{O}(\bar{l}^3) \right] N^2 v_0 + \mathcal{O}(N v_0),
\]

where

\[
A = \frac{3}{16} + \frac{\beta_0}{32}(7 - 4\sqrt{6}) + \frac{\beta_0^2}{256}(64\sqrt{6} - 109),
\]

\[
B = \frac{1}{512}(4 + 85\beta_0),
\]

(43)

and \(\beta_0 = \beta(0)\). The actual numbers which appear in Eq. (44) are

\[
\langle V \rangle \approx \left[ 0.1773 - 0.0467\bar{l} + 0.0170\bar{l}^2 + \mathcal{O}(\bar{l}^3) \right] N^2 v_0 + \mathcal{O}(N v_0).
\]

(45)

There is no change in the slope of the interaction energy as \(L\) passes \(2N\). Figure 5 shows lines of constant density, \(|\Psi|^2 = \text{constant}\), for \(L/N = 2\). The occurrence of two nodes in the density reflects the presence of two displaced vortices, and thus we see that the lowest-energy state of the system has two separated vortices and not a doubly quantized vortex. This clearly demonstrates the instability of the double-quantized vortex state to formation of two vortices plus surface waves.

IV. BEYOND THE MEAN-FIELD APPROXIMATION

Another way of approaching the problem of rotation, is to diagonalize the Hamiltonian within the space of degenerate states. This approach goes beyond the mean-field approximation, since in mean field theory the many-body wavefunction is the product of the single-particle states, whereas the diagonalization allows for the many-body state to have all kinds of correlations between the particles. This technique can be used by taking into account the whole set of states [1], but it is convenient and pedagogical to work in a restricted space, appropriately chosen.

As an example we consider small negative \(L/N - 1\). From the analysis of Sec. III C we know that in this limit the states with \(m = 1, 0\), and \(2\) are dominant. Therefore the eigenstates

\[
|\mu, \bar{l}\rangle = |0\rangle^{l+\mu}, |1\rangle^{N-l-2\mu}, 2^\mu
\]

(46)

with \(N\) particles and \(L = N - \bar{l}\) units of angular momentum are expected to provide a good basis for describing the low-lying states for \(\bar{l} \ll N\). We restrict ourselves to this limit and demonstrate how one can derive an effective Hamiltonian which can be diagonalized exactly. In the limit we consider, \(\bar{l} \ll N\), and thus \(\mu \sim \bar{l} \ll N\). The diagonal matrix elements in the Hamiltonian are, up to terms of order \(N\),

\[
\langle \mu | V | \mu \rangle = \left( \frac{1}{4} N(N-1) + \frac{1}{2} \bar{l} N + \frac{3}{4} \mu N \right) v_0,
\]

(47)

and the off-diagonal matrix elements are

\[
\langle \mu + 1 | V | \mu \rangle \approx \sqrt{\frac{2}{4}} N v_0 \sqrt{(\mu + \bar{l} + 1)(\mu + 1)}.
\]

(48)

Ignoring for the moment the (diagonal) first term of Eq. (47), which corresponds to the interaction energy of the state \(|1^N\rangle\), we see from Eqs. (47) and (48) that we have to diagonalize the Hamiltonian

\[
\tilde{H} = \left[ \frac{1}{2} a_0^{\dagger} a_0 + \frac{1}{4} a_2^{\dagger} a_2 + \frac{\sqrt{2}}{4} (a_2^{\dagger} a_0 + a_0 a_2) \right] N v_0,
\]

(49)

