ABSTRACT
High-energy astrophysical systems frequently contain collisionless relativistic plasmas that are heated by turbulent cascades and cooled by emission of radiation. Understanding the nature of this radiative turbulence is a frontier of extreme plasma astrophysics. In this paper, we use particle-in-cell simulations to study the effects of external inverse Compton radiation on turbulence driven in an optically thin, relativistic pair plasma. We focus on the statistical steady state (where injected energy is balanced by radiated energy) and perform a parameter scan spanning from low magnetization to high magnetization (0.04 ≲ σ ≲ 11). We demonstrate that the global particle energy distributions are quasi-thermal in all simulations, with only a modest population of nonthermal energetic particles (extending the tail by a factor of ∼ 2). This indicates that nonthermal particle acceleration (observed in similar non-radiative simulations) is quenched by strong radiative cooling. The quasi-thermal energy distributions are well fit by analytic models in which stochastic particle acceleration (due to, e.g., second-order Fermi mechanism or gyroresonant interactions) is balanced by the radiation reaction force. Despite the efficient thermalization of the plasma, nonthermal energetic particles do make a conspicuous appearance in the anisotropy of the global momentum distribution as highly variable, intermittent beams (for high magnetization cases). The beamed high-energy particles are spatially coincident with intermittent current sheets, suggesting that localized magnetic reconnection may be a mechanism for kinetic beaming. This beaming phenomenon may explain rapid flares observed in various astrophysical systems (such as blazar jets, the Crab nebula, and Sagittarius A*).

1 INTRODUCTION
High-energy astrophysical systems often contain dilute, hot plasmas in a turbulent state. Examples include pulsar wind nebulae, supernovae remnants, radiatively inefficient accretion flows onto stellar mass black holes in X-ray binaries (XRBs) or supermassive black holes in active galactic nuclei (AGN), jets emanating from XRBs or AGN, giant radio lobes, the intracluster medium, and gamma-ray bursts (GRBs). More exotic possibilities include the mass flows resulting from tidal disruption events and compact object (e.g., neutron star) mergers. These plasmas often contain relativistic particles that are efficient emitters of radiation, providing an energy sink to the system and yielding radiative signatures that are ultimately observed from Earth. To develop accurate physical models of these systems, it is important to understand the role of radiative cooling on collisionless plasma turbulence. Likewise, to interpret observations and constrain the physical conditions in these systems, it is crucial to understand the radiative signatures of turbulence.

Radiative emission in these environments is commonly due to synchrotron, external inverse Compton (IC), and synchrotron self-Compton (SSC) mechanisms (in contrast to collisional mechanisms such as Bremsstrahlung). For an optically thin plasma, the resulting photons channel energy out of the system. A detailed understanding of the radiative emission requires statistical knowledge of charged particles at the microscopic level, where the plasma is generally dynamic (due to kinetic turbulence and other physical processes) and out of thermal equilibrium (since the collisional timescale is much longer than the relevant dynamical timescales). Thus, a proper study of radiative collisionless plasma demands use of a first-principles kinetic model.

The consequences of radiative cooling have recently been investigated in kinetic particle-in-cell (PIC) plasma
simulations for a number of high-energy astrophysical settings and processes. This includes relativistic magnetic reconnection (Jaroschek & Hoshino 2009; Cerutti et al. 2013, 2014a,b; Kagan et al. 2016a,b; Hakobyan et al. 2019; Werner et al. 2019; Schoeffler et al. 2019), decay of magnetostatic equilibria (Yuan et al. 2016; Nalewajko et al. 2018), pulsar wind (Cerutti & Philippov 2017), and pulsar magnetospheres (Cerutti et al. 2016; Philippov & Spitkovsky 2018). The (synchrotron and jitter) radiative signatures of collisionless shocks have also been explored (Medvedev & Spitkovsky 2009; Sironi & Spitkovsky 2009, Kirk & Reville 2010; Nishikawa et al. 2011).

In this work, we incorporate radiative cooling into PIC simulations of driven turbulence in relativistic plasma for the first time. This is a numerically unexplored regime of turbulence, which we call radiative turbulence. Recent analytic works studied radiative turbulence in various relativistic astrophysical contexts, including blazar jets (specifically, BL Lac objects) (Uzdensky 2018; Sobacchi & Lutvbarsky 2018) and GRBs (Zrake et al. 2018). There have also been a number of numerical works investigating radiation spectra from test particles in random magnetic fields, mimicking turbulence (e.g., Teraki & Takahara 2011). Our self-consistent numerical simulations of kinetic turbulence with the radiation backreaction force can address several questions that are beyond the scope of these previous studies.

One major question about radiative turbulence is: how does cooling affect the statistical properties of kinetic turbulence? The turbulent cascade progressively transfers energy from fluctuations at large scales (where energy is injected) to those at small scales (where collisionless dissipation mechanisms damp the fluctuations). The heating of the plasma is inhomogeneous in space, leading to localized hot spots where radiative cooling (from synchrotron, IC, and SSC mechanisms) may be important (e.g., Zhdankin et al. 2016, and references therein). Radiative cooling can thus influence the small-scale dynamics, altering the properties of the kinetic cascade (at scales below the typical particle Larmor radius or inertial length) and coherent structures. Furthermore, the presence of strong cooling allows turbulence to be maintained in the high-magnetization regime, where the magnetic energy density exceeds the total particle energy density (including rest mass). In this regime, the rapid conversion of magnetic energy to plasma kinetic energy can locally energize the plasma, driving compressions and relativistic flows. Shocks and magnetic reconnection may complicate the nature of turbulence and cause nonthermal particle acceleration. This regime of sustained relativistic turbulence has been studied in the framework of force-free electrodynamics (e.g., Thompson & Blaes 1998; Cho 2005; Cho & Lazarani 2013; Zrake & East 2016), which neglects the plasma inertia and does not self-consistently include dissipation channels. It has also been studied with simulations of relativistic magnetohydrodynamics (MHD) (Zrake & MacFadyen 2011; Zrake 2014). Our present work is the first to study fully developed turbulence in this relativistic regime with kinetic simulations.

A second major question about radiative turbulence is: what is the effect of radiative cooling on the kinetic aspects of collisionless plasma turbulence, i.e., on the momentum distribution of the charged particles? The particle distribution is linked to the spectrum and time-variability of outgoing radiation, and thus may provide useful constraints for future observational campaigns. Recent studies of kinetic turbulence in relativistic plasmas without radiative cooling have indicated that turbulence produces a significant population of high-energy, nonthermal particles with a power-law energy distribution extending to energies limited only by the outer scale of turbulence (Zhdankin et al. 2017; Zhdankin et al. 2018b; Comisso & Sironi 2018). Since radiative cooling acts mainly on particles in the high-energy tail of the distribution, it may suppress the nonthermal population above certain energies. For sufficiently strong cooling, the power-law tail may be completely eliminated, leading to a narrow energy distribution. For stochastic particle acceleration described by a Fokker-Planck equation in momentum space with a radiative cooling term, analytic work has demonstrated that the steady-state particle distributions are generally quasi-thermal (Schlickeiser 1984, 1985; Stawarz & Petrosian 2008). However, despite recent progress (e.g., Wong et al. 2019), the validity and appropriate form of the Fokker-Planck equation for turbulence is not yet known (e.g., Isliker et al. 2017), particularly in this physical regime, so first-principles kinetic simulations are necessary to test and further develop the models. One of the main objectives of our present work is to determine the functional form of the steady-state particle distribution, thus unveiling whether or not it can maintain a significant nonthermal component.

In addition to the energy distribution of particles, another key kinetic quantity is the anisotropy of their momentum distribution, which is linked to the directions of outgoing radiation (assuming particles are relativistic). At any given time, high-energy particles may be coherently beamed in random directions due to localized bulk flows or asymmetric acceleration processes. This can potentially lead to distinct radiative signatures on a global scale, including rapid, intense flares when a beam crosses the line of sight of an observer. An important question is whether dissipative events are sufficiently intermittent and anisotropic to make the turbulent plasma appear inhomogeneous and temporally variable to a distant observer. This has implications for high-energy flares observed in a broad range of astrophysical systems. For example, the beaming of radiation by relativistic flows (minijets) powered by turbulence (or reconnection sites) has been invoked to explain blazar and GRB flares (Lyutikov 2006; Giannios et al. 2009; Narayan & Kumar 2009; Kumar & Narayan 2009; Giannios et al. 2010). Kinetic beaming of high-energy particles has previously been observed in PIC simulations of relativistic magnetic reconnection, being proposed as an explanation for the Crab nebula flares (Cerutti et al. 2012, 2013, 2014b) and blazar flares (Nalewajko et al. 2012). Our present paper investigates the properties of intermittent high-energy particle beams in relativistic turbulence, which is a first step toward connecting to radiative signatures.

In this study, we focus on driven turbulence in relativistic pair plasma cooled by external IC radiation (deferring the cases of synchrotron and SSC cooling to future work). The plasma is assumed to be optically thin, so that radiated energy effectively evacuates the domain, allowing a rigorous statistical steady state to be achieved and maintained. In Section 2, we analytically calculate the steady-state physical conditions (i.e., temperature) and describe the PIC simulation campaign. In Section 3, we present an overview of
the turbulence statistics in the simulations. In Section 4, we describe the particle statistics, showing that radiative cooling efficiently thermalizes the bulk of the plasma, and that the steady-state distribution is well fit by a Fokker-Planck model for stochastic particle acceleration (associated with, e.g., the second-order Fermi mechanism or gyroresonant interactions). At the same time, for high magnetization cases, we identify a modest high-energy nonthermal population that is spatially correlated with current sheets and is beamed intermittently in direction. These results have important implications for high-energy astrophysical systems such as blazar jets, as we discuss in Section 5. Finally, we summarize our results and conclude in Section 6. This work builds on our previous studies of relativistic pair plasma turbulence without any cooling mechanism (Zhidenkii et al. 2017; Zhidenkii et al. 2018a).

2 METHODS

2.1 Background on radiative turbulence

In this section, we provide a brief theoretical overview of the physical problem under consideration (turbulence in relativistic pair plasma with external IC radiative cooling) and formulate the physical conditions (in particular, temperature) necessary to maintain turbulence in statistical steady state (see also Uzdensky 2018, for the case of synchrotron and SSC radiation). The statistical steady state is a novel aspect of radiative turbulence, in the sense that a rigorous steady state is absent in kinetic turbulence without an energy sink (since dimensionless parameters evolve in time due to the turbulent heating).

In this paper, given a field \( F(x, t) \), we will consider spatial and temporal averages, denoted as follows. We use an overbar, \( \overline{\cdot} \), to denote a spatial average or average over all particles in the domain (if a kinetic quantity). We use angular brackets, \( \langle \cdot \rangle \), to denote a temporal average, generally taken over the period in which the turbulence is in a statistical steady state (beginning after a few Alfvén crossing times).

