(Dated: February 3, 2023)

We study the nonlinear magnon spin current induced by an ac electric field under light irradiation in collinear antiferromagnets with broken inversion symmetry. For linearly polarized light, we find that a dc spin current appears through “the magnon spin shift current” mechanism, which is driven by a spin polarization generation in the two magnon creation process and has a close relationship to the geometry of magnon bands through Berry connection. For circularly polarized light, a dc spin current appears through “the spin injection current” mechanism, which is proportional to the relaxation time of magnons and can be large when the magnon lifetime is long. We demonstrate the generation of the magnon spin shift and injection currents, based on a few toy models and a realistic model for a multiferroic material $M_2\text{Mo}_5\text{O}_{8}$.

I. INTRODUCTION

Spin transport plays a central role in researches of spintronics [1, 2]. In particular, the magnon transport is attracting keen attention since magnons have a long lifetime and are able to transfer energy and spin angular momentum without Joule heating. Utilizing these advantages of magnons led to a research field of magnon spintronics [3]. Typical methods to create magnons in spin systems include spin pumping with an application of a microwave [4, 5] and thermal responses by the application of a temperature gradient [6–21]. Among the thermal responses of magnons, the thermal Hall responses are closely related to the geometry of the magnon band. For example, the Berry curvature of the magnon bands induces the thermal Hall effect and the spin Nernst effect [22, 23], and the Berry curvature dipole of the magnon bands leads to the nonlinear spin Nernst effect [24].

Besides the spin pumping and thermal responses, it has been proposed that photoirradiation generates magnon spin current through a nonlinear response [25–30]. Such nonlinear magnon spin current is analogous to a nonlinear current response of electrons to an external electric field. Electron systems with broken inversion symmetry exhibit photovoltaic effects, such as shift current [31–33] and injection current [32, 34–37]. In particular, shift current is governed by a geometric quantity called the shift vector which quantifies the shift of the Bloch wave packet in optical transition. Similarly, in spin systems, the application of gigahertz (GHz) or terahertz (THz) laser light can create magnons and leads to magnon spin currents. The application of circularly polarization light generates magnon excitations through injection of angular momentum to spin systems [25]. Furthermore, the linearly polarized light is predicted to generate the magnon spin current even without angular-momentum transfer [29, 30]. Generation of those magnon spin currents relies on a coupling of spins to the magnetic field component of light, because magnons are charge neutral and their coupling to the electric field is not considered usually. Since the magnetic field of light is small, large spin current responses through the above mechanisms require high intensity of light.

Spin systems with a broken inversion symmetry generally support electrical polarization, exhibiting a multiferroic nature [38–39]. As a consequence, an electric field can directly couple with spins and generate magnetic excitations. For example, nonlinear responses to the electric field were studied using the spinon description for 1D systems, which includes dc spin current generation [40, 41] and high harmonic generations [42, 43]. In higher dimensions, the low-energy excitations of the ordered magnets are usually magnons, and the magnons in multiferroic materials accompany electric polarization, known as electromagnons [44–46]. In particular, electromagnons can be optically excited through their coupling to the electric field, leading to optical magnetoelectric effects, such as directional dichroism [46–48], and can be potentially applied for electric field control of magnetic order [49, 50]. Recently, the application of circularly polarized light was predicted to generate spin current via a two magnon Raman process with the coupling to the electric field [51]. Also, it was predicted that optical excitation of electromagnons supports the electric current generation through the shift current mechanism [52]. Yet, the magnon transport induced by the electric field has not been fully explored. In particular, the relationship between the nontrivial geometry of magnon bands and nonlinear magnon current responses is still unclear.

In this paper, we study the magnon spin current induced by the electric field in collinear antiferromagnets with broken inversion symmetry. Here, we focus on the dc spin current responses, and we derive the formula for the magnon spin current induced by the linearly and circularly polarized lights, using the Holstein-Primakoff transformation and the resulting magnon Hamiltonian. For linearly polarized light, we find that a dc spin current appears through “the magnon spin shift current” mechanism. The magnon spin shift current can be described by a geometric quantity called the shift vector of the magnon band which represents the positional shift of magnons. In addition to the shift of magnons of the same spin in the usual interband transitions, the shift vector of magnons also incorporates the positional shift between the up-spin magnon and the down-spin magnon associated with the 2-magnon excitation, which is schemati-
In this section, we derive the formulas of the dc magnon spin current induced by an external ac electric field. We first summarize notations and then derive the nonlinear magnon spin current conductivity for collinear magnets from a standard perturbation theory. Under the effective time-reversal symmetry (TRS), we obtain a concise expression for the magnon spin shift current conductivity for collinear magnets described by the spin Hamiltonian

\[ H_S = \sum_{i,j} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j + \sum_i \Delta_i (S_i^z)^2, \]

where \( \mathbf{S}_i \) is a spin operator at the \( i \)th site. We note that our theory is also applicable to more general Hamiltonians, such as the XXZ model. Hereafter, we take the z-axis parallel to the spin direction. The low-energy excitations of the ordered magnets are usually magnons, thus we consider magnons via the Holstein Primakoff transformation.

\[
\begin{cases}
S_i^+ \simeq \hbar \sqrt{2} S a_i, & S_i^- \simeq \hbar \sqrt{2} S a_i^\dagger, \quad S_i^z = \hbar (S - a_i^\dagger a_i) \\
S_i^+ \simeq \hbar \sqrt{2} S b_i, & S_i^- \simeq \hbar \sqrt{2} S b_i, \quad S_i^z = \hbar (-S + b_i^\dagger b_i)
\end{cases}
\]

where \( S \) is a spin of \( S_i \), and \( a_i^\dagger \) and \( b_i^\dagger \) are creation operators of the magnon of the \( i \)th site. Hereafter, we set \( \hbar = 1 \). By using the Holstein Primakoff transformation, we obtain the magnon Hamiltonian

\[ \hat{H} = \sum_{R, R'} \Psi_R^\dagger H_{RR'} \Psi_{R'}, \]

