Abstract
The magnetic ground state of polycrystalline Néel skyrmion hosting material GaV₄S₈ has been investigated using ac susceptibility and powder neutron diffraction. In the absence of an applied magnetic field GaV₄S₈ undergoes a transition from a paramagnetic to a cycloidal state below 13 K and then to a ferromagnetic-like state below 6 K. With evidence from ac susceptibility and powder neutron diffraction, we have identified the commensurate magnetic structure at 1.5 K, with ordered magnetic moments of 0.23(2) μB on the V1 sites and 0.22(1) μB on the V2 sites. These moments have ferromagnetic-like alignment but with a 39(8)° canting of the magnetic moments on the V2 sites away from the V4 cluster. In the incommensurate magnetic phase that exists between 6 and 13 K, we provide a thorough and careful analysis of the cycloidal magnetic structure exhibited by this material using powder neutron diffraction.

1. Introduction
There has been widespread interest in skyrmion hosting materials, both for their fascinating magnetic properties, as well as their potential application in fields such as spintronics [1]. These topological magnetic quasi-particles have been found in an increasing number of systems but the majority of these materials stabilise Bloch as opposed to Néel skyrmions. In order to explain the physics of Néel skyrmions we need a deeper understanding of the materials in which they form, including the various types of magnetism that these systems exhibit [2].

GaV₄S₈ is a member of the lacunar spinel family (AB₄X₈) which has been shown to stabilise a variety of magnetic phases including a cycloidal state and Néel skyrmions [3]. It adopts a high-temperature face centred cubic F43m structure with a lattice made up of heterocubane-like [V₄S₄]₅⁺ and [GaS₄]₅⁻ tetrahedra [4]. A first-order structural phase transition occurs at 42 K distorting the cubic lattice into a low-temperature rhombohedral (R3m) crystal structure. In this paper we use the hexagonal setting of the R3m space group. This phase transition causes a deformation of the V₄ tetrahedra, elongating along one of the four possible ⟨111⟩ directions, creating two distinct V sites. Figure 1 depicts the low temperature crystal structure of GaV₄S₈. The V1 (3a Wyckoff) site corresponds to the V ion on the elongated node of the tetrahedra while the V2 (9b Wyckoff) site corresponds to the three remaining symmetric V ions within the tetrahedra. As this distortion can occur in any of the four possible ⟨111⟩ directions, micro-domains of each orientation are formed.

The magnetic behaviour of GaV₄S₈ arises from the sharing of a single unpaired electron among the V ions within the V₄ tetrahedron similar to other members of the lacunar spinel family [6]. GaV₄S₈ undergoes a paramagnetic to cycloidal magnetic transition at 13 K in zero field. Application of a magnetic field to the cycloidal magnetic phase stabilises magnetic...
A further reduction in temperature produces a ferromagnetic-like state below 6 K [4, 7]. Due to the easy axis anisotropy, the direction of the applied field with respect to the crystal lattice strongly affects the magnetic phases present. For example, aligning the field along the [111] pseudo-cubic crystallographic direction has been found to stabilise the largest extent of the skyrmion phase in magnetic field-temperature space [8].

The magnetic properties of GaV$_4$S$_8$ have previously been investigated using a variety of techniques such as muon-spin rotation ($\mu^+$ SR) [9, 10], small angle neutron scattering (SANS) [3, 11, 12], and electric polarisation [13]. Magnetisation measurements [13] have shown that at temperatures below 6 K and low fields, the magnetic structure of GaV$_4$S$_8$ is not a simple collinear FM phase as suggested by previous work [3]. High temperature magnetisation measurements have also emphasised the magneto-structural link in this material, with discontinuities being seen in the inverse susceptibility at the structural phase transition [4, 13]. Both the zero-field magnetic and structural transitions are able to be seen in heat capacity measurements, while the structural transition is also evident in resistivity data [13].

Our previous powder neutron diffraction studies on the ferromagnetic-like state revealed a magnetic spin texture where the moments on the V1 sites align with the hexagonal crystallographic $c$ axis and the moments on the V2 sites cant outwards from the centre of the V$_4$ cluster [4]. Investigations of GaV$_4$S$_8$ support the evidence for a commensurate magnetic ground state below 6 K and a cycloidal magnetic phase has been identified to propagate along the [1 1 0] pseudo-cubic direction from SANS measurements, although due to complex micro-twinning, the propagation vector of the magnetism with respect to the rhombohedral phase has not been reported to date [3, 11].

We have therefore carried out ac susceptibility measurements on a single crystal of GaV$_4$S$_8$ and have identified a new commensurate ferromagnetic-like zero-field phase at low temperatures that undergoes a transition to a ferromagnetic state with applied magnetic fields. In order to investigate this ferromagnetic-like region in more detail, we have performed high-intensity powder neutron diffraction experiments on GaV$_4$S$_8$. We describe the magnetic structure in this low temperature commensurate phase and the incommensurate state, with reference to the existing literature.