We consider an ultra-relativistic electron-positron (pair) plasma. Specifically, we assume that the mean particle Lorentz factor is large, \( \gamma \gg 1 \), where \( \gamma = (1 - v^2/c^2)^{-1/2} \) for a particle of velocity \( v \). Such a turbulent pair plasma can be characterized by two dimensionless physical parameters (see discussion in, e.g., Zhidenkii et al. 2018a), as follows.

The first parameter is the magnetization \( \sigma \), which is defined to be the ratio of the magnetic enthalpy to relativistic plasma enthalpy: \( \sigma = B_{\text{rms}}^2/4\pi n_0 \), where \( B_{\text{rms}} \) is the characteristic (rms) magnetic field in the system and \( n_0 \) is the (electron plus positron) number density, and \( B \) is the average plasma pressure. In our case, approximating the particle distribution as isotropic, \( n_0 = n_0 \gamma m_e c^2/3 \), so that \( \sigma = 3B_{\text{rms}}^2/16\pi n_0 \gamma m_e c^2 \). The magnetization sets the characteristic Alfvén velocity, \( v_A = c\sigma/\gamma (\sigma + 1)^{1/2} \), and thus determines to what extent the turbulent motions (which are predominantly Alfvénic) are relativistic. Note that the magnetization also determines the relationship between the two primary plasma kinetic scales: the characteristic Larmor radius, \( \rho_e = \gamma m_e c^2/eB_{\text{rms}} \), and the plasma skin depth, \( d_e = (\gamma m_e c^2/4\pi n_0 e^2)^{1/2} \), are related by \( d_e/\rho_e = [(4/3)\sigma]^{1/2} \). We also note that for an ultra-relativistic pair plasma, the plasma beta parameter is inversely proportional to magnetization, \( \beta = 8\pi T/B_{\text{rms}}^2 = 1/(2\sigma) \).

The second parameter is \( L/2\pi \rho_e \), which is the ratio of the driving scale \( (L/2\pi) \) to the characteristic Larmor radius. In the case of \( \sigma \lesssim 1 \), \( L/2\pi \rho_e \) essentially describes the extent of the large-scale (MHD) inertial-range cascade, which is generally terminated by collisionless plasma effects at scales comparable to and smaller than \( \rho_e \). In the case of \( \sigma \gg 1 \), the transition may instead occur at scales comparable to \( d_e \), making \( L/2\pi d_e \) more representative of the inertial range extent (Chen et al. 2014; Boldyrev et al. 2015; Franci et al. 2016).

For most collisionless plasmas in space and astrophysical systems, \( L/2\pi \rho_e \gg 1 \), a limit that is difficult to achieve in numerical simulations. It is thus important to do scaling studies to identify which quantitative properties of turbulence are sensitive to \( L/2\pi \rho_e \) (in the limit of large values) and which are not.

External IC radiative cooling occurs due to the upscattering of low-energy seed photons (from an external radiation field) by relativistic particles (see, e.g., Blumenthal & Gould 1970; Rybicki & Lightman 2008). The energy density of the ambient photon field \( U_{\text{ph}} \) controls the strength of this cooling process. However, as we explain next, for turbulence in a statistical steady state, where injected energy is balanced by radiated energy, \( U_{\text{ph}} \) is only relevant for setting the steady-state mean particle energy, \( \bar{E} \). As long as \( \bar{E} \gg 1 \) is maintained, the precise value of \( \bar{E} \) is dynamically irrelevant because it only sets an arbitrary energy scale (assuming \( \sigma \) and \( L/2\pi \rho_e \) are held fixed). Thus, we do not consider it to be an independent free parameter in our simulation campaign.

The IC emission process exerts a radiation backreaction force, \( F_{\text{IC}} \), that is added to the Lorentz force describing the evolution of electrons and positrons. The motion of the \( i \)th particle is thus governed by

\[
\frac{dp_i}{dt} = q_i \left[ E(x, t) + \frac{v_i}{c} \times B(x, t) \right] + F_{\text{IC}}(v_i),
\]

where \( p_i = \gamma_i m_i v_i \) is the particle momentum, \( q_i \) is the particle charge, \( E(x, t) \) and \( B(x, t) \) are the electric and magnetic fields, \( x \) is the particle position, and \( v_i = dx_i/dt \) is the particle velocity. The IC radiation backreaction force is given by (Landau & Lifshitz 1975)

\[
F_{\text{IC}}(v) = -\frac{4}{3}\pi \sigma T U_{\text{ph}} \gamma^2 c \gamma^2 c,
\]

where we assumed an isotropic external photon density (in the laboratory frame) and ultra-relativistic particles \( (\gamma_i \gg 1) \). Here, \( \sigma_T = (8\pi/3)c^2 \) is the Thomson cross section, with \( \sigma_T = e^2/m_e c^2 \) the classical electron radius.

In our case of IC radiative cooling acting on an optically thin, relativistic pair plasma \( (\nu \approx c) \), the radiative cooling rate (normalized to the total number of particles \( N_{\text{part}} \)) is then given by

\[
\dot{E}_{\text{rad}} = -\frac{1}{N_{\text{part}}} \int d^3x d^3p \langle f(x, p) \rangle v \cdot F_{\text{IC}}
= \frac{4}{3} \pi \sigma T U_{\text{ph}} \frac{1}{N_{\text{part}}} \int d^3x d^3p \langle f(x, p) \rangle \gamma^2
= \frac{4}{3} \pi \sigma T U_{\text{ph}} \gamma \gamma^2,
\]

in the limit of large values of \( \sigma \) and \( L/2\pi \rho_e \) (Zhidenkii et al. 2018a).
where \( f(x, p) \) is the combined (electron plus positron) distribution function.

On the other hand, the energy injection rate (from an external driving source) can be estimated by assuming that the turbulent magnetic energy \( \delta B_{\text{rms}}^2/8\pi \) dissipates within a cascade time that is comparable to the large-scale Alfvén crossing time, \( L/v_A \), where \( L \) is the system size. We consider strong turbulence with a fluctuating magnetic field that is comparable to the mean field, so that the rms fluctuating magnetic field component is \( \delta B_{\text{rms}} \approx B_0 \), implying a total rms field given by \( B_{\text{rms}}^2 = B_0^2 + \delta B_{\text{rms}}^2 \approx 2B_0^2 \). The energy injection rate normalized to the number of particles is then

\[
\dot{\mathcal{E}}_{\text{inj}} = \frac{\eta_{\text{inj}}}{8\pi n_0 L} \frac{v_A}{c}.
\]

We included a coefficient \( \eta_{\text{inj}} \approx 1 \) that describes the efficiency of the external driving coupling to the plasma.

Because of the dependence of cooling on \( \gamma^2 \), regardless of initial conditions, the plasma internal energy will adjust (by net heating or cooling) until the cooling compensates the energy injection, \( \dot{\mathcal{E}}_{\text{rad}} \approx \dot{\mathcal{E}}_{\text{inj}} \). For a given \( U_{\text{ph}} \), the expected steady-state mean square particle Lorentz factor is obtained by balancing Eq. 3 with Eq. 4, giving

\[
\overline{\gamma^2} = \frac{3\eta_{\text{inj}}}{4} \frac{B_0^2}{8\pi U_{\text{ph}} \sigma T n_0 L} \frac{v_A}{c} = \frac{3\eta_{\text{inj}}}{4} \frac{B_0^2}{8\pi U_{\text{ph}} \sigma T} \frac{v_A}{c},
\]

where the Thomson optical depth of the system is \( \tau_T \equiv \pi n_0 \sigma T L \). We consider the special case of a thermal (Maxwell-Jüttner) distribution with temperature \( T = \theta m_e c^2 \), in the ultra-relativistic limit (\( \theta \gg 1 \)),

\[
f_0(x, p) = \frac{n_0}{\pi^3 \theta m_e^2 c^3} \exp(-p/\theta m_e c).
\]

In this case, the mean energy and mean squared energy are related to the temperature by \( \overline{\gamma} = 3\theta \) and \( \overline{\gamma^2} = 12\theta^2 \), respectively. The steady-state temperature for a thermal plasma can then be written as

\[
\theta_{ss} = \frac{\eta_{\text{inj}}}{16} \frac{m_e c^2}{\sigma T U_{\text{ph}} L} \frac{v_A}{c} = \frac{\eta_{\text{inj}}}{16} \frac{1}{\ell} \gamma^{5/2},
\]

where we defined the compactness parameter \( \ell \equiv \sigma_T U_{\text{ph}} L/m_e c^2 \) (describing the ratio of the system light crossing time to the particle cooling timescale, all divided by the particle’s Lorentz factor). We thus initialize our simulations with a temperature close to \( \theta_{ss} \) in order to quickly arrive at a steady state. In general, the actual average energy during steady state may deviate from this estimate if the distribution is significantly nonthermal.

### 2.2 Numerical simulations

We perform the simulations with the explicit electromagnetic PIC code ZELTRON (Cerutti et al. 2013), which incorporates the radiation backreaction force from IC emission. We use the same numerical set-up as in our previous studies of nonradiative relativistic plasma turbulence (e.g., Zhdankin et al. 2018a). The domain is a periodic cube of side length \( L \) with uniform background magnetic field \( B_0 = B_0 \hat{z} \). We initialize electrons and positrons from a uniform Maxwell-Jüttner distribution (Eq. 6). We drive turbulence by applying a fluctuating external current density \( J_{\text{ext}} \) (TenBarge et al. 2014). This driving is characterized by four quantities: the wavevector \( k_0 \), the frequency \( \omega_0 \), the decorrelation rate \( \gamma_0 \), and the amplitude \( A_0 \); we optimize these parameters based on simulations at \( \sigma \approx 1 \).

We drive \( J_{\text{ext}} \) at eight modes, \( k_0 L/2\pi \in \{(1, 0, \pm 1), (0, 1, \pm 1), (-1, 0, \pm 1), (0, -1, \pm 1)\} \), and each of \( J_{\text{ext},x} \) and \( J_{\text{ext},y} \) at four modes to enforce \( \nabla \cdot J_{\text{ext}} = 0 \). We choose a driving frequency of \( \omega_0 = 0.6 \cdot 2\pi v_A / \sqrt{3}L \) and decorrelation rate \( \gamma_0 = 0.5 \cdot 2\pi v_A / \sqrt{3}L \). Finally, we fix \( A_0 \) such that the rms magnetic fluctuations are comparable to the background field, \( \delta B_{\text{rms}} \approx B_0 \). The simulation timestep is fixed at \( \Delta t \approx (\Delta x/c)/\sqrt{3} \) to satisfy the Courant-Friedrichs-Lewy condition. Most cases have 64 total particles per cell and cell size \( \delta x \approx \min(\rho_\sigma/2, d_e/2) \); however, for low-\( \sigma \) cases, we choose a greater number of particles per cell to reduce the inherent PIC noise, which is high in this regime due to thermal energy dominating the energy in turbulent fluctuations. In particular, we choose 128 particles per cell for cases with \( \sigma = 0.2 \) and 256 particles per cell for \( \sigma = 0.04 \).