Here \( \Psi_R = (a_{R_1}^\dagger \cdots a_{R_N}^\dagger, b_{R_1}^\dagger \cdots b_{R_N}^\dagger) \) and \( R \) is a position of the unit cell. \( a_{R}^\dagger \) and \( b_{R}^\dagger \) are creation operators of the magnon of the \( i \)th site of the unit cell at \( R \), and \( R_i = R + r_i \) denotes the position of the \( i \)th site in the unit cell at \( R \). The magnon Hamiltonian in the momentum space is

\[ \hat{H} = \sum_k \Psi_k^\dagger H_k \Psi_k, \]

where \( \Psi_k = (a_{k}^\dagger \cdots a_{Nk}^\dagger, b_{-k}^\dagger \cdots b_{-Mk}) \). Here,
\[
\begin{align*}
\Psi_k^\dagger &= \frac{1}{\sqrt{N}} \sum_R \Psi_R^\dagger e^{ik \cdot (R + r_i)} \text{ and } \Psi_k &= \frac{1}{\sqrt{M}} \sum_R \Psi_R^\dagger e^{ik \cdot (R + r_i)}
\end{align*}
\]

and \( N \) is the total number of unit cells.

We can diagonalize the Hamiltonian by the paramutary matrix \( V_k \), which satisfies \( V_k^\dagger B V_k = B \). Here, \( B \) is a diagonal matrix

\[ B = \text{diag}(\eta_a), \]

where \( \eta_a = 1 \) if \( (\Psi_k^\dagger)_a \) is a creation operator and \( \eta_a = -1 \) if \( (\Psi_k^\dagger)_a \) is a annihilation operator. Thus \( B \) satisfies \( (B)_{ab} = [(\Psi_k^\dagger)_a, (\Psi_k^\dagger)_b] \) and we obtain

\[
\hat{H} = \sum_k \Psi_k^\dagger E_k V_k^{-1} \Psi_k
\]

\[ = \sum_k \Phi_k^\dagger E_k \Phi_k, \]

where

\[ \Phi_k = \frac{1}{\sqrt{M}} \sum_R \Psi_R^\dagger e^{ik \cdot R} \]

is the eigenvector of the Hamiltonian. The magnon spin current conductivity numerically based on a few toy models and realistic models for multiferroics.
Here, $E_k$ is diagonal matrix
\[ E_k = V_k^\dagger H_k V_k \]  
(7)
and $\Phi_k$ is a transformed operator
\[ \Phi_k = V_k^{-1}\Psi_k, \]
(8)
and $\Phi_k$ satisfies a commutation relation $[(\Phi_k)_a, (\Phi_k)_b] = (B)_{ab}$. Matrix elements of $E_k$ are positive when the ground state is stable, and matrix elements of $E_k$ have physical meaning as the excitation energies of magnons.

Here, we consider the distribution function
\[ \rho_{ka} = \langle \Phi_k^\dagger \Phi_{ka} \rangle, \]
(9)
where $\langle O \rangle$ is the expectation value of $O$ in the equilibrium state. Since $\Phi_k$ is the basis of the diagonalized form of the Hamiltonian, we obtain
\[
\begin{cases}
\rho_{ka} = 1/(\exp\{\beta(E_{ka})_{aa}\} - 1) & \text{for } [(\Phi_k)_a, (\Phi_k)_a] = 1 \\
\rho_{ka} = -1/(\exp\{-\beta(E_{ka})_{aa}\} - 1) & \text{for } [(\Phi_k)_a, (\Phi_k)_a] = -1
\end{cases}
\]
To simplify $\rho_{ka}$, we introduce $\epsilon_k$
\[
\epsilon_k = BE_k = BV_k^\dagger H_k V_k = V_k^{-1}BH_k V_k, \]
(11)
and we can write $\rho_{ka} = B_{aa}/(\exp\{\beta(\epsilon_{ka})\} - 1)$

Now, we consider the general operator
\[ \hat{O} = \sum_k \Psi_k^\dagger O_k \Psi_k \]
\[ = \sum_k \Phi_k^\dagger B\hat{O}_k \Phi_k, \]
(12)
where we define
\[ \hat{O}_k \equiv V_k^{-1}BO_k V_k. \]
(13)
Here, we note that $\hat{O}_k$ is generally non-Hermitian matrix. However, matrix elements of $\hat{O}_k$ satisfies
\[ (\hat{O}_k)_{ab} = B_{aa}B_{bb}(\hat{O}_k)_{ba}^\dagger. \]
(14)