2. Experimental details

Polycrystalline samples of GaV$_4$S$_8$ were synthesised by solid-state reaction as described in reference [4]. Phase purity was confirmed by laboratory powder x-ray diffraction using monochromatic Cu K$_\alpha$ radiation. Powder neutron diffraction experiments were carried out on the D2B and D20 diffractometers at the Institut Laue-Langevin, in line with our previous experiments on these diffractometers [4, 7]. A standard orange cryostat was used for neutron diffraction with the $\sim$ 9.5 g powder sample sealed in a thin-walled cylindrical vanadium tube.
of 12 mm diameter. Magnetic structure determination measurements were performed on the D20 diffractometer with a neutron wavelength of 2.417 Å at three temperatures: 1.5, 9, and 15 K representing the lowest temperature achievable in the cryostat in the ferromagnetic-like region, in the centre of the cycloidal phase, and in the paramagnetic phase, respectively. The magnetic refinements were carried out using the FullProf software suite [5]. Ac susceptibility measurements as a function of dc applied field were performed on a single crystal of GaV₄S₈ grown as described in reference [4]. An ac field of 113 Hz and 0.3 mT was applied after zero-field-cooling then application of a dc magnetic field along the cubic [111] direction at intervals of approximately of 0.25 K and 2 mT.

3. Results and discussion

3.1. Ac susceptibility

Figure 2 depicts the ac susceptibility phase diagram obtained on a GaV₄S₈ single crystal. Comparison with the magnetic phase diagram by Kézsmárki et al [3] enables identification of the low field cycloidal (C) and skyrmion (S) phases and the high field cycloidal (C*) and skyrmion (S*) phases. However, an additional low temperature ferromagnetic-like (F-L) phase can be identified from the ac susceptibility map in figure 2, which is not present in most previously published phase diagrams. Based on SANS measurements from the literature

[3, 11, 12] and our previous powder neutron diffraction measurements [4], this low temperature magnetic state has been confirmed to be a commensurate structure. This is commonly identified in the literature as a ferromagnetic state although more careful ac susceptibility measurements in the low-temperature low-field region shows a peak in the susceptibility with application of a dc magnetic field that extends from 6 K down to the lowest temperatures measured, as seen in figure 2. The F-L phase had not been identified in previous studies using techniques such as SANS and atomic force microscopy [3] that are often not sensitive to small changes in a commensurate magnetic structure, although a non-collinear magnetic state, possibly with short-range order, was suggested from magnetisation measurements [13]. The inset of figure 2 highlights this peak at 2 K in the ac susceptibility which is present at ~65 mT on decreasing field after saturation at 1 T. As this peak is observed after both zero-field-cooling and saturation with a high magnetic field, it precludes the peak’s origin being from magnetic domains and thus indicates a change in the dynamics of magnetic moments that is often associated with a magnetic phase transition. The high-field low-temperature magnetic phase can be associated with a ferromagnetic state as it has previously been seen to be commensurate and no additional phase transitions have been observed with the application of larger magnetic fields. Powder neutron diffraction in this ferromagnetic-like region, can help us further understand this magnetic phase and allow us to determine its magnetic structure.

3.2. Powder neutron diffraction at 1.5 K: commensurate structure

Figure 3 shows the magnetic peaks in the 1.5 K–15 K powder neutron diffraction difference pattern. The nuclear R₃m hexagonal structure was first refined at 15 K, a temperature at which GaV₄S₈ is paramagnetic. At 1.5 K the peaks can be indexed by a \( k = 0 \) propagation vector, in agreement with literature [3, 4, 12]. Magnetic symmetry analysis was performed using BASIREPS to determine the magnetic irreducible representations (IR) and their basis vectors (BV) [14, 15]. The only IR that can be found to fit the data is \( \Gamma_2 \) for both the V1 and V2 sites. The corresponding BV are given in table 1 and details of these refinements in table 2. The refinement yields a magnetic structure shown in figure 3 with a total moment of 0.23(2) \( \mu_B \) on the V1 sites and 0.22(1) \( \mu_B \) on the V2 sites. The V2 moments are canted outwards from the V₄ cluster, as seen in figure 3 with total moment of the cluster being 0.88(5) \( \mu_B/V_4 \). The magnetic structure is in agreement with our previous neutron diffraction results [4] although the data presented in this paper show an equal moment distributed across all of the V atoms and have allowed us to determine a canting of the moments on the V2 sites of 39(8)°, indicating that the low-temperature magnetic phase identified in the ac susceptibility measurements is not fully collinear. In a recent SANS study, Dally et al suggested that the moments are constrained to point along the magnetic easy axis (the c axis in the hexagonal setting of the R₃m space group) at 3 K [12]. Constraining the refinement of our data in this way...
leads to nearly identical simulated pattern and $R$ factor, (see table 2) but with a moment of $0.382(13) \mu_B$ on the V1 sites and $0.117(12) \mu_B$ on the V2 sites, hence to a total moment per cluster of $0.73(4) \mu_B/V_6$. The unconstrained fit at 1.5 K gives better agreement with our previous magnetisation results [4] along with the magnitude of ordered moment per cluster calculated by Dally et al [12]. The slight difference of magnetic structure determined from our measurements and those of Dally et al can be attributed to how similar the diffraction patterns of the canted and collinear state are, making it difficult to distinguish between them. It is worth noting that our observed pattern could not be fitted with a moment only residing on a single atom.