We have optimized these numerical parameters by conducting a thorough convergence study with respect to resolution and number of particles per cell.

We initialize all simulations with a temperature of \( \theta = 100 \), corresponding to \( \overline{\gamma} = 300 \). We always choose \( U_{\text{ph}} \) such that the predicted steady-state temperature, calculated from Eq. 7 with initial parameters\(^1\) and \( \eta_{\text{inj}} = 1 \), is \( \theta_{ss} = 75 \), which corresponds to \( \gamma_{ss} = 225 \). As a result, \( U_{\text{ph}} \) varies with system size \( L \), in a way such that the dimensionless compactness parameter \( \ell \) is fixed. Our choice of \( U_{\text{ph}} \) ensures that simulations quickly approach the equilibrium (as confirmed in Sec. 3.2).

We show the steady-state parameters and durations for the primary simulations employed in this study in Table 1. Our largest, fiducial case (768\(^3 \) cells) has \( \sigma = 0.90 \) and \( \rho_\sigma = 2.0 \Delta x \), giving an effective system size of \( L/2\pi \rho_\sigma = 61 \). We also have three cases on 512\(^3 \)-cell lattices, constituting moderately large cases with modest variation in \( \sigma \). In the next tier, we have five cases on 384\(^3 \)-cell lattices, constituting a broad scan in \( \sigma \in \{0.04, 0.2, 0.8, 3.3, 11.0\} \). Since the resolution is fixed by the smallest kinetic scale (\( \rho_\sigma \) or \( d_e \)), the system size \( L/2\pi \rho_\sigma \) does not necessarily correspond to the number of lattice cells; the low-\( \sigma \) cases have smaller \( L/2\pi \rho_\sigma \) in order to properly resolve \( d_e \) in. In addition to these primary simulations, two of the simulations in the table are repeats of other cases (rM4 and rS1) with additional diagnostics: rM4\(^* \) has a higher cadence of particle momentum distribution dumps (for Sec. 4.4-Sec. 4.6) and rS1\(^* \) has a higher cadence of electric field and current density dumps (for Sec. 3.5). The durations for the simulations typically range between 25L/v_A and 35L/v_A, providing a long steady

\(^1\) In terms of physical (dimensional) parameters, required as input parameters to ZELTRON, we do the following procedure: the cell size \( \Delta x \) is arbitrarily set, \( B_0 \) is chosen to get \( \rho_\sigma/\Delta x \) as determined by the resolution requirements, \( \eta_{\text{inj}} \) is chosen to obtain the prescribed \( \sigma \), and then we set \( U_{\text{ph}} = \eta_{\text{inj}} m_e c^2 v_A / (16\pi n_0 L c) \) with \( \theta_{ss} = 75 \) and \( \eta_{\text{inj}} = 1 \).
Table 1. List of simulations and parameters

Figure 1. Surface plot of the emissivity proxy $n\gamma_{\text{avg}}^2$ for the 768$^3$, $\langle \sigma \rangle = 0.9$ simulation.

state for gathering statistics (from here onwards, we compute $v_A$ using the time-averaged magnetization $\langle \sigma \rangle$).

3 TURBULENCE STATISTICS

3.1 Visuals

We first show visuals from our large case, the 768$^3$ simulation with $\langle \sigma \rangle = 0.9$. In Fig. 1, we show the surface visual for the isotropic emissivity proxy, given by $n\gamma_{\text{avg}}^2$, where $n(x)$ is the plasma number density and $\gamma_{\text{avg}}(x)$ is the local (cell-averaged) mean particle Lorentz factor.

To convey a qualitative picture of the steady-state turbulence at low and high magnetizations, we next show visuals for several quantities in the 512$^3$ simulations with $\langle \sigma \rangle = 0.2$ ($L/2\pi\langle \rho_e \rangle = 30$) and $\langle \sigma \rangle = 3.4$ ($L/2\pi\langle \rho_e \rangle = 39$). For clarity, we show images of the data in an $xy$ slice, arbitrarily taken at $z = L/2$ in the final snapshots of the simulations.

In Fig. 2, we show the current density component along the guide field, $J_z$. A large number of intermittent current sheets form in the turbulence. The high-$\sigma$ case exhibits current sheets that are more intense and more strongly clustered than in the low-$\sigma$ case, suggesting that energy dissipation may be more localized. In Fig. 3, we show the particle number density $n$ (on a logarithmic scale). Density fluctuations are much stronger in the high-$\sigma$ case, with $n/n_0 \gtrsim 10$ in some regions, concentrated in thin sheet-like structures. In Fig. 4, we show the magnetic energy density $B^2/8\pi$. We find that the low-$\sigma$ case exhibits structures in the form of magnetic holes: circular coherent structures of size several $\rho_e$ inside which the magnetic energy density drops to a small value, also seen in our previous non-radiative simulations (Zhdankin et al. 2018a) and in non-relativistic kinetic turbulence (e.g., Roytershteyn et al. 2015). These structures are correlated with high densities, consistent with local pressure equilibrium. Although they bear some resemblance to plasmoids resulting from the tearing instability in 2D MHD turbulence with high Reynolds number (Dong et al. 2018;
Walker et al. 2018), these magnetic holes appear to have a different structure and origin in our simulations, which we defer to future study. In the high-$\sigma$ case, there are no magnetic holes; instead, the magnetic energy is more strongly concentrated in clumps, correlated with high density regions, indicating that the magnetic field may be compressed into thin sheets. Finally, in Fig. 5, we show the local average particle Lorentz factor $\gamma_{\text{avg}}$, which coincides with regions where radiative cooling occurs (since the radiation backreaction force is proportional to $\gamma^2$). The figure indicates that particle energization is more spatially localized in the high-$\sigma$ case, with intense hot spots that often coincide with current sheets.

### 3.2 Equilibrium temperature

Before analyzing the turbulence statistics in detail, we confirm that the plasma attains the steady-state temperature expected for the given simulation parameters. In the top panel of Fig. 6, we use a set of 256$^3$ simulations with $\langle \sigma \rangle \approx 1$ to demonstrate that simulations attain the same mean particle energy $\gamma$ at late times despite significantly different initial temperatures: $\theta_0 \in \{\theta_{ss}/4, \theta_{ss}, 4\theta_{ss}\}$. Recall that temperature and mean energy are related by $\theta = \gamma^2/3$ for an ultra-relativistic Maxwell-Jüttner distribution. In the bottom panel of Fig. 6, we show the steady-state mean particle energy $\langle \gamma \rangle$ versus magnetization $\langle \sigma \rangle$ for the 384$^3$ simulation series. As expected from our numerical setup (in particular, tuning $U_{\text{ph}}$ to get fixed $\theta_{ss}$), $\langle \gamma \rangle$ does not vary significantly with $\langle \sigma \rangle$, showing only a slight increase with $\langle \sigma \rangle$. We compare $\langle \gamma \rangle$ to the equilibrium values predicted from the initial parameters, $\gamma_{\text{ss,0}}$, and predicted from the time-averaged parameters, $\gamma_{ss}$, both calculated from Eq. 7 with $\eta_{\text{inj}} = 1.4$ chosen to get good agreement between the simulation measurement and the predictions. This value of $\eta_{\text{inj}}$ is close to the injection efficiency measured in our previous non-radiative simulations (Zhdankin et al. 2018a). Hence, we conclude that Eq. 7 provides an accurate prediction for the steady-state temperature. Since the plasma is ultra-relativistically hot, $\langle \gamma \rangle \gg 1$, the absolute value of the temperature is irrele-
3.3 Energetics

We now consider the overall energetics of the simulations. In Fig. 7, we show the evolution of the different contributions to total energy in the system, for simulations in three magnetization regimes: low (⟨σ⟩ = 0.2), moderate (⟨σ⟩ = 0.8), and high (⟨σ⟩ = 11), for the 3843 simulation series. Specifically, we show magnetic, electric, internal, and bulk kinetic energy, with the latter two defined as in Zhdankin et al. (2018a). For the given initial conditions, the energies arrive at a statistical steady state after a couple of large-scale Alfvén crossing times (L/vA).

Next, we consider the time-average of the different energies in steady state for varying σ (for the 3843 series), shown in Fig. 8. For σ ≲ 1, there are comparable amounts of turbulent energy in the bulk flows and in fluctuating magnetic fields (which are in turn comparable to the mean field energy), consistent with an Alfvénic character. The electric energy is significantly smaller, roughly by a factor of \((v_A/c)^2\), consistent with it arising from the ideal MHD electric field component \(E \approx \mathbf{v}_f \times \mathbf{B}\), where \(v_f\) is the bulk flow velocity. The internal energy is much larger than the turbulent energy, and thus the plasma has a high effective mass density and subsonic motions. For σ ≫ 1, on the other hand, the total particle energy becomes small compared to the electric and magnetic energies. A large portion of the particle energy is contained in the bulk flows rather than the internal energy. The electric energy in this case is comparable to the magnetic energy. This is nominally the regime of relativistic force-free electrodynamics, as considered in previous works in the literature (Thompson & Blaes 1998; Cho 2005; Cho & Lazarian 2013; Zrake & East 2016).
Figure 7. Evolution of various energies at $\langle \sigma \rangle = 0.2$ (top), $\langle \sigma \rangle = 0.8$ (center), and at $\langle \sigma \rangle = 11.0$ (bottom), taken from $384^3$ simulations. Turbulent magnetic energy (red), electric energy (blue), internal energy (magenta), and bulk kinetic energy (green) are shown, all normalized to the energy of the mean magnetic field $E_{\text{mean}}$ (black).

3.4 Turbulence spectrum

We proceed to describe the power spectra for various turbulent quantities. In the following, we integrate the power spectra across wavenumbers parallel to the global mean field and angles around it, showing the resulting spectra with respect to the perpendicular wavenumber $k_\perp = (k_x^2 + k_y^2)^{1/2}$.

We show a series of power spectra (compensated by $k^{-5/3}_\perp$) in Fig. 9. We find that the magnetic energy spectrum $E_{\text{mag}}(k_\perp)$, electric energy spectrum $E_{\text{elec}}(k_\perp)$, and particle density spectrum $E_{\rho}(k_\perp)$ all approach a scaling consistent with $k^{-5/3}_\perp$ in the inertial range ($k_\perp \rho_e \lesssim 1$) as the size is increased, for the cases with fixed $\langle \sigma \rangle \approx 1$. The largest case, on a $768^3$ lattice with $L/(2\pi\rho_e) = 60.3$, has an inertial range roughly from $k_\perp \rho_e \approx 0.05$ to $k_\perp \rho_e \approx 0.3$. At small scales, $k_\perp \rho_e > 1$, we find that the magnetic and electric energy spectra substantially steepen; although not a clear power law, these kinetic (sub-inertial) range spectra steepen to a scaling comparable to $k^{-6}_\perp$. The spectral indices in the kinetic range, however, are sensitive to numerical parameters such as filtering, resolution, and number of particles per cell; hence, we leave their asymptotic scaling to future work.