### B. Polarization and spin current

Based on the above conventions, let us study the nonlinear spin current induced by an external light field. The electric field $E$ creates magnon excitations via the coupling to the electric polarization in magnetic systems. The total Hamiltonian in the presence of the external electric field can be written as
\[ \hat{H}_{tot} = \hat{H} - E \cdot \hat{P}, \]
(15)
where $\hat{P}$ is the polarization operator
\[
\hat{P} = -\sum_k \Psi_k^\dagger \Pi_k \Psi_k. \]
(16)
Thus the spin current $J$ defined via the continuity equation $-\nabla J = \partial_i S^z = -i[S^z, \hat{H}]$ is expressed as
\[
\hat{J}^\mu = \sum_k \Psi_k^\dagger \frac{\partial H_k}{\partial \mu} \Psi_k + \sum_k \Psi_k^\dagger \frac{\partial \Pi_k}{\partial k^\mu} \cdot E \Psi_k \\
= \hat{J}_1^\mu + \sum_\alpha \hat{J}_2^{\alpha 1} E_\alpha. \]
(17)
Here, we decompose $\hat{J}_1^\mu$ into $\hat{J}_1^\mu$ and $\hat{J}_2^{\alpha 1}$. $\hat{J}_1^\mu$ is a term consisting of the $k$-derivative of $\hat{H}_k$ and $\hat{J}_2^{\alpha 1}$ is a term consisting of the $k$-derivative of external field $E \cdot \Pi_k$. The nonlinear magnon spin current response $J^{\mu(2)}$ can be written as
\[
\langle J^{\mu(2)}(\omega) \rangle = \sigma^{\mu,\alpha\beta}(\omega, \omega_1, \omega_2)E_\alpha(\omega_1)E_\beta(\omega_2), \]
(18)
By using the Green function formalism (for details, see Appendix A), we obtain the nonlinear magnon spin conductivity $\sigma^{\mu,\alpha\beta}(0, \omega, -\omega)$ as
\[
\sigma^{\mu,\alpha\beta}(0, \omega, -\omega) = \\
-\int \frac{dk}{(2\pi)^d} \left[ \sum_{a,b} J_{2ab} \Pi_{ba} \frac{f_{ab}}{\epsilon_{ab} + \omega + i\delta} + \sum_{a,b,c} J_{1abc} \Pi_{ac} \Pi_{cb} \frac{f_{ab}}{\epsilon_{ab} + \omega + i\delta} + \frac{f_{ab}}{\epsilon_{bc} - \omega + i\delta} \right] \uparrow (\alpha, \omega \leftrightarrow \beta, -\omega). \]
(19)
Here, $\epsilon_{ab} = \epsilon_{ka} - \epsilon_{kb}$ is the difference of the band dispersion and $f_{ab} = f(\epsilon_{ka}) - f(\epsilon_{kb})$, where $f(\epsilon_{ka}) = (\exp\{\beta\epsilon_{ka}\} - 1)^{-1} = B_{aa}\rho_{ka}$. In the low temperature limit, we obtain $\rho_{ka} = 0$ when $\epsilon_{ka}$ is positive and $\rho_{ka} = 1$ when $\epsilon_{ka}$ is negative. Here we note that we use $\epsilon_{ka}$ instead of using the excitation energy $E_k = B\epsilon_k$. Thus we
have a formulation which counts states with $\varepsilon_{ka} < 0$ by "negative counts" via $f(\varepsilon_{ka}) = B_{aa} \rho_{ka}$. The last term of (19) diverges as $\propto 1/\delta$ when $a = c$ and is analog of the magnon spin injection current.

C. Magnon spin shift current

Now, we consider the shift current

$$J_{\text{shift}}^\mu(\omega) = \sigma_{\text{shift}}^{\mu,\alpha\alpha}(0, \omega, -\omega) E_{\alpha}(\omega) E_{\alpha}(-\omega), \quad (20)$$

under the effective TRS: $H_k = H^*_{-k}$ and $\Pi_k^\alpha = (\Pi_{-k})^\alpha$. From the effective TRS, matrix elements satisfy

$$J_{1k}^\mu = -(\tilde{J}_{1-k}^\mu)^*, \quad (21a)$$

$$J_{2k}^\mu = -(\tilde{J}_{2-k}^\mu)^*, \quad (21b)$$

$$\varepsilon_{ka} = \varepsilon_{-ka}. \quad (21c)$$

Using Eqs. (21) and the relation $1/\pi + \pi = \mathbb{P} \frac{1}{x} - i \pi \delta(x)$ with $\mathbb{P}$ representing the principal value, terms containing principal value are odd in $k$ and vanish. Thus we obtain

$$\sigma_{\text{shift}}^{\mu,\alpha\alpha}(0, \omega, -\omega) =$$

$$-\pi \int \frac{dk}{(2\pi)^d} \sum_{ab} \text{Im}[\tilde{J}_{ab}^{\mu,\alpha\alpha} \tilde{\Pi}_{ba}^{\alpha}] f_{ab}(\varepsilon_{ab} - \omega)$$

$$+ \sum_{a,b,c} \text{Im}[\tilde{J}_{ac}^{\mu,\alpha\alpha} \tilde{\Pi}_{cb}^{\alpha} \tilde{\Pi}_{ba}^{\alpha}] (f_{ab}(\varepsilon_{ab} + \omega) + f_{ab}(\varepsilon_{bc} - \omega))$$

$$+ (\omega \leftrightarrow -\omega). \quad (22)$$

The last term vanishes when $a = c$ under the effective TRS, and we can remove $2i\delta$ in the denominator of the last term. By using Eq. (19), Eq. (22) can be written as

$$\sigma_{\text{shift}}^{\mu,\alpha\alpha}(0, \omega, -\omega) =$$

$$-2\pi \int \frac{dk}{(2\pi)^d} \sum_{ab} \text{Im}[\tilde{J}_{ab}^{\mu,\alpha\alpha} \tilde{\Pi}_{ba}^{\alpha}] f_{ab}(\varepsilon_{ab} - \omega)$$

$$+ \sum_{a,b,c} \text{Im}[\tilde{J}_{ac}^{\mu,\alpha\alpha} \tilde{\Pi}_{cb}^{\alpha} \tilde{\Pi}_{ba}^{\alpha}] \frac{f_{ab}(\delta(\varepsilon_{ab} + \omega) + \delta(\varepsilon_{ab} - \omega))}{\varepsilon_{ac} + 2i\delta}. \quad (23)$$

Furthermore, we can rewrite $\tilde{J}_{1k}^\mu$ and $\tilde{J}_{2k}^\mu$ by using the expression for the gauge covariant derivative,

$$\frac{\partial \tilde{O}_k}{\partial k_\mu} = V_k^{-1}_\alpha B_{ka} \frac{\partial \tilde{O}_k}{\partial k_\alpha} V_k$$

$$= \frac{\partial \tilde{O}_k}{\partial k_\mu} - \tilde{O}_k V_k^{-1} \frac{\partial V_k}{\partial k_\mu} - \frac{\partial V_k^{-1}}{\partial k_\mu} V_k \tilde{O}_k$$

$$= \frac{\partial \tilde{O}_k}{\partial k_\mu} - [i A_k^\mu, \tilde{O}_k], \quad (24)$$

where $A_k^\mu = i V_k^{-1}_\alpha \frac{\partial V_k}{\partial k_\alpha}$ is a Berry connection. By using Eq. (24) for $H_k$ and $\Pi_k$, we can rewrite Eq. (23) as

$$\sigma_{\text{shift}}^{\mu,\alpha\alpha}(0, \omega, -\omega) =$$

$$-2\pi \int \frac{dk}{(2\pi)^d} \sum_{ab} \text{Im}\left[\tilde{\Pi}_{ab}^{\alpha}(\partial_{k_\mu} \ln \tilde{\Pi}_{ab}^{\alpha}) + i(\tilde{A}_{ab}^{\mu} - A_{ab}^{\mu}) \right]$$

$$+ \text{Im}\left[\sum_{c \neq a} i(\tilde{A}_{ac}^{\mu} \tilde{\Pi}_{cb}^{\alpha} - \tilde{A}_{ac}^{\mu} \tilde{\Pi}_{cb}^{\alpha}) \right] f_{ab}(\varepsilon_{ab} - \omega)$$

$$= -2\pi \int \frac{dk}{(2\pi)^d} \sum_{a,b} \left|\tilde{\Pi}_{ab}^{\alpha}\right|^2 R^{\mu} f_{ab}(\varepsilon_{ab} - \omega). \quad (25)$$