which can be done exactly by use of a Bogoliubov transformation. Here \(a_m\) is an annihilation operator that destroys a particle with angular momentum \(m\hbar\). Introducing the operators \(c\) and \(d\) given by
we may write the Hamiltonian as
\[
\hat{H} = \frac{N}{4} (d^\dagger d - 1) v_0. \tag{51}
\]
Acting on states of the type \( \lvert \Omega \rangle \) the operator \( d^\dagger d - c^\dagger c \)
is diagonal, and has an eigenvalue \( N - L \). Therefore \( d^\dagger d \) can be eliminated and from Eq. \((51)\) we obtain
\[
\hat{H} = \frac{N}{4} (N - L - 1) v_0 + \frac{N v_0}{4} c^\dagger c. \tag{52}
\]
The total interaction energy is thus the eigenenergy of \( \hat{H} \) plus the diagonal part \( N(N - 1) v_0 / 4 \), or
\[
\langle V \rangle = \frac{N}{4} (N - 1) v_0 + \frac{N}{4} (N - L - 1 + \langle c^\dagger c \rangle) v_0 + O(v_0)
\]
\[
= \frac{N}{4} (2N - L - 2) v_0 + \frac{1}{4} \langle c^\dagger c \rangle N v_0 + O(v_0). \tag{53}
\]
In the ground state \( \langle c^\dagger c \rangle = 0 \), and the energy given by Eq. \((53)\) is the same as that derived numerically in Ref. 7. The presence of the term \( \langle c^\dagger c \rangle \) in Eq. \((53)\) implies that the excited states in this limit of small negative \( L/N - 1 \) are separated from the ground state by an amount
\[
\Delta E = \frac{N}{4} v_0 + O(v_0). \tag{54}
\]
We have also performed numerical diagonalization, and we have confirmed the above result \((53)\), as well as Eq. \((54)\). The average occupancy of the states of the non-interacting problem is, for the lowest-energy state and \( L = N \):
\[
|c_1|^2 = 1 - \frac{2}{N} + O \left( \frac{1}{N^2} \right); \quad |c_0|^2 = |c_2|^2 = \frac{1}{N} + O \left( \frac{1}{N^2} \right),
\]
and thus in the limit \( N \to \infty \) there is agreement between the mean-field approximation and the present one.

V. SUMMARY AND CONCLUSIONS

To summarize, we have studied the lowest-energy states of a system of rotating, weakly interacting harmonically trapped bosons. Within the mean-field approximation, for \( L/N \to 0 \) we find that the angular momentum is carried mainly by quadrupole \( \langle |m| = 2 \rangle \) excitations. We have demonstrated that diagrammatic perturbation theory also leads to the same results as the method we have used here.

For \( L/N = 1 \) the angular momentum is carried by particles in the \( m = 1 \) state, while for small negative \( L/N - 1 \) the \( m = 0 \) and \( m = 2 \) states are also populated. In the limits \( L/N \to 0 \) and \( L/N \to 1 \) the energy is a linear function of the angular momentum up to the order we have explored, while numerically this linearity persists in the whole region \( 0 \leq L/N \leq 1 \). This result is specific to the contact form of the effective interaction, and does not hold for more general interactions.

For small positive \( L/N - 1 \), the states which carry the additional angular momentum are those with \( m = 5 \) and \( m = 6 \). In addition, as \( L \) passes \( N \) the derivative of the interaction energy with respect to the angular momentum changes abruptly. We have also found that for \( L/N \approx 1.75 \) there is a second order phase transition and for \( 1.75 \leq L/N \leq 2.03 \) the lowest energy state has two-fold symmetry. At \( L/N \approx 2.03 \), there is a first order phase transition to a state with three-fold symmetry. More generally, for higher values of \( L/N \) a vortex array develops.

The Gross-Pitaevskii wavefunction is a power series in \( \tilde{z} = x + iy \). Thus if one truncates the series at \( m = m_{\text{max}} \), the wavefunction will have \( m_{\text{max}} \) nodes. In the vicinity of a node at \( \tilde{z} = \tilde{z}_0 \) the wavefunction varies as \( \tilde{z} - \tilde{z}_0 \) and therefore each node corresponds to a singly quantized vortex having the same sense as the total angular momentum. It is instructive to study how the vortex lines move as the angular momentum is increased. For low angular momentum, the condensate wavefunction has only \( m = 0 \) and \( m = 2 \) components, and it is therefore proportional to \( [1 - (1/2^2 / 2) (\rho/\alpha_{\text{osc}})^2 \tilde{z} \tilde{z}^\ast] \exp(-\rho^2 / 2\alpha_{\text{osc}}^2) \) for the choice of \( \phi_2 = \pi \), according to Eq. \((19)\) with \( \phi_1 = 0 \). This has vortices on the x axis at \( x = \pm (2/1/2) \alpha_{\text{osc}} \). With increasing angular momentum, components of the wavefunction with odd \( m \) grow, and the two-fold symmetry of the cloud is broken, as may be seen in Fig. 1 for \( L/N = 0.1 \), one of the vortices moving to larger distances, and the other to smaller ones. The \( c_3 \) term leads to a third vortex at large distances from the origin. For \( L/N = 1 \) there is only one vortex, which is at the origin. With further increase in \( L/N \), the velocity field is at first still dominated by a vortex close to the origin, but subsequently a second vortex moves into the cloud until at \( L/N \approx 1.75 \) the two-fold symmetry is restored. As \( L/N \) increases towards the value 2.03, at which the first-order transition to the state with three-fold symmetry mentioned above occurs, the separation of the two vortices changes little.