In Fig. 10, we again show the three spectra $E_{\text{mag}}(k_\perp)$, $E_{\text{elec}}(k_\perp)$, and $E_{\rho}(k_\perp)$, compensated by $k^{5/3}_\perp$; this time for varying $\langle \sigma \rangle$ (taken from the $512^3$ simulations; recall that $L/(\langle \rho_e \rangle$ is not strictly the same for these three cases). The magnetic energy spectrum is consistent with $k^{-5/3}_\perp$ for $\langle \sigma \rangle \lesssim 1$, but becomes steeper for the high-magnetization case, $\langle \sigma \rangle = 3.4$, with no clear power law. Evidently, the break near $k_\perp \rho_e \sim 1$ becomes broader at high $\langle \sigma \rangle$, perhaps indicating that the transition to the kinetic range occurs at $d_\perp$ rather than $\rho_e$. The electric energy spectrum appears to be similar for all three cases (slightly steeper than $k^{-5/3}_\perp$). The $\langle \sigma \rangle \lesssim 1$ cases have density spectra close to $k^{-5/3}_\perp$, as expected for subsonic MHD turbulence; this becomes drastically shallower for the $\langle \sigma \rangle = 3.4$ case, with a scaling near $k^{-1}_\perp$. This shallow spectrum is qualitatively similar to the case of supersonic MHD turbulence, where the density spectrum becomes dominated by intense, small-scale compres-
3.5 Energy transfer spectrum

A primary objective in studies of kinetic turbulence is to identify the nature of energy transfer from electromagnetic fields to internal energy (e.g., Matthaeus et al. 2015). To take a first step in this direction, in this subsection, we measure the irreversible transfer of energy from the turbulent electromagnetic field to the plasma as a function of scale. To accomplish this, we implement the following diagnostic. We first expand the electric field and current density in terms of Fourier modes:

$$E(x,t) = \int d^3k \tilde{E}(k,t)e^{ik \cdot x}/(2\pi)^3$$

and

$$J(x,t) = \int d^3k \tilde{J}(k,t)e^{ik \cdot x}/(2\pi)^3$$

for the electric field and current density, respectively. The power spectra for these fields are then calculated using:

$$P(k) = \frac{1}{2\pi^2} \int d^3k \tilde{E}(k,t)\tilde{E}^{*}(k,t)$$

and

$$P(k) = \frac{1}{2\pi^2} \int d^3k \tilde{J}(k,t)\tilde{J}^{*}(k,t)$$

for the electric and current density fields, respectively. These power spectra are then fit to inertial-range scalings of $k^{-5/3}$ for the electric field and current density, and $k^{-2}$ for the magnetic field, as shown in Fig. 9. Fits from Fig. 9 are also shown, along with steeper $k^{-2}$ inertial-range scalings for $E_{\text{mag}}(k_{\perp})$ and $E_{\text{elec}}(k_{\perp})$, and a shallower $k^{-1}$ scaling for $E_{\text{elec}}(k_{\perp})$ (dash-dotted line).

For varying system size and fixed magnetization $\langle \sigma \rangle \sim 1$, inertial-range fits (prior to compensation) of $k^{-5/3}_{\perp}$ are shown for all cases (dashed lines). Kinetic-range scalings of $k^{-6}_{\perp}$ for $E_{\text{mag}}(k_{\perp})$ and $E_{\text{elec}}(k_{\perp})$, and $k^{-2.3}_{\perp}$ for $E_{\text{elec}}(k_{\perp})$, are also shown for reference (dotted lines).

Sive structures in the high Mach number regime (e.g., Beresnyak et al. 2005; Kowal et al. 2007).

3.5 Energy transfer spectrum

A primary objective in studies of kinetic turbulence is to identify the nature of energy transfer from electromagnetic fields to internal energy (e.g., Matthaeus et al. 2015). To take a first step in this direction, in this subsection, we measure the irreversible transfer of energy from the turbulent electromagnetic field to the plasma as a function of scale. To accomplish this, we implement the following diagnostic. We first expand the electric field and current density in terms of Fourier modes:

$$E(x,t) = \int d^3k \tilde{E}(k,t)e^{ik \cdot x}/(2\pi)^3$$

and

$$J(x,t) = \int d^3k \tilde{J}(k,t)e^{ik \cdot x}/(2\pi)^3$$

for the electric field and current density, respectively. The power spectra for these fields are then calculated using:

$$P(k) = \frac{1}{2\pi^2} \int d^3k \tilde{E}(k,t)\tilde{E}^{*}(k,t)$$

and

$$P(k) = \frac{1}{2\pi^2} \int d^3k \tilde{J}(k,t)\tilde{J}^{*}(k,t)$$

for the electric and current density fields, respectively. These power spectra are then fit to inertial-range scalings of $k^{-5/3}_{\perp}$ for the electric field and current density, and $k^{-2}$ for the magnetic field, as shown in Fig. 9. Fits from Fig. 9 are also shown, along with steeper $k^{-2}$ inertial-range scalings for $E_{\text{mag}}(k_{\perp})$ and $E_{\text{elec}}(k_{\perp})$, and a shallower $k^{-1}$ scaling for $E_{\text{elec}}(k_{\perp})$ (dash-dotted line).

For varying system size and fixed magnetization $\langle \sigma \rangle \sim 1$, inertial-range fits (prior to compensation) of $k^{-5/3}_{\perp}$ are shown for all cases (dashed lines). Kinetic-range scalings of $k^{-6}_{\perp}$ for $E_{\text{mag}}(k_{\perp})$ and $E_{\text{elec}}(k_{\perp})$, and $k^{-2.3}_{\perp}$ for $E_{\text{elec}}(k_{\perp})$, are also shown for reference (dotted lines).
The normalized energy transfer rate of energy from the electromagnetic field to the plasma can then be written as

$$\Gamma(k) = \frac{\langle E(k, t) \cdot \mathbf{J}^*(k, t) \rangle}{\langle E(k) \rangle},$$

where \(\Gamma(k)\) is the electromagnetic energy transfer rate within a given logarithmic interval in wavenumbers. We interpret this as a signature of the energy cascade, where energy is transferred from the electromagnetic field to the plasma. The rate then increases strongly at high \(k\) at a constant (scale-independent) rate, thus siphoning energy out of the electromagnetic field. This cascade occurs through nonlinear energy transfer through Alfvénic motions. The energy transfer rate then drops just below the driving scales, and increases with wavenumber until \(k(\rho_0) \approx 1\), with a scaling somewhat steeper than \(k^{-5/3}\) (the scaling expected from a k^{-5/3} energy spectrum; this is due to the simulation size being too small for a converged inertial-range spectral index). The rate then increases strongly at \(k(\rho_0) \gtrsim 1\), peaking near \(k(\rho_0) = 2\), indicative of damping at sub-inertial scales.

Thus, the integrand \(E(k, t) \cdot \mathbf{J}^*(k, t)\) describes the rate of energy transfer from the electromagnetic field to the plasma (involving bulk flows, adiabatic compressions, heating, and nonthermal particle acceleration) for modes with the given wavenumber \(k\). Note that the energy transfer rate between the electric field and flows/compressions can be positive or negative, while irreversible energy dissipation (heating and nonthermal particle acceleration) has a net positive value. Thus, the signatures of flows and compressions are removed after integrating over directions of \(k\) and averaging over sufficiently long times. We are therefore led to define the energy transfer spectrum

$$\mathcal{D}(k) = k^2 \int d\Omega/\langle E(k, t) \cdot \mathbf{J}^*(k, t) \rangle,$$

where \(d\Omega\) is the solid angle differential in \(k\) space (we do not take into account anisotropy with respect to \(B_0\) here). The integral of the energy transfer spectrum is proportional to the (average) rate of radiative energy loss, \(\int dk \mathcal{D}(k) \propto E_{\text{rad}}\).

We measure \(\mathcal{D}(k)\) for a simulation with 384^3 cells and \(\langle \sigma \rangle \sim 1\), run rS1^* in Table 1, identical to run rS1 except with a longer duration and higher cadence of dumps for \(E\) and \(J\) fields (174 snapshots from \(tv_A/L = 5.3\) to \(tv_A/L = 40.5\)). The result is shown in the first panel of Fig. 11. We find that \(\mathcal{D}(k)\) is very strongly peaked at driving scales, consistent with the secular injection of energy into the cascade by the electromagnetic driving. In the inertial range, \(\mathcal{D} \propto k^{-1}\), indicating that the energy transfer is scale-invariant throughout this range, in the sense that \(f dk \mathcal{D}(k)\) is constant for any given logarithmic interval in wavenumbers. We interpret this as a signature of the energy cascade, which secularly transfers energy from bulk flows at low \(k\) to bulk flows at high \(k\) at a constant (scale-independent) rate, thus siphoning energy out of the electromagnetic field (which is continuously replenished from large-scale energy transfer). This result is consistent with the absence of dissipation mechanisms at MHD scales. Finally, \(\mathcal{D}(k)\) strongly decreases at scales \(k(\rho_0) \approx 1\), becoming negative (indicating net cooling) at large wavenumbers, \(k \gtrsim 2/(\rho_0)\). However, we find that this cooling region diminishes as the number of particles per cell is increased (not shown), indicating that it is likely a numerical artifact.

We next divide \(\mathcal{D}(k)\) by the electromagnetic energy spectrum, \(E_{\text{em}}(k) = E_{\text{mag}}(k) + E_{\text{ion}}(k)\), to obtain the rate of energy transfer (which we normalize to \(v_A/L\)). \(\Gamma_D(k) = (L/v_A)\mathcal{D}(k)/E_{\text{em}}(k)\). As shown in the second panel of Fig. 11, \(\Gamma_D \sim 1\) at driving scales, consistent with nonlinear energy transfer through Alfvénic motions. The energy transfer rate then drops just below the driving scales, and increases with wavenumber until \(k(\rho_0) \sim 1\), with a scaling somewhat steeper than \(k^{-5/3}\) (the scaling expected from a k^{-5/3} energy spectrum; this is due to the simulation size being too small for a converged inertial-range spectral index). The rate then increases strongly at \(k(\rho_0) \gtrsim 1\), peaking near \(k(\rho_0) = 2\), indicative of damping at sub-inertial scales.