Here, $R^{\mu} = \text{Im}[\partial_{k_\mu} \ln \tilde{\Pi}_{ab}^{\alpha} - i(\tilde{A}_{ab}^{\mu} - A_{ab}^{\mu})]$, which can be regarded as an analog of a shift vector that appears in the expression for electronic shift current in semiconductors [32]. This magnon shift vector contains the difference of Berry connections of two magnon bands involved in the optical transition and is a gauge invariant quantity as a whole, which effectively measures the spin polarization induced by the two optically created magnons.

D. Magnon spin injection current under the circular polarization light

Now, we consider the injection current by focusing on the $a = c$ term in Eq. (19). For linearly polarized light, this term vanishes under the effective TRS as seen in Sec. III C. Thus we consider the circularly polarized light $E(\omega) = E_\gamma(\omega)\hat{\alpha} + i E_\delta(\omega)\hat{\beta}$ as the external field to break the effective TRS. Here, $\hat{\alpha}$ ($\hat{\beta}$) is a unit vector of direction $\alpha$ ($\beta$). The injection current can be described by the
conductivity $\sigma_{inj}^{\mu,\alpha\beta}$, which is defined by
\[
J_{inj}^{\mu} = \sigma_{inj}^{\mu,\alpha\beta} E_\alpha(\omega) E_\beta(-\omega),
\] (26)

Since we consider the circularly polarized light, the $a = c$ term in Eq. (19) is given by
\[
\sigma_{inj}^{\mu,\alpha\beta}(0,\omega, -\omega) = -2i \int \frac{dk}{(2\pi)^d} \sum_{b,a=c} \frac{\bar{\tilde{\Pi}}^\alpha_{ba} \bar{\tilde{\Pi}}^\beta_{ba}}{\varepsilon_{ac} + 2i\delta} \frac{f_{ab}}{\varepsilon_{ab} + \omega + i\delta} 
+ \frac{f_{cb}}{\varepsilon_{bc} - \omega + i\delta} \bigg) + (\alpha, \omega \leftrightarrow \beta, -\omega) 
\times \left( \frac{1}{\varepsilon_{ab} + \omega + i\delta} - \frac{1}{\varepsilon_{ab} + \omega - i\delta} \right) + (\alpha, \omega \leftrightarrow \beta, -\omega).
\] (27)

With the relation $\frac{1}{x+i\delta} = \mathcal{P} \frac{1}{x} - i\pi \delta(x)$, only resonant terms containing the delta function becomes nonzero and we obtain
\[
\sigma_{inj}^{\mu,\alpha\beta}(0,\omega, -\omega) = -4\pi \int \frac{dk}{(2\pi)^d} \sum_{a,b} \frac{\bar{\tilde{\Pi}}^\alpha_{ba} \bar{\tilde{\Pi}}^\beta_{ba}}{2i\delta} 
\times f_{ab} \delta(\varepsilon_{ab} + \omega) + (\alpha, \omega \leftrightarrow \beta, -\omega) 
= -2\pi \tau \int \frac{dk}{(2\pi)^d} \sum_{a,b} (\bar{\tilde{\Pi}}^\alpha_{ba} - \bar{\tilde{\Pi}}^\beta_{ba}) 
\times \text{Im} \left[ \bar{\tilde{\Pi}}^\alpha_{ba} \bar{\tilde{\Pi}}^\beta_{ba} \right] f_{ab} \delta(\varepsilon_{ab} + \omega). \quad (27)
\]

Here, we introduce the relaxation time $\tau = 1/\delta$. This expression is analogous to that for the injection current in the electronic system. We note that, in the electronic case, the above expression had a geometrical meaning in the two band limit in that the term $\text{Im} \left[ \bar{\tilde{\Pi}}^\alpha_{ba} \bar{\tilde{\Pi}}^\beta_{ba} \right]$ reduces to the Berry curvature of the electronic bands. In the present case, the polarization operator $\mathbf{P}$ is not necessarily proportional to the position operator $\mathbf{r}$ and the term $\text{Im} \left[ \bar{\tilde{\Pi}}^\alpha_{ba} \bar{\tilde{\Pi}}^\beta_{ba} \right]$ does not have a direct relationship to the Berry curvature of magnon bands.

III. 2D MODEL

To demonstrate the magnon spin shift current and injection current, we consider an inversion-broken 2D model on a square lattice obtained as an extension of the Rice-Mele Hubbard model into the two dimensions. Specifically, we introduce a staggered potential and staggered hopping on the square-lattice Hubbard model, which leads to the broken inversion symmetry and nonvanishing polarization.