In this paper we have also investigated effects not included in mean-field theory by diagonalizing a model Hamiltonian for \( L \) close to, but less from, \( N \). We find that for \( L = N \) the occupancy of the \( m = 1 \) state is 1, with corrections of order \( 1/N \). We have calculated the energy up to terms of order \( N \). Finally we also found that the low-lying excited states are separated from the lowest state by energies of order \( N v_0 \) of the same angular momentum.

In this study we have examined the limit of weak interactions. When the interaction energy per particle \( nU_0 \) becomes comparable to or greater than \( \hbar \omega \), components of the wavefunction that are not members of the lowest multiplet in the absence of interaction must be in-
cluded. Calculations for this regime based on the Gross-Pitaevskii equation have been carried out by Isoshima and Machida [13]. Comparison of our results with theirs is difficult because these authors calculated the lowest energy state in a rotating frame, rather than the lowest energy state for a given angular momentum.

One question of importance both conceptually and because of its relevance to experiment is whether or not the states are stable to small perturbations, and if they are not, what is the lifetime of the state. The answer to these questions depends on the nature of the perturbation, whether it is due to a deformation of the trap, or to interactions with particles outside the condensate, and we shall discuss it elsewhere.

In our calculations above we have shown for a particular example that the Gross-Pitaevskii approach gives correctly the contribution to the energy of order $N^2$. This result, which is alluded to in Ref. [4], is more general, and in a future publication [14] it will be shown how the Gross-Pitaevskii approach is recovered as the first term in an expansion in powers of $1/N$. The method may be extended to calculate contributions to the energy of order $N$ which are in excellent agreement with results obtained by numerical diagonalization of the Hamiltonian.

**APPENDIX: PERTURBATION THEORY APPROACH**

We show in this appendix that one can use perturbation theory to derive an effective Hamiltonian in the region $L/N \to 0$, corresponding to Eq. (22). We assume that only the states with $m = 0, 2,$ and 3 are macroscopically occupied. However, other states (the $m = 1, 4, 5$ and 6 in this case) give corrections to the energy that can be treated perturbatively. Let us demonstrate how this works by considering the interaction energy up to $l^2$. As long as both $c_2$ and $c_3$ vary as $l^{1/2}$, the only processes that contribute to the interaction energy up to $l^2$ are shown in Fig. 7.

Let us consider the first process on the left as an example. The matrix element $M$ corresponding to the vertex, where two particles with $m = 2$ scatter to states with $m = 0$ and $m = 4$, is equal to

$$M = \frac{\sqrt{6}}{16} N_2 \sqrt{N} v_0.$$  \hspace{1cm} (A1)

From Eq. (16) we find that the difference in the energy between the intermediate state and the initial state is

$$\delta \epsilon = -\frac{N v_0}{8} + O(v_0),$$  \hspace{1cm} (A2)

and thus perturbation theory implies that the correction to the energy is

$$\frac{|M|^2}{\delta \epsilon} = -\frac{3}{16} N_2^2 v_0 = -\frac{3}{16} |c_2|^2 N^2 v_0,$$  \hspace{1cm} (A3)

which is precisely the correction $\Delta \epsilon$ given by Eq. (24) (plus terms of order $N v_0$). Similarly the other diagrams shown below give $-5|c_3|^4/544$, $-|c_2|^2|c_3|^3/8$, and $-3|c_2|^2|c_3|^2/4$ in units of $N^2 v_0$, respectively, and are identical to the corrections given by the terms in the last four lines of Eq. (18).