These results are broadly consistent with kinetic-scale dissipation mechanisms, such as gyroresonant particle acceleration, which is further discussed in the context of steady-state particle distributions in Sec. 4.2. We cannot preclude nonlocal contributions to the energy transfer (damping of compressive modes, magnetic reconnection, etc.), which are difficult to distinguish from the signatures of large-scale driving and the cascade.

### 3.6 Magnetic field and density fluctuations

In this subsection, we comment on the statistics of the magnetic and density fluctuations. In the top panel of Fig. 12, we show the probability distribution for the magnetic field magnitude \(B\) in the 384^3 series of simulations with \(\langle \sigma \rangle \in \{0.04, 0.8, 11\}\). We find that although all cases have distributions peaked near \(B/B_0 \approx \sqrt{2}\) (as dictated by the driving amplitude), the low \(\sigma\) case has a much narrower distribution.
Radiative turbulence

Figure 12. Top panel: probability distribution for the magnetic field magnitude $B$ for the $384^3$ simulations with $\langle \sigma \rangle \in \{0.04, 0.81, 11\}$. Bottom panel: probability distribution for the fluctuating magnetic field components $\delta B_x$ (dashed) and $B_x$ (solid) for the same simulations.

than the other two cases. In the bottom panel of Fig. 12, we show the probability distribution for the magnetic field components $B_x$ and $\delta B_x = B_x - B_0$, showing that while the perpendicular magnetic fluctuations have similar distributions for all of the simulations, the component along $B_0$ has a narrower distribution in the low $\sigma$ case. Together, these results indicate that the magnetic fluctuations become rotationally dominated at low $\sigma$, which may be a consequence of kinetic instabilities or constraints from pressure anisotropy at high $\beta$ (Tenerani & Velli 2018; Squire et al. 2019). This appears to be a nontrivial signature of collisionless plasma physics affecting fluctuations at large scales, which would not appear in an MHD simulation.

In the top panel of Fig. 13, we show the scaling of the rms fluctuations in number density, $\delta n_{\text{rms}}$, and in velocity, $v_{f, \text{rms}}$, with respect to $\langle \sigma \rangle$ (for the $384^3$ series). We find that the velocity scaling can be fit by $(2/3)v_{A}/c$, consistent with Alfvénic fluctuations. We find that density fluctuations also increase with $\sigma$, with fluctuations becoming comparable to the mean ($\delta n_{\text{rms}} \sim n_0$) at $\sigma \sim 3$. Since the speed of sound in a relativistic ideal gas is $c_s = c/\sqrt{3} \approx 0.58c$ (e.g., Weinberg 1972), shocks are formed for $\sigma \gtrsim 1$. In the bottom panel of Fig. 13, we show the time-averaged probability distribution for the particle density $n$, for the $512^3$ series of simulations.

We find that the log-normal distribution provides a reasonable fit for the distributions (for the given range of $\langle \sigma \rangle$), apart from at low values of the density, where there is a noticeable excess of particles compared to the fit. This excess diminishes when the number of particles per cell is increased (not shown), thus we consider it a numerical artifact due to PIC noise.

3.7 Pressure anisotropy

The pressure tensor in a collisionless plasma is generally anisotropic with respect to the local magnetic field. The establishment of a significant pressure anisotropy can affect the thermodynamics of the plasma and trigger kinetic (mirror and firehose) instabilities, as observed in, e.g., numerical simulations (Kunz et al. 2014; Servidio et al. 2014) and the solar wind (Bale et al. 2009). In this subsection, we consider the statistics of the pressure anisotropy ratio $P_\perp/P_\parallel$, with the pressure components parallel and perpendicular to the
local magnetic field $\mathbf{B}$ defined by

$$P_\parallel = B \mathbf{B} : \mathbf{P},$$

and $\mathbf{P} = f d^3\mathbf{p}(p_f)/\sqrt{m_e^2 c^2 + p^2}$ is the pressure tensor (with ram pressure terms from bulk flows included).

In Fig. 14, as per convention, we show the 2D distribution of pressure anisotropy ratio, $P_\perp/P_\parallel$, versus the plasma beta using the pressure component parallel to the magnetic field, $\beta_\parallel = 8\pi P_\parallel/B^2$, for the simulations in the $384^3$ series. We find that the distributions are peaked at isotropic pressure, $P_\perp/P_\parallel \sim 1$, and $\beta_\parallel \sim \beta \sim 1/(2\langle \sigma \rangle)$ (at least, for high $\beta$). The low-$\beta$ (high-$\sigma$) cases have a broad spread in pressure anisotropy, ranging from $P_\perp/P_\parallel \sim 0.1$ to $P_\perp/P_\parallel \sim 10$, while the high-$\beta$ (low-$\sigma$) cases have much narrower distributions. We find that all of the simulations are within the marginal thresholds for the mirror and firehose instabilities (Kunz et al. 2014),

$$P_\.parallel \left|_{\text{Firehose}} \right. \lesssim 1 - \frac{2}{\beta_\parallel},$$

$$P_\parallel \left|_{\text{Mirror}} \right. \gtrsim \frac{1}{2} \left( 1 + \frac{4}{\beta_\parallel} \right).$$

Note that both thresholds here are taken from the non-relativistic limit\(^3\). These results suggest that mirror and firehose instabilities may become important in some regions of space for the high-$\beta$ cases, constraining the kinetic physics and possibly influencing aspects of the turbulence (such as the magnetic field fluctuations described in Sec. 3.6).

\(^3\) For a discussion of the relativistic MHD mirror and firehose thresholds in the doubly polytropic approximation, which may not be strictly applicable for a collisionless plasma, see Chou & Hau (2004). In this case, the firehose threshold remains unchanged for an ultra-relativistic plasma, but the mirror threshold shifts.

---

**Figure 14.** 2D probability distribution of pressure anisotropy ratio $P_\perp/P_\parallel$ versus $\beta_\parallel$ (for the $384^3$ series). Contours are shown at five values for each case: $\{1/2, 1/4, 1/8, 1/16, 1/32\}$ of the maximum value of the $\langle \sigma \rangle = 0.04$ distribution. Thresholds for the firehose instability (black, solid) and non-relativistic mirror instability (black, dashed) are shown for reference.

**Figure 15.** Top panel: Time-averaged particle energy distributions $\langle f(\gamma) \rangle$ for varying $\langle \sigma \rangle$ (for the $384^3$ series). For reference, a Maxwell-Jüttner distribution with the same mean energy is also shown (black, dashed). Bottom panel: similar distributions for varying system size (at fixed $\langle \sigma \rangle \sim 1$).

4 PARTICLE STATISTICS

4.1 Steady-state particle energy distributions

We now proceed to describe the particle statistics in our simulations, starting with the system-integrated energy distribution, $f(\gamma)$ (combined for electrons and positrons). Since $f(\gamma)$ is a global distribution, it in principle includes non-thermal signatures both from bulk flows and from particle acceleration. In the top panel of Fig. 15, we show the time-averaged particle energy distributions $\langle f(\gamma) \rangle$ for varying $\langle \sigma \rangle$ in the $384^3$ series of simulations. Our first main result is that the distributions are fairly close to the Maxwell-Jüttner distribution (Eq. 6) for all $\sigma$. This is in contrast to the broad power-law distribution (extending up to the system-size limited energy $\gamma_{max} = Lc/B_0/m_e c^2$) observed in simulations without radiative cooling (Zhdankin et al. 2017), indicating that radiative cooling effectively thermalizes the plasma. In the bottom panel of Fig. 15, we similarly show $\langle f(\gamma) \rangle$ for varying system size $L/2\pi(\nu_e)$ at fixed $\langle \sigma \rangle \sim 1$. We find that the system size weakly affects the far tail of the distribution, perhaps indicating that those high-energy particles are sensitive to fluctuations in the inertial range of turbulence. For $L/2\pi(\nu_e) \gtrsim 25$, the dependence on the system size is negligible; this scale separation is achieved by most simulations in...
our study, apart from the $384^3$ low-$\langle \sigma \rangle$ cases. Note that the system-size limited energy $\gamma_{\text{max}}$ is significantly higher than the energies obtained by any particles in these simulations: for example, the smallest case ($256^3$) in the system-size scan has $\gamma_{\text{max}} = 1.28 \times 10^4 \approx 43\gamma$ while the largest case ($768^3$) has $\gamma_{\text{max}} = 3.84 \times 10^7 \approx 128\gamma$.

Although the particle energy distributions are generally close to thermal, there are modest nonthermal deviations. We characterize these deviations by decomposing the distributions into thermal and nonthermal components, following the procedure in Zhdankin et al. (2019). We define the thermal part $f_{\text{th}}(\gamma)$ to be a Maxwell-Jüttner distribution with temperature and normalization such that the peak coincides with the peak of the measured distribution. We also include all of the measured distribution at energies below the peak value in the thermal component. The nonthermal part $f_{\text{nth}}(\gamma)$ is then defined to be the difference between the measured distribution and the thermal fit, $f_{\text{nth}}(\gamma) = f(\gamma) - f_{\text{th}}(\gamma)$.

The top panel of Fig. 16 shows the thermal and nonthermal component distributions, $f_{\text{th}}(\gamma)$ and $f_{\text{nth}}(\gamma)$, for varying $\langle \sigma \rangle$ (time-averaged in the $384^3$ simulations). We find that all cases have a well-defined nonthermal population of high-energy particles, albeit without a power-law tail. The center panel of Fig. 16 shows the fraction of kinetic energy in the nonthermal population, $E_{\text{nth}}/E_{\text{tot}}$, and the fraction of total particles in the nonthermal population, $N_{\text{nth}}/N_{\text{tot}}$, as functions of $\langle \sigma \rangle$. We find that both nonthermal fractions increase with $\langle \sigma \rangle$, with a scaling that is close to linear for $\langle \sigma \rangle \lesssim 1$, and weaker than linear for $\langle \sigma \rangle \gtrsim 1$. The linear scaling at low $\sigma$ suggests that the efficiency of nonthermal particle acceleration is related to the dissipation of the available magnetic energy relative to the thermal kinetic energy. We note that $\sim 25$% of the energy and $\sim 10$% of the particles are in the nonthermal population at $\langle \sigma \rangle \approx 1$. For the most extreme case, $\langle \sigma \rangle = 11$, about $\sim 50$% of energy and $\sim 30$% of particles are in the nonthermal population, indicating that although the distribution does not span a broad range of energies, it does have a significantly nonthermal shape. The characteristic energy of the nonthermal population does not increase with $\langle \sigma \rangle$, as demonstrated in the bottom panel of Fig. 16, which shows the average particle energy of the nonthermal population relative to the overall average energy, $\gamma_{\text{nth}}/\gamma = (E_{\text{nth}}/N_{\text{nth}})/(E_{\text{tot}}/N_{\text{tot}})$, for varying $\langle \sigma \rangle$. Rather, the average energy of the nonthermal population is only twice the overall average energy in the highest-$\langle \sigma \rangle$ case, while it is a factor of $\sim 5$ greater than the overall average in the lowest-$\sigma$ case, indicating that the nonthermal population moves further into the tail at low $\sigma$. We find that $\gamma_{\text{nth}}/\gamma$ is well fit by $1 + 1.5(\langle \sigma \rangle)^{-0.3}$.