![Diagram of the Heisenberg model with alternating exchange interaction](image)

**A. Definition of the model**

First, we consider the inversion broken Hubbard model on the square lattice defined by
\[
\hat{H}_0 = \sum_{i_x,i_y,s} \left[ \{ t_x + (-1)^{i_x+i_y} \delta t_x \} c_{i_x+1,i_y,s}^\dagger c_{i_x,i_y,s} + h.c. 
+ \{ t_y + (-1)^{i_x+i_y} \delta t_y \} c_{i_x,i_y+1,s}^\dagger c_{i_x,i_y,s} + h.c. 
+ (-1)^{i_x+i_y} m c_{i_x,i_y,s}^\dagger c_{i_x,i_y,s} \right] 
+ U \sum_{i_x,i_y} n_{i_x,i_y,\uparrow} n_{i_x,i_y,\downarrow}, \quad (28)
\]

where $c_{i_x,i_y,s}$ is an annihilation operator of the electrons at $(i_x,i_y)$th site and spin $s = \uparrow, \downarrow$, and $n_{i_x,i_y,s} = c_{i_x,i_y,s}^\dagger c_{i_x,i_y,s}$ is a density operator. $t_x$ ($t_y$) is the over-all hopping strength for $x$ ($y$) direction, $\delta t_x$ ($\delta t_y$) is the hopping alternation for $x$ ($y$) direction, $m$ is a staggered potential, and $U$ is an onsite Coulomb potential. For sufficiently large $U$, the ground state is in the Mott-insulating phase, and we can derive effective spin model. Figure 2 shows the schematic picture of the spin model.

Now, we apply the electric field $\mathbf{E}$ and consider the strong coupling expansion. Hereafter, we set electric charge $e$ as $e = 1$. The electric field plays a role of a site-dependent onsite potential, and we obtain the ef-
effective spin model as shown in Fig. 2(a) as
\[ H_S = \sum_{i_x,i_y} \left[ J_{x,i} S_{i_x+1,i_y} \cdot S_{i_x,i_y} + J_{y,i} S_{i_x,i_y+1} \cdot S_{i_x,i_y} \right] + \sum_{i_x,i_y} \left[ E_x \Pi_x,i S_{i_x+1,i_y} \cdot S_{i_x,i_y} + E_y \Pi_y,i S_{i_x,i_y+1} \cdot S_{i_x,i_y} \right] + O(E^2), \] (29)

where \( i \) is a simplified notation of \((i_x, i_y)\) and
\[ J_{\alpha,i} = 2(t_{\alpha} + (-1)^{i_x+i_y} \delta t_{\alpha})^2 \left( \frac{1}{U-2m} + \frac{1}{U+2m} \right), \] (30a)
\[ \Pi_{\alpha,i} = 2a_{\alpha} (t_{\alpha} + (-1)^{i_x+i_y} \delta t_{\alpha})^2 \times \left( \frac{(-1)^{i_x+i_y}}{(U-2m)^2} + \frac{(-1)^{i_x+i_y}}{(U+2m)^2} \right). \] (30b)

Here, \( \alpha \) denotes the direction \( x \) or \( y \), and \( a_{\alpha} \) is a lattice constant. For simplification of notation, we introduce \( J_{\alpha} = (J_{\alpha,o} + J_{\alpha,e})/2, \delta J_{\alpha} = (J_{\alpha,o} - J_{\alpha,e})/2, \) and \( \delta \Pi = (\Pi_{\alpha,o} - \Pi_{\alpha,e})/2 \). Here \( J_{\alpha,e} \) (\( J_{\alpha,o} \)) denotes \( J_{\alpha,i} \) where \( i_x + i_y \) is even (odd).

Now, we assume \((S_x^x) = S \) for even sites and \((S_x^x) = -S \) for odd sites, and apply Holstein-Primakoff transformation \( \hat{S}_{\alpha} \) to obtain the magnon Hamiltonian
\[ H_k = 2S \left( \gamma_x(k_x) + \gamma_y(k_y) \right). \] (31)
Here, \( \gamma_x(k_x) = J_x \cos(k_xa_x) - i\delta J_x \sin(k_xa_x) \) and \( \gamma_y(k_y) = J_y \cos(k_ya_y) - i\delta J_y \sin(k_ya_y) \). The polarization is given by
\[ \Pi_k = 2S \left( \eta_x(k_x) + \eta_y(k_y) \right). \] (32)
Here, \( \eta_x(k_x) = \Pi_x \cos(k_xa_x) - i\delta \Pi_x \sin(k_xa_x) \) and \( \eta_y(k_y) = \Pi_y \cos(k_ya_y) - i\delta \Pi_y \sin(k_ya_y) \). By diagonalizing the Hamiltonian \( (31) \), we obtain the energy dispersion
\[ E_k = 2S \sqrt{(J_x + J_y)^2 - |\gamma_x(k_x) + \gamma_y(k_y)|^2}. \]

**B. Photoinduced spin current**

Next, we study the photoinduced spin current of the shift and injection origins in this model. Since the spin shift current appears along the polar direction with the linearly polarized light, we consider the 1D limit of the above model as a minimum setup for spin shift current, for simplicity. In the presence of effective TRS, the spin injection current appears with the circularly polarized light and requires the 2D nature of the model. Therefore, we treat the full 2D model to demonstrate the spin injection current.

**1. Spin shift current in the 1D limit**

Now, we consider the magnon spin shift conductivity \( \sigma_{x,xx}^{\text{shift}}(0,\omega,\omega) \). In this section, for simplicity, we consider the 1D limit, namely the case where \( J_y \) and \( \delta J_y \) are weak as shown in Fig. 2(b). We show the magnon dispersion and magnon spin shift conductivity in Fig. 3. In the 1D limit, the excitation energy of magnons is
\[ E_k = 2S \sqrt{J_x^2 - \delta J_x^2} \sin |k_xa_x| \] as shown in Fig. 3(a), and we can derive the analytical expression as
\[ \sigma_{x,xx}^{\text{shift}}(0,\omega,\omega) = \frac{-\delta J (J \delta \Pi - \delta J \Pi)^2 \omega}{2S a_x (J^2 - \delta J^2)^2 \sqrt{4(J^2 - \delta J^2) - (\omega/2S)^2}}. \] (33)

From this analytical expression, \( \sigma_{x,xx}^{\text{shift}}(0,\omega,\omega) \) has a peak around the resonant frequency \( \omega = 4S \sqrt{J^2 - \delta J^2} \sin |k_xa_x| \) which is associated with two-magnon excitations around \( k_x = \pi/2a_x \). Around \( k_x = \pi/2a_x \), the magnon dispersion has a
maximum value and the density of states of magnons is large.