These zero-field measurements show a canting of the V2 spins away from the hexagonal $c$ axis, which is along the pseudo-cubic [111] direction. This is consistent with the $ac$ susceptibility measurements that show the application of a $dc$ magnetic field along this [111] direction leads to a change in orientation of the magnetic moments from the canted to a collinear ferromagnetic structure as the field is increased. The peak in $\chi'$ suggests this reorientation occurs at a well-defined field (a phase boundary) rather than via a more gradual rotation of the magnetic moments.

3.3. Powder neutron diffraction at 9 K: incommensurate structure

Measurements carried out at 9 K within the incommensurate phase identified by SANS [3, 11] (spanning from approximately 6 to 13 K) are shown in figure 4. The magnetic Bragg peaks in the magnetic difference pattern can be seen to have broadened relative to 1.5 K, which highlights the incommensurate nature of the magnetism at 9 K. Without previous knowledge of the form of magnetic structure, Occam’s razor might be used to argue that the propagation vector would be along a primary crystallographic direction or the magnetic easy axis. Refinements show that a solution using the $k = 0K$ propagation vector with BV 001 (table 1), to be significantly better than any allowed $k = 00L$ refinement. Due to symmetry the $k = 0K$ propagation vector will give the same results as the $h = H00$ propagation vector therefore only $k = 0K$ is examined. The $k = 0K$ refinement shown in figure 4 also gives a visibly better fit than the $k = 00L$ solution. However, the $k = 0K$ refinement provides a solution that is a modulated sinusoidal wave propagating along the $k = 0K$ direction with the magnetic moments aligned with the $c$ axis but a larger moment on the V1 site compared to the V2 sites. The magnetic modulation length is slightly longer from the refinement compared to the value from SANS but due to the limitations of powder neutron diffraction for resolving magnetic structures with large length scales, this value seems reasonable [3]. The symmetry of this propagation vector precludes the possibility of cycloidal winding, going against existing evidence from measurements such as SANS [3, 11].

SANS results by White et al [11] show the presence of a cycloidal winding (region C in figure 2) and they determine the magnetic propagation vector to be perpendicular to the hexagonal $c$ axis with no preferential direction in the plane. As the propagation direction is ill defined but in the $ab$ plane, BASIREPS can be used to find a suitable IR and BV (table 1) for an arbitrary in-plane propagation vector $k_{ip}$. Using BV2 and BV3 with one real and one imaginary, a cycloidal magnetic structure can be created. From the literature [11] we know there is a cycloidal magnetic winding in the plane of the propagation vector and the $c$ axis, therefore only solutions with this form of winding will be examined. This yields two possible refinements, one with the moments on the distinct V Wyckoff sites being the same, and one where each type of site is refined separately and will be referred to as $k_{ip-c}$ and $k_{ip}$ respectively. Both solutions give similar refinements, with the major difference being the size of the magnetic moment. $k_{ip-c}$ gives a good agreement with the commensurate state which indicated an approximately equal moment on each V site.

4. Summary and conclusions

Using a detailed analysis of powder neutron diffraction data, combined with evidence from $ac$ susceptibility in the temperature region of interest, we have been able to establish that in low magnetic fields, a commensurate spin structure exists at 1.5 K with a canting of the magnetic spins as well as confirming a cycloidal magnetic structure at 9 K.
At 1.5 K the magnetic structure determined is shown to be in agreement with our previous studies [4]. Taking into account the reported density functional theory calculations [10, 12], results from our magnetisation measurements [4], and the presence of a phase transition in the ac susceptibility, the evidence supports a magnetic structure where the magnetic moments are, within error, spread equally across the V₄ cluster with a canting of the V₂ spins.

In treating the incommensurate structure at 9 K, numerous models that differ only slightly in terms of the quality of the refinements, appear to be possible solutions. The simplest solution suggests a sinusoidal magnetic structure with spin modulation along the \( k = 0 \) direction. However, this is inconsistent with previous SANS measurements of GaV₄S₈ which show a cycloidal magnetic structure propagating in the \( ab \) plane while the moments can rotate between the c axis and the propagation direction. We have used this information to constrain the possible propagation directions in the \( R3m \) phase for our refinements. Fits then give a value for the modulation length close to that of SANS and two reasonable magnetic structures with the moments either the same on both the V₁ and V₂ sites, or varying by a factor of \( \sim 3.5 \).

This study highlights the need for further investigations, using techniques such as small angle neutron diffraction of materials that have the potential to host skyrmions which have been reported as having a sinusoidal modulating spin structures. If, instead, the magnetic order in such materials show cycloidal winding this would leave open the possibility that these materials could be potential skyrmion hosts.