4.2 Fokker-Planck model fits

To explain the nature of the quasi-thermal distributions observed in our simulations, we compare them to theoretical expectations from stochastic particle acceleration. Analytic models of nonthermal particle acceleration in a turbulent environment are generally formulated using the Fokker-Planck advection-diffusion equation in momentum space (e.g., Blandford & Eichler 1987; Schlickeiser 1989; Chandran 2000). In Appendix A, we derive an analytic solution to the Fokker-Planck equation with a radiative cooling term, as...
Table 2. Fokker-Planck parameters

| Case     | $\langle \sigma \rangle$ | $\Gamma_0 = \Gamma_2$ | $\Gamma_h$ | $\Gamma_a$ |
|----------|-------------------------|----------------------|------------|------------|
| rM1d4    | 0.29                    | 3.0                  | -1.0       | -20.0      |
| rL1      | 0.90                    | 1.8                  | -3.0       | -8.0       |
| rM4      | 3.4                     | 1.4                  | -5.0       | -3.5       |

Assuming that the advection coefficient is linear in momentum and the diffusion coefficient is quadratic in momentum:

$$A_p \propto \Gamma_h \gamma_0 + \Gamma_a \gamma,$$

$$D_{pp} \propto \Gamma_0 \gamma_0^2 + \Gamma_2 \gamma^2.$$  \hfill (12)

These terms thus model first-order and second-order Fermi acceleration processes, respectively (Fermi 1954, 1949). We choose the characteristic energy $\gamma_0 = 300$, comparable to the mean particle energy in the simulations. The remaining four parameters describe the rates for the various terms in the Fokker-Planck equation: energy-independent diffusion $\Gamma_0$, second-order diffusive acceleration $\Gamma_2$, energy-independent advection (heating) $\Gamma_h$, and first-order acceleration $\Gamma_a$. Note that the second-order acceleration term ($\Gamma_2$) alone yields the Maxwell-Jüttner distribution as a solution, while other terms contribute to the modest nonthermal population. As a simplification, we choose $\Gamma_0 = \Gamma_2$. After these restrictions, the resulting steady-state solution (Eq. A8) that we fit to has three free parameters ($\Gamma_2$, $\Gamma_a$, and $\Gamma_h$) which may vary with $\langle \sigma \rangle$ and, in principle, $L/2\pi\rho$.

In Fig. 17, we fit the particle energy distributions from the largest simulations (cases rM1d4, rL1, and rM4) with the solution from the Fokker-Planck model. We are able to obtain very good fits to all three simulations, with the fitting parameters depending on $\langle \sigma \rangle$ as shown in Table 2. In these fits, we limited ourselves to $\Gamma_2 \propto c/v_A$, motivated by second-order Fermi acceleration or gyroresonant interactions with Alfvén waves (Eq. A11) (Miller et al. 1990). Curiously, the advection terms are negative, implying that there is a first-order cooling (or deceleration) process, consistent with measurements from tracked particles in previous non-radiative turbulence work (Wong et al. 2019). The first-order acceleration term ($\Gamma_a$) becomes less negative as $\langle \sigma \rangle$ increases, indicating that there may be a competing first-order acceleration process that becomes important in the high-$\sigma$ regime. Given the admittedly considerable amount of freedom in fitting to the Fokker-Planck solution and interpreting the parameters, we limit this work to a proof of concept. Thus, we defer a more complete, self-consistent analysis of the Fokker-Planck equation (using tracked particles to directly measure the diffusion and advection coefficients) to future work.

4.3 Temporal variability of energy distribution

Having completed our characterization of the steady-state particle energy distribution, we next turn to the temporal variability of the distribution. To illustrate the overall variability of the energy distributions, in Fig. 18 we overlay $f(\gamma)$ at 20 different times (during statistical steady state) for two simulations: a high-magnetization case ($\langle \sigma \rangle = 3.4, 512^3$) and a low-magnetization case ($\langle \sigma \rangle = 0.2, 512^3$). We find that the high-magnetization case exhibits a significant amount of variability in the high-energy tail, with the tail often shifting by a factor of $\sim 2$ in energy. The low-magnetization case, on the other hand, is very stable in time.

We now consider the temporal variability of the $\langle \sigma \rangle = 3.4, 512^3$ case in more detail. In the top panel of Fig. 19, we show the time-evolution of the nonthermal energy and particle number fractions, $E_{nth}/E_{tot}$ and $N_{nth}/N_{tot}$. We find that $E_{nth}/E_{tot}$ and $N_{nth}/N_{tot}$ both typically vary by a factor of $\sim 2$ on timescales of $\sim L/v_A$ (with values ranging from $\sim 0.1$ to $\sim 0.5$ for the former and $\sim 0.05$ to $\sim 0.25$ for the latter). There are several nonthermal energization events indicated...
by spikes in the energy and number of nonthermal particles. We focus on one particular energization event, at time $t v_A / L \sim 26.0$, which we refer to as the *fiducial event* in the remainder of the paper. We show the particle distribution corresponding to the fiducial event, along with an earlier time $t v_A / L = 24.5$ and later time $t v_A / L = 27.4$, in the center panel of Fig. 19. Whereas $f(\gamma)$ is close to thermal at an earlier time ($t v_A / L = 24.5$), it becomes significantly harder and extends to higher energies during the event. This indicates that the system exhibits significant kinetic variability on global scales. In the bottom panel of Fig. 19, we show the evolution of turbulent magnetic energy and particle kinetic energy (bulk and internal combined) for the simulation, with the fiducial event marked by a dashed line. We find that the magnetic energy has a noticeable drop (by $\sim 50\%$) just before the event; the particle energy grows to a local maximum just after the event, although its increase is small compared to the decrease in magnetic energy (indicating that a significant fraction of the energy was lost to radiation). These results together suggest that magnetic reconnection of the large-scale fields may play a role in the energization, which we revisit in Sec. 4.7. We will investigate the fiducial event in more detail in the following subsections.

4.4 Momentum anisotropy distributions

The next topic that we tackle is the anisotropy of the global particle momentum distribution $F(p)$. Since radiation is emitted in the direction of particle motion, the momentum anisotropy has implications for observable radiative signatures. In particular, phenomena such as the kinetic beaming of high-energy particles may cause rapid time variability in the overall momentum anisotropy, as discussed by Cerutti et al. (2012, 2013); Mehlhaff et al. (2019) in the context of relativistic magnetic reconnection.

To characterize the anisotropy of the momentum distribution, we condition $F(p)$ on particles in given energy ranges. We define the particle momentum anisotropy distribution for energies between a lower threshold $\gamma_{\text{thr,1}}$ and

![Figure 19](image2.png)

**Figure 19.** Top panel: Evolution of nonthermal energy fraction (blue) and number fraction (red) for the $(\sigma) = 3.4, 512^3$ case. The fiducial nonthermal energization event at $t v_A / L = 26.0$ is marked with the vertical dashed line. Center panel: Particle energy distributions $f(\gamma)$ at times $t v_A / L \in \{24.5, 26.0, 27.4\}$, showing hardening of the distribution during the fiducial event. The thermal part at $t v_A / L = 26.0$ is also shown (black, dashed). Bottom panel: Evolution of turbulent magnetic energy (red) and particle kinetic energy (magenta) relative to the energy of the mean magnetic field $E_{\text{mean}}$. 

MNRAS 000, 1–25 (2019)
upper threshold $\gamma_{\text{thr},2}$ by

$$f(\theta, \phi | \gamma < \gamma_{\text{thr},1}, 1 < \gamma < \gamma_{\text{thr},2}) \equiv \int_{\gamma_{\text{thr},1}}^{\gamma_{\text{thr},2}} d\gamma f(\theta, \phi, \gamma),$$

where $f(\theta, \phi, \gamma) = \frac{m_e c^2 \sin \theta F(p)}{\gamma}$, with $F(p)$ being the (spatially averaged) three-dimensional particle momentum distribution (for positrons and electrons combined) and $p/m_e c = (\gamma \cos \phi \sin \theta, \gamma \sin \phi \sin \theta, \gamma \cos \theta)$. We assumed ultra-relativistic particles. Thus, $\theta$ and $\phi$ are the polar and azimuthal angles (respectively) of the momentum vector with respect to the global mean field $B_0$. In the following, we use the Mollweide projection to display the particle anisotropy distributions in an area-preserving way. We normalize $f(\theta, \phi, \gamma)$ to the time- and direction-averaged value for the given range of $\gamma$.

We first consider the momentum anisotropy distributions for the low-energy particles, defined as those with $\gamma < 800$. In Fig. 20, we show the low-energy anisotropy distributions, $f(\theta, \phi | \gamma < 800)$, in nine snapshots of the $512^3$, $\langle \sigma \rangle = 3.4$ case (spanning from $tv_A/L = 12.0$ to $tv_A/L = 28.0$, shown every $\approx 2L/v_A$). We find that the anisotropy distribution typically exhibits wide-angle particle beams, which are signatures of large-scale bulk flows. An example of a particularly conspicuous bulk flow is at time $tv_A/L = 16.0$, where a beam with amplitude $\sim 3$ times the mean isotropic value dominates the anisotropy map.

Next, in Fig. 21, we show similar momentum anisotropy distributions for high-energy particles ($\gamma > 1600$) in the same nine snapshots of the $512^3$, $\langle \sigma \rangle = 3.4$ case. In contrast to the low-energy particles, we find that the energetic particle populations are characterized by finer angular structure, organized in an ensemble of narrow beams. These beams have random orientations, but are most commonly directed perpendicular to $B_0$. We find that the intense high-energy particle beams are often correlated with the low-energy bulk flows (e.g., at time $tv_A/L = 16.0$), indicating that the nonthermal population is boosted by the flow, not unlike minijet models (Lyutikov 2006; Giannios et al. 2009; Narayan & Kumar 2009; Kumar & Narayan 2009). However, we also find cases of multiple narrow high-energy beams in the absence of significant low-energy bulk flows (e.g., at times $tv_A/L = 20.0$ and $tv_A/L = 24.0$), suggesting inherently kinetic beaming phenomena. We also find some times where beams are almost entirely absent (e.g., at times $tv_A/L = 12.0$ and $tv_A/L = 22.0$). An animation of the momentum anisotropy distribution is available as supplementary material.