We show $\sigma_{\text{shift}}^{x,x}(0, \omega, -\omega)$ in Fig. 3(b) with various damping $\delta$. For a large $\delta$ ($\delta = 0.1J$), the peak is broadened. However, $\sigma_{\text{shift}}^{x,x}(0, \omega, -\omega)$ does not show much dependence on $\delta$ in the region where $\omega$ is small ($\omega/2SJ < 1.5$). In particular, when the damping $\delta$ is smaller than 0.01, $\sigma_{\text{shift}}^{x,x}(0, \omega, -\omega)$ is almost independent of $\delta$ except for $\omega/2SJ \sim 2$. Thus $\sigma_{\text{shift}}^{x,x}(0, \omega, -\omega)$ is a shift current that is not dependent on the damping $\delta$.

The origin of the shift current is a broken inversion symmetry. Indeed, the analytical expression (33) shows a tribute to the spin current.

magnons accompany nonzero polarization and excited by the light, and the shift of the magnon wave packet contribute to the spin current.

2. Magnon spin injection current

Now, we consider the magnon spin injection current induced by the circular polarization light in 2D model depicted in Fig. 2(a). Figure 4 shows the magnon dispersion and the magnon spin injection current. We show the 2D model in the reciprocal space in Fig. 4(a). For simplicity, we assume that $J_x = J_y$ and $\delta J_x = \delta J_y$. Thus the magnon dispersion has maximum points $E_k = 4SJ \kappa_x$ at $(k_x, a_x, k_y, a_y) = (\pm \pi, 0), (0, \pm \pi)$ as shown in Fig. 4(b). Around the $X'$ point, a saddle point exists. Figure 4(c) shows the frequency and $\delta$ dependence of the magnon spin injection conductivity divided by $\tau$ $\sigma_{\text{inj}}^{x,x}(0, \omega, -\omega)/\tau$. As with the magnon spin shift current, $\sigma_{\text{inj}}^{x,x}(0, \omega, -\omega)/\tau$ has a peak around the resonant frequency $\omega = 4SJ$ and does not depend on $\delta$ except around the peak. However, the magnon relaxation time $\tau = 1/\delta$ depends on $\delta$ and $\sigma_{\text{inj}}^{x,x}(0, \omega, -\omega)$ is proportional to $\tau = 1/\delta$. Thus, when the magnon relaxation time is long, $\sigma_{\text{inj}}^{x,x}(0, \omega, -\omega)$ can be large and becomes the dominant contribution for the photoinduced spin current. We estimate the order of the magnon spin injection current in Sec. V.

IV. MAGNON SPIN SHIFT CURRENT IN M₂M₀₃O₈

In this section, we consider $M₂M₀₃O₈ (M$: 3d transition metal) as a candidate system for the photoinduced spin current since $M₂M₀₃O₈$ exhibits a collinear magnetic order and an electric polarization. The crystal structure of $M₂M₀₃O₈$ is composed of the alternative stacking of the $M$ layer and Mo layer. Due to the trimerization of the Mo ions, the Mo ions are nonmagnetic, while $M$ ions have magnetic moments. In the magnetic $M$ layer, $M$ ions compose a honeycomb lattice and have two types of distinct coordination, denoted as $A$ and $B$ sites with tetrahedral and octahedral coordination of oxygen atoms, respectively. We show a schematic spin structure of $M₂M₀₃O₈$, magnon dispersion, and the magnon spin shift conductivity in Fig. 5. The ground state of $M₂M₀₃O₈$ shows a ferrimagnetic spin structure as sketched in Fig. 5(a). The $A$ sites and $B$ sites are inequivalent and magnitudes of spins at the $A$ sites ($S_A$) and $B$ sites ($S_B$) are generally different. However, it is reported that spontaneous magnetization asymptotically decreases to zero at zero temperature. Thus, as far as we focus on spin current responses in low temperatures, we can approximately set $S_A = S_B$ as we do so in the following. Here we note that even if $S_A \neq S_B$, the formula (25) for spin shift current in terms of the magnon shift vector is still valid since the spin current operator is expressed with the $k$ derivative of the Hamiltonian as in Eq. (17) in the case of collinear ferrimagnets with antiferromagnetic orders. Furthermore, Fe₃Mo₃O₈ also has the ferrimagnetic phase as the ground state when a magnetic field $H \parallel c$ is applied or when doped with Zn. This ferrimagnetic order allows the polarization $P \parallel c$. Below, we focus on the polarization along the $c$ axis and study the magnon spin shift current induced by the linear polarized light along the $c$ axis. We note that spin injection current under the circularly polarized light requires a nonzero polarization operator along either $a$ or $b$ direction, so that the spin shift current is the only contribution to the spin current in this case.

Now, we consider the spin model of the $M₂M₀₃O₈$, following Ref. 60, as

$$H_s = \frac{1}{2} \sum_{i,j} J_{ij} S_i \cdot S_j + \Delta_A \sum_{i \in A} (S_i^z)^2 + \Delta_B \sum_{i \in B} (S_i^z)^2 .$$

(34)

Here, the bond exchange interaction $J_{ij}$ has four different nonzero values depending on the type of bonds: intralayer nearest neighbor coupling $J_1$, interlayer nearest neighbor coupling $J_2$ and $J_2'$, and interlayer nearest neighbor coupling between tetrahedrally coordinated spins $J_3$ as shown in Fig. 5(a). While parameters of $J_2 = J_2'$ are adopted in Ref. 60, the different interspin distances associated with the tetrahedral configuration either above or below the octahedral configuration can lead to $J_2 \neq J_2'$. The polarization $P_s$ can be written as

$$P_s = -\frac{1}{2} \sum_{i,j} \Pi_{ij} S_i \cdot S_j .$$

(35)

Here, the polarization $\Pi_{ij}$ has four different nonzero values depending on the type of bonds as well as $J_{ij}$.