In contrast to the high magnetization cases, we find that the low magnetization cases ($\langle \sigma \rangle \lesssim 1$) do not exhibit significant kinetic beaming. To demonstrate this, we show the probability distribution function (PDF) for the momentum anisotropy distribution bin values. This PDF highlights the probability for $f(\theta, \phi, \gamma)$ to reach extreme values. The measured PDF is shown in Fig. 22 for $384^3$ simulations with $\sigma \in \{0.04, 0.8, 11\}$, both for low-energy particles ($\gamma < 800$) and for high-energy particles ($\gamma > 1600$). The PDF for high-energy particles has broader tails when $\sigma$ is higher, indicat-

Figure 20. Momentum anisotropy distributions for low-energy particles, $f(\theta, \phi | \gamma < 800)$, at nine different times for the $512^3$, $\langle \sigma \rangle = 3.4$ case.

Figure 22. The probability distribution function for the momentum anisotropy distribution $f(\theta, \phi, \gamma)$ bin values, for low-energy particles ($\gamma < 800$, dashed) and high-energy particles ($\gamma > 1600$, solid), in $384^3$ simulations with $\sigma \in \{0.04, 0.8, 11\}$. 
Momentum anisotropy distributions averaged over Figure 23. The two curves correspond to different energy bands: low energy (γ < 800) and high energy (γ > 1600). The low-energy population typically varies by a factor of ~ 2 on timescales comparable to ~ L/υ_A, while the high-energy population exhibits a much more intermittent evolution, characterized by rapid beaming events. Nevertheless, enhancements in both high-energy particle and low-energy particle populations are strongly correlated, indicating that beaming is enhanced by bulk motion. We find that during the fiducial event, the population in the high-energy band increases by a factor of ~ 40 over the time- and direction-averaged value. For comparison, in the bottom panel of Fig. 25, we show the evolution of the anisotropy distribution in the direction of the strongest beam in the simulation (occurring at tv_A/L = 28.7). f(θ = 110°, ϕ = 74°|γ), which attains an even stronger peak, ~ 100 greater than the average. In terms of radiative signatures, these results imply that kinetic beams can appear as flares that are orders of magnitude more intense than the average emission.

4.6 System size dependence

An important question is whether the properties of intermittent high-energy particle beams depend on system size. Indeed, if the structures responsible for the beam have sizes comparable to the kinetic scales, one may anticipate that the momentum anisotropy distribution will become increasingly homogeneous for larger systems, due to the beaming events becoming weaker or due to the large number of superimposed beaming events being washed out in the global anisotropy. As a first step toward answering this question, we consider the PDF for the momentum anisotropy distribution bin values for simulations of varying system size (similar as we did for varying |σ| in Fig. 22). The measured PDF is shown in Fig. 26 for |σ| = 3.4 cases with two different sizes: L/2π(ρ_c) = 18.0 (256^3) and L/2π(ρ_c) = 39.1 (512^3). We find that low-energy particles (with γ < 800) have similar PDFs in both cases, but the high-energy particles (with γ > 1600) have a narrower PDF in the larger simulation, with a high-energy cutoff that is roughly a factor of two smaller in energy. This suggests that the beams are less intense at larger system sizes, and the PDF in the limit of asymptotically large sizes is unclear. A more careful, complete investigation of the system size dependence of kinetic beaming is left to future work.

4.7 High-energy particle density profile

To better understand the physical origin of the kinetic beams, we next consider the spatial profile of the high-energy particle density. In the following, we define the high-energy particles as particles with γ > 800 (roughly 2.5γ), and subsequently describe the number density field of these high-energy particles, which we denote by n_{he}(x).

In the three panels of Fig. 27, we show contours of the high-energy particle density on a snapshot of the 512^3.
V. Zhdankin et al.

Figure 24. Momentum anisotropy distributions for high-energy particles, \( f(\theta, \phi | \gamma > 1600) \), over a duration of \( 0.24L/v_A \) covering the fiducial beaming event at \( \theta = 122^\circ \) and \( \phi = 174^\circ \), from the \( 512^3 \), \( \langle \sigma \rangle = 3.4 \) case. Note that the coordinate system has been shifted by \( 180^\circ \) in \( \phi \) for clarity.

Figure 25. The evolution of the momentum anisotropy distribution \( f(\theta, \phi | \gamma) \) versus time in two different energy bands (\( \gamma < 800 \), blue; \( \gamma > 1600 \), red), for the \( 512^3 \), \( \langle \sigma \rangle = 3.4 \) case, taken in two different directions. Top panel: \( \theta = 122^\circ \) and \( \phi = 174^\circ \), coinciding with the beam from the fiducial event at \( tv_A/L = 26.0 \) (shown in Fig. 24). Bottom panel: \( \theta = 119^\circ \) and \( \phi = 74^\circ \), coinciding with the strongest beam in the simulation at \( tv_A/L = 28.7 \).

\( \langle \sigma \rangle = 3.4 \) case, averaged in the \( z \) direction across \( L/32 \) of the domain (to reduce noise from the small population size). These contours are overlaid on top of images of the cell-averaged particle Lorentz factor \( \gamma_{\text{avg}} \) (top panel), the heating rate proxy \( \mathbf{E} \cdot \mathbf{J} \) (center panel), and the magnitude of the current density \( J \) (bottom panel). We find that \( n_{\text{he}} \) is strongly localized in space and strongly correlated with all three quantities (\( \gamma_{\text{avg}} \), \( \mathbf{E} \cdot \mathbf{J} \), and \( J \)). The strong correlation of \( n_{\text{he}} \) with \( \gamma_{\text{avg}} \) suggests that high-energy particles are energized locally at the same sites as where much of the overall bulk plasma heating occurs. The correlation of \( n_{\text{he}} \) with \( \mathbf{E} \cdot \mathbf{J} \) indicates that this energization is rapid, with high-energy particles confined to locations near the sites of energization. The correlation of \( n_{\text{he}} \) with intense, intermittent current sheets (and filaments) hints that magnetic reconnection may play a role in energizing and beaming the particles. Note, however, that the correlation is imperfect: there are some current sheets which lack high-energy particles (perhaps indicating that reconnection is inefficient in those structures, e.g., Zhdankin et al. 2013), and some clusters of high-energy particles that are far away from current sheets (possibly a consequence of alternative channels of energy dissipation). High-energy particles are less well localized in the low magnetization simulations, consistent with weaker kinetic beaming in that regime (not shown).

4.8 Tracked particle properties

Finally, to gain insight into the underlying charged particle dynamics, we consider some properties of tracked particles in the simulations. We randomly track \( 20,000 \) of the simulated particles in each case, recording their positions, momenta, and field values starting at a time \( t_0 \) that is during statis-
Figure 27. The cell-averaged particle energy $\gamma_{\text{avg}}$ (top), heating rate proxy $E \cdot J$ (center), and current density $J$ (bottom), all with overlaid contours of the high-energy particle number density, $n_{\text{he}}$ (with green contours at 4 and 8 times $n_{\text{he}}$). All quantities are averaged in the $z$ direction over $L/32$ of a snapshot from the $\langle \sigma \rangle = 3.4$, 512$^3$ case.

Figure 28. The different contributions to the energy gain $\Delta \gamma$ for representative tracked particles in the 512$^3$ simulations with $\langle \sigma \rangle = 0.2$ (top) and $\langle \sigma \rangle = 3.4$ (bottom). The lines correspond to contributions from the parallel electric field (blue), perpendicular electric field (red), and overall electric field (black, dashed). We also show the energy radiated by the particle (green).

With this information, we measure the amount of energy that each particle gains from the electric field component parallel to the magnetic field ($E || = E \cdot \hat{B}$, absent in ideal MHD) and from the component perpendicular to it ($E \perp = E - E ||$, representative of the ideal MHD component), along with the energy lost to radiation. These energy contributions can be expressed, respectively, for the $i$th tracked particle, as

$$
\Delta \gamma_{||,i}(t) = \frac{q_i}{m_e c^2} \int_{t_0}^{t} dt' \left( E_{||}(x_i(t'), t') \cdot v_i(t') \right),
$$

$$
\Delta \gamma_{\perp,i}(t) = \frac{q_i}{m_e c^2} \int_{t_0}^{t} dt' \left( E_{\perp}(x_i(t'), t') \cdot v_i(t') \right),
$$

$$
\Delta \gamma_{\text{rad},i}(t) = -\frac{1}{m_e c^2} \int_{t_0}^{t} dt' \left( F_{\text{IC}}(v_i(t')) \cdot v_i(t') \right),
$$

(14)

obtained by integrating Eq. 1 from the reference time $t_0$ to the given time $t$.

We first show, in Fig. 28, these contributions to the particle energy change $\Delta \gamma$ for two representative electrons: one from the 512$^3$, $\langle \sigma \rangle = 0.2$ case and the other from the 512$^3$, $\langle \sigma \rangle = 3.4$ case. In the low $\sigma$ case, changes in the particle...
energy are very slow and irregular, and are almost entirely
due to $E_\perp$. In the high $\sigma$ case, the energization is also
dominated by $E_\perp$, and occurs from a mixture of gradual heat-
ing and rapid, isolated energization events. It is tempting
to associate the latter events with energization in current
sheets, and thus with the kinetic beams. Indeed, these ac-
celeration episodes are often preceded by a small energy kick
from $E_\parallel$, reminiscent of results from 2D relativistic kinetic
turbulence that suggest a two-stage acceleration process in
which $E_\parallel$ (within intermittent current sheets) injects parti-
cles to energies where they can resonantly interact with the
turbulent fluctuations (Comisso & Sironi 2018). In contrast
to the rough evolution of energization from the electric fields,
the amount of radiated energy shows a relatively smooth in-
crease in time. On average, the amount of radiated energy
balances out the energy gain from electric fields.

We next show the different contributions to $\Delta \gamma$ averaged
for all tracked particles, again for the $512^3$ cases, in Fig. 29. We find that these contributions
increase linearly in time, consistent with the statistical
steady state and constant rate of energy injection. We com-
pare the radiated energy with Eq. 4 to extract an injection
efficiency of $\eta_{\text{inj}} = 1.4$ and $\eta_{\text{inj}} = 2.1$ for the two cases,
respectively. The first value is consistent with $\eta_{\text{inj}}$ inferred
from the thermal equilibrium condition in Section 3.2, while
the second is somewhat larger. The differences between the
two approaches at high $\sigma$ may be attributed to significant
deviations from a uniform Maxwell-Jüttner distribution (an
assumption required to estimate the equilibrium tempera-
ture).

To get a sense of the relative importance of the different
electric field components at varying magnetizations, in Fig. 30 we show the relative energy gain from perpendicular
electric fields, $\Delta \gamma_{\perp,i}/(\Delta \gamma_{\perp,i} + \Delta \gamma_{\parallel,i})$, versus $\langle \sigma \rangle$, averaged
for all tracked particles in the $384^3$ simulation series. We
find that at low $\langle \sigma \rangle$, more than 90% of the energization is
due to $E_\perp$. At high $\langle \sigma \rangle$, however, this percentage decreases,
with only $\sim 50\%$ of the energization from $E_\perp$, and the rest
from $E_{\parallel}$, at $\langle \sigma \rangle \sim 10$. The preferential perpendicular en-
ergization is qualitatively similar to recent results from hy-
brid kinetic simulations of non-relativistic turbulence (Arza-
maskiy et al. 2019) and from PIC simulations of the kink
instability (Álvés et al. 2018, 2019).