According to the first-principles calculations in Ref. 60, we adopt the parameters $J_1 = 1$, $J_2/J_1 \sim 0.4$, $J_2'/J_1 \sim 0.3$, $J_3/J_1 \sim 0.006$, $\Delta_A/J_1 \sim -0.05$, $\Delta_B/J_1 \sim 0.008$, and $S_A = S_B = 5/2$. Here, for numerical stability,
we use the larger value of $|\Delta_A|$ than the value of $|60|$. For the electric polarization from the exchange striction mechanism, we used the parameters $\Pi_1 = 1$, $\Pi_2 = 2$, $\Pi_3 = 0.1$, and $\Pi_4 = 0.005$. These parameters are chosen so that the relative magnitude for the four type of bonds are consistent with the magnitudes of the Heisenberg couplings. Here the minus sign reflects the negative polarization of $M_2\text{Mo}_3\text{O}_8$ along the $c$ axis.

Since the unit cell of the $\text{Mn}_2\text{Mo}_3\text{O}_8$ contains 4 Mn ions, the magnon Hamiltonian of Eq. (34) is a $4 \times 4$ Hamiltonian. Thus the magnon dispersion consists of two positive energy modes and two negative energy modes. Magnon bands of the positive energy modes in the $k_z = 0$ plane are shown in Fig. 5(b). Here, we note that Mn ions compose a honeycomb lattice in $k_z = 0$ plane. We show the magnon spin dispersion $\sigma_{zz}(0, \omega, -\omega)$ in Fig. 5(c). The magnon spin shift conductivity $\sigma_{\text{shift}}(0, \omega, -\omega)$ has a broad peak structure around $\omega = 15 \sim 18 J$ where the inter-band optical transition is large. As in the 1D case in Fig. 5(c), the peak structure around $\omega \sim 18 J$ corresponds to twice the maximum value of the magnon dispersion. Furthermore, Fig. 5(c) shows a shoulder structure around $\omega \sim 15 J$ which corresponds to twice the minimum values of the top magnon band.

We note on the magnitude of $\delta$. Because of computational complexity in 3D systems, we used a relatively large value of $\delta = 0.1$. As we show in Fig. 3(c), $\sigma_{\text{shift}}(0, \omega, -\omega)$ is expected to show a qualitatively same behavior with those for smaller $\delta$, except around the peak. The peak structure is expected to be sharper for smaller $\delta$ and $\sigma_{\text{shift}}(0, \omega, -\omega)$ in the peak region becomes larger by reducing $\delta$.

V. DISCUSSION

We have derived the expression of the second order magnon spin conductivity and clarify the relationship between the magnon spin shift current and the shift vector, for collinear magnets. In noncentrosymmetric systems, the electric field can generally excite electromagnons, where photoinduced magnons exhibit a positional shift and induce spin polarization. Furthermore, we have stud-
ied the magnon spin injection current which is proportional to the relaxation time \( \tau \). Our numerical calculation demonstrates that the collinear spin systems with an electric polarization from the exchange striction mechanism support the magnon spin shift current and injection current.

The magnon spin current can be experimentally observed using setups with Kerr rotation or Faraday effect, or a two-terminal setup with a non-centrosymmetric magnetic insulator sandwiched between two metallic leads, as suggested in the previous theoretical proposal [29]. The nonlinear magnon spin conductivity and the strength of the electric field to support a realistic value of spin current, which is of the order of \( J_s = 10^{-16} \text{ J/cm}^2 \) [29, 40, 62], can be estimated as follows.

First, we consider the magnitude of the magnon spin shift conductivity \( \sigma_{\text{shift}} \). One candidate material for magnon spin current is \( \text{M}_{2}\text{M}_{2}\text{O}_{5}\), as we detailed in Sec. [IV]. The parameters for \( \text{M}_2\text{M}_2\text{O}_5 \) are given as follows: The lattice constants in the in-plane and perpendicular directions are \( a_x \sim 6 \text{ Å} \) and \( a_c \sim 10 \text{ Å} \), respectively [61]. The exchange interaction \( J_1 \) is 0.8 meV [60]. The spin-induced spontaneous polarization of \( \text{M}_2\text{M}_2\text{O}_5 \) at low temperature \( P - P_T \sim -1500 \mu \text{C/m}^2 \). Assuming that \( P_1 \) gives a dominant term for the electric polarization operator, and given that the number of intralayer nearest neighbor bonds is 6 in the unit cell, we estimate \( 6P_1/V \sim -1500 \mu \text{C/m}^2 \) from the above value of \( P - P_T \). Since \( V \) is the volume of the unit cell, the value of \( P_1/V \) is consistent with that of \( P_1 \) in \( \text{Fe}_2\text{M}_2\text{O}_5 \) calculated from the first-principles calculations [63]. From these values and our numerical result in Fig. 4(c), we obtain \( \sigma_{\text{shift}} \sim 5 \times 10^{-24} \text{ C}^2/\text{J} \), which indicates that applying an ac electric field of \( E \sim 10^4 \text{ V/cm} \) leads to an experimentally detectable magnon spin current of \( J_s \sim 5 \times 10^{-16} \text{ J/cm}^2 \).

Next, let us estimate the order of the magnon spin injection conductivity \( \sigma_{\text{inj}}^{a,0,0}(\omega, -\omega) \). The magnon spin injection current can be greater than the shift current when the relaxation time is long. We use the antiferromagnetic spin model in Sec. [I] for the estimation. We assume the energy gap \( \varepsilon_{ab} \simeq J_x = J_y \) of the order of \( 10 \text{ meV} \), the exchange striction with \( \Pi_x/V = \Pi_y/V = 250 \mu \text{C/m}^2 \), and the lattice constant \( a \sim 5 \text{Å} \). The relaxation time \( \tau \) can be estimated from \( \tau = 1/\alpha \omega \), where \( \alpha \) is Gilbert damping constant. Using the parameter \( \alpha = 2 \times 10^{-4} \) for the antiferromagnet NiO [64] and the resonant frequency \( \omega \sim \varepsilon_{ab} \simeq 10 \text{ meV} \), we estimate \( \tau \sim 3 \times 10^{-10} \text{ s} \). From these values and the result in Fig. 4(c), we obtain \( \sigma_{\text{inj}} \sim 3 \times 10^{-22} \text{ C}^2/\text{J} \). If we apply the ac electric field \( E \sim 10^4 \text{ V/cm} \), the estimated magnon spin current amounts to \( J_s \sim 3 \times 10^{-14} \text{ J/cm}^2 \), which shows that the magnon spin injection current is much larger than the magnon spin shift current. Since the energy scale of the magnon is around 10 meV which corresponds to a few THz in the frequency range, the magnon spin current is well feasible for experimental detection with an irradiation of the THz light field of the order of \( 10^3 \sim 10^4 \text{ V/cm} \).

Finally, we comment on the validity of our expression of the magnon spin shift current in terms of the shift vector. In deriving Eq. (25), we relied on the fact that the spin current can be written as the \( k \)-derivative of the Hamiltonian, which is true for collinear magnets. However, in the noncollinear magnets, the magnon Hamiltonian contains three-magnon terms and the spin current operator cannot be written as the \( k \)-derivative of the Hamiltonian. Furthermore, in the noncollinear magnets, there are contributions of the single-magnon resonance to the spin conductivity, which is not considered in our research. Thus our geometric description of the magnon shift current is only valid for collinear magnets, and its extension for more general cases is left for a future work.

Appendix A: Derivation of the nonlinear spin conductivity in Eq. (19)

In this appendix, we present a derivation of the nonlinear spin conductivity in Eq. (19) from a standard perturbation theory. To this end, we introduce the Matsubara Green function of the magnon

\[
G_{a,b}(\tau, \bm{k}) = \langle \{\Phi_{c,0}(\tau)\}_{a} \} \langle \{\Phi_{c,0}(0)\}_{b} \rangle \tag{A1}
\]

Here, \( \tau \) is the imaginary time and \( \mathcal{T} \) is the time-ordered product. Since the transformed operator \( \Phi_{c,0} \) is the basis of the diagonalized Hamiltonian, we obtain

\[
-\frac{\partial}{\partial \tau} \langle \{\Phi_{c,0}(\tau)\}_{a} \} \langle \{\Phi_{c,0}(0)\}_{b} \rangle = B_{c,d} - B_{c,c}(E_{k,c}) \mathcal{T} \langle \{\Phi_{c,0}(\tau)\}_{c} \} \langle \{\Phi_{c,0}(0)\}_{d} \rangle \tag{A3}
\]

By using the Fourier transformation, the Matsubara Green function can be written as

\[
G_{a,b}(i\omega, \bm{k}) = \sum_{c,d} \langle \{V_{k,c}\}_{d} \rangle \langle \{V_{k,c}\}_{d} \rangle \frac{B_{c,d}}{i\omega - (BE_{k})_{cd}} \tag{A4}
\]
Thus we obtain
\[ G(i\omega, k) = V_k(i\omega - \varepsilon_k)^{-1} B V_k^\dagger \]
\[ = V_k(i\omega - \varepsilon_k)^{-1} V_k^{-1} B \]
\[ = (i\omega - BH_k)^{-1} B, \] (A5)
where we used the diagonalized representation as in Eq. (11).

The second order magnon spin conductivity can be obtained by combining these two contributions as which directly leads to Eq. (19) by performing analytic continuation of the Matsubara frequency \( \Omega \) to the case of \( J \)

Next, we consider the contribution of the \( J_1 \) term, we can write \( \sigma^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) \) to \( \sigma^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) \). Here, \( \Omega_m \) is a Matsubara frequency of boson and \( F(z) = \frac{1}{2} \coth \frac{z}{2} \) is a Matsubara weighting function. We rewrite the Green function by using Eq. (A6) and perform the Matsubara frequency summation, we obtain

\[
\sigma_1^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) = \int \frac{d^d k}{(2\pi)^d} \int \frac{dz}{2\pi i} F(z) \text{Tr} \left[ J_{1k}^\mu G(z + i\Omega_m + i\Omega_n, k) \Pi_k^\alpha G(z + i\Omega_m, k) \Pi_k^\beta G(z, k) \right] \]
\[ + (\alpha, \Omega_m \leftrightarrow \beta, \Omega_n), \] (A7)

where \( \sigma_1^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) \) is the contribution of \( J_1 \) to \( \sigma^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) \). Next, we consider the contribution of the \( J_2 \) term which is a first-order term with respect to the electric field. As in the case of \( J_1 \) term, we can write \( \sigma_2^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) \) as the contribution of \( J_2 \) to \( \sigma^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) \) and obtain

\[
\sigma_2^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) = \int \frac{d^d k}{(2\pi)^d} \int \frac{dz}{2\pi i} F(z) \text{Tr} \left[ J_{2k}^\mu G(z, k) \Pi_k^\alpha G(z + i\Omega_m, k) \right] \]
\[ + (\alpha, \Omega_m \leftrightarrow \beta, \Omega_n) \]
\[ = \int \frac{d^d k}{(2\pi)^d} \int \frac{dz}{2\pi i} \sum_{a,b,c} F(z) \frac{j_{abc}^\mu \Pi_{ba}^\alpha \Pi_{cb}^\beta}{(z + i\Omega_m + \varepsilon_c)(z + i\Omega_m - \varepsilon_b)} + (\alpha, \Omega_m \leftrightarrow \beta, \Omega_n) \]
\[ = - \int \frac{d^d k}{(2\pi)^d} \sum_{a,b,c} j_{abc}^\mu \Pi_{ba}^\alpha \Pi_{cb}^\beta F(z) \frac{1}{(z + i\Omega_m + \varepsilon_c)(z + i\Omega_m - \varepsilon_b)} + (\alpha, \Omega_m \leftrightarrow \beta, \Omega_n). \] (A8)

The second order magnon spin conductivity can be obtained by combining these two contributions as

\[
\sigma^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) = \sigma_1^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n) + \sigma_2^{\mu,\alpha\beta}(i\Omega_m + i\Omega_n, i\Omega_m, i\Omega_n), \] (A9)

which directly leads to Eq. (19) by performing analytic continuation of the Matsubara frequency \( \Omega_m \to \omega + i\delta \) and \( \Omega_n \to -\omega + i\delta \).