The energization of particles by $E_\perp$ is generally con-
sistent with diffusive acceleration mechanisms (e.g., second-
order Fermi or gyroresonant scattering), further supporting
results in Section 4.2. The energization by $E_{\parallel}$ in the high
$\sigma$ regime, on the other hand, may be attributed to parti-
cles that are directly accelerated by the electric field within
the current sheets during magnetic reconnection (also pre-
viously suggested in the low $\beta$ non-relativistic regime, e.g.,
Makwana et al. 2017).

5 DISCUSSION

5.1 Generic blazar emission

In this section, we consider the implications of our numerical
results for high-energy astrophysical systems, choosing to
focus on blazar jets.

The generally thermal character of the particle distributions
obtained from radiatively balanced driven turbulence
suggests that a single-zone model of this kind does not account for the bulk of the relatively stable power-law emission spectrum from blazar jets (as well as other sources such as pulsar wind nebulae and black-hole accretion flows). If the radiative cooling is strong, these spectra likely reflect the cumulative particle acceleration from numerous transient events (such as discrete reconnection events or decaying turbulence), distributed within the source, each contributing a burst of nonthermal particles which cool radiatively at later times (i.e., after the end of the energization event).

However, an intriguing alternative is that a power-law spectrum could result from the superposition of thermal peaks from an array of radiatively balanced turbulent regions with a power-law distribution of relativistic temperatures along the blazar jet (see, e.g., Henri & Saugé 2006; Boutelier et al. 2008). For example, consider a Poynting flux-dominated jet, comprising pair plasma, carrying a luminosity

\[ L_j = 10^{46} L_{46} \text{ erg s}^{-1} = \Omega_j r_j^2 \Gamma_j^2 B_0^2 4\pi c, \]

(15)

where \( \Omega_j \) is the jet solid angle, \( \Gamma_j r_j \) is the bulk Lorentz factor, \( r = 10^8 r_{18} \) cm is the distance from the black hole, and \( B_0(r) \) is the typical magnetic field in the jet comoving frame. We consider photons upscattered from an external radiation field \( U_{ph}(r) \) (e.g., supplied by the broad emission line region or dusty torus, and expressed in the jet comoving frame),

\[ U_{ph} = 4\pi \sigma_{ph} \delta_{ph} \frac{L_j}{4\pi c r^2}, \]

(16)

where \( \delta_{ph} \sim 0.01-0.1 \) is the fraction of jet power in the seed photon field. Following the analysis in Section 2.1, assuming a pair plasma composition, we then obtain the average particle Lorentz factor,

\[ \gamma = \frac{3\pi}{4} \sigma_{ph} \frac{\eta_{inj} \left( \frac{r}{\Gamma_j L_{18}} \right)}{\sigma_T L_j \Gamma_j} \sim \frac{\eta_{inj} \left( \frac{r}{\Gamma_j L_{18}} \right)}{L_{46} \Gamma_1}, \]

(17)

where \( L_{18}(r) \) represents the size of a turbulent region inside the jet, presumably driven by internal instabilities such as the kink mode (Begelman 1998; Dus & Begelman 2019). For the sake of argument, if we assume \( L_{18} \sim 0.1 r / \Gamma_j \) and \( \eta_{inj} \sim 0.1 \), then from Eq. 17 we would estimate

\[ \gamma \sim \frac{\sigma_{inj} \left( \frac{r}{\Gamma_j L_{18}} \right)}{\sigma_{ph} L_{46} \Gamma_1}. \]

(18)

If we next assume that \( \Omega_j \) and \( \Gamma_j \) are independent of \( r \), then conservation of both Poynting flux and particle flux implies that \( \gamma \propto r^{-1/2} \) (solving Eqs. 15 and 18) and the energy of produced Compton photons is \( \epsilon \propto r \) (given a fixed seed photon energy). The volume emissivity in the comoving frame is then \( n_0 \epsilon^2 / 4 \pi \propto r^{-3} \propto dI / dr \), the derivative of the frequency-integrated intensity entering the line of sight from radius \( r \). If we assume that the solid angle contributing to this intensity is proportional to \( r^2 \) (consistent with \( \Omega_j \) independent of \( r \)), then the frequency integrated flux satisfies \( dF / d\nu \propto r^{-1} \), which gives a spectral index comparable to observed values in the \( \gamma \)-ray band (Madejski & Sikora 2016). Elaboration of this model to more realistic turbulent jet propagation will have to await further work.

5.2 Blazar flares

The strong anisotropies and flaring behavior obtained from radiatively cooled kinetic turbulence at \( \sigma \gg 1 \) provide an appealing model for high-energy flares from blazars. In standard models, where the flare variability timescale is assumed to be associated with the bulk dynamics of the jet or a localized energy release process within it, there is a tension between the short flare timescales and constraints that place the emitting region rather far from the black hole. This tension is particularly acute when considering very-high-energy gamma-ray (TeV) flares from flat-spectrum radio quasars (FSRQs), where the flares must be produced on parsec scales in order to avoid being absorbed in pair production against the ambient diffuse radiation background (Begelman et al. 2008; Nalewajko et al. 2014; Madejski & Sikora 2016). Such flares have been observed to be as short as a few minutes (Aharonian et al. 2007; Albert et al. 2007). If, however, the flares represent extremely relativistic beams of particles swinging past the observer’s line of sight, the timescale and energetics are largely decoupled from the size and location of the emitting region.

Returning to the model in Section 5.1, to create a flare at \( \epsilon_{\gamma} \times 10^{-6} \text{ TeV} \) energies by upscattering seed photons of energy \( \epsilon_{\nu,0} \times 10^{-7} \text{ eV} \), typical of the broad line region, we need \( \gamma \approx 10^{4} \Gamma_1^{-1/2} \epsilon_{\gamma} / \epsilon_{\nu,0} 1/2 \) (assuming scattering by particles from a narrow quasi-thermal distribution), implying \( \sigma \sim 10^{-3} - 10^{-4} \) for fiducial values of \( L_{18} \) and \( r \). Thus, a self-consistent model invoking radiatively cooled turbulence in an FSRQ would have to have an enormous \( \sigma \) and could therefore, extrapolating our numerical results, presumably produce extremely short and intense flares even at large distances from the black hole.

Since we know very little about how mass is loaded onto the base of a jet, it is quite possible that jets start out with enormous values of \( \sigma \), especially if they are powered by black hole spin via the Blandford-Znajek mechanism (in which case they are also likely to be pair-dominated) (Blandford & Znajek 1977). Whether such high values of \( \sigma \) can be sustained out to parsec-scale distances is a separate question. In ideal MHD models for relativistic jet production assuming cold plasma, with a ratio of jet power to its rest mass energy flux \( \mu \gg 1 \), the flow typically accelerates to Lorentz factor \( \Gamma \sim \mu^{1/3} \) near the light-cylinder radius (near the fast magnetosonic point: e.g., Begelman & Li 1994) and can accelerate (more slowly) subsequently to \( \Gamma \sim O(\mu/2) \), corresponding to approximate equipartition between Poynting flux and relativistic enthalpy flux, \( \sigma \sim O(1) \). However, these results apply primarily to cold, non-dissipative flows, whereas the entire premise of our analysis here is that internal instabilities lead to dissipation while drag in an external radiation field hampers acceleration. If these effects are operating at relatively small radii within the flow, it would seem possible for a large value of \( \sigma \) to get “frozen” into the jet flow, since once the magnetic field twists into an overwhelmingly toroidal configuration, as measured in the comoving jet frame, it is very difficult for it to share additional energy with the particle flow (Begelman & Li 1994).

The above results apply to a pair-dominated jet; the effect of an ion component on radiatively cooled turbulence is outside the scope of this paper. The ions would effectively not cool at all, but would probably receive the majority of
dissipated energy (Zhdankin et al. 2019), suggesting that the true value of $\sigma$ could be much lower due to a hot ion component. A self-consistency condition that needs to be met in order for external IC to dominate over synchrotron cooling, $B_0^2/8\pi < U_{\gamma\text{ph}}$, could be violated if $\delta_{\text{ph}}$ or $\Gamma_j$ is too small.

A cooled turbulence model is also attractive for explaining flares from BL Lac-type blazars, which lack an intense ambient radiation field. Here it is plausible that the jet emission is self-contained and likely due to the SSC process, and even larger values of $\sigma$ (at least the $\sigma$ associated with the electron or pair content) would be required.

6 CONCLUSION

In this work, we conducted and studied the results from a series of PIC simulations of driven turbulence in relativistic collisionless pair plasma with external IC radiation. We focused on understanding the statistical properties of turbulent fluctuations and particle distributions during the statistical steady state, where injected energy from external driving is balanced by radiative energy losses. We performed a parameter scan over the steady-state magnetization $\langle \sigma \rangle$ and system size $L/2\pi \langle \rho_e \rangle$, to the extent that computational resources allowed. We now summarize our main results:

(i) Regardless of initial conditions, turbulence acquires a rigorous statistical steady state (by heating or cooling) with an equilibrium temperature that is close to analytic predictions (Eq. 7) and can be controlled by adjusting the energy density of the external photon bath, $U_{\gamma\text{ph}}$. Radiative turbulence thus provides an ideal scenario for studying the fundamental properties of kinetic turbulence.

(ii) The properties of turbulence change from low $\langle \sigma \rangle$ to high $\langle \sigma \rangle$. The former looks like standard non-relativistic MHD turbulence, apart from the tendency to have rotational magnetic fluctuations. The latter has fluctuations that are highly relativistic, compressible, and electromagnetically dominated.

(iii) The steady-state particle energy distributions are always close to the thermal (Maxwell-Jüttner) distribution, with only a modest nonthermal population (broadening the tail by a factor of $\sim 2$ in energy). The nonthermal population is more temporally variable and energetically significant at high $\langle \sigma \rangle$.

(iv) These steady-state particle energy distributions are well fit by analytic solutions to the Fokker-Planck equation describing stochastic particle acceleration, for simple forms of the momentum advection and diffusion coefficients (linear and quadratic in energy, respectively). The diffusion coefficient scales with $\langle \sigma \rangle$ in a way that is consistent with second-order Fermi acceleration or gyroresonant interactions with Alfvén modes. Tracked particles are mainly energized by the perpendicular electric field (for the accessible $\langle \sigma \rangle$), lending further evidence for this mechanism.

(v) In the high magnetization regime, the nonthermal particle population is intermittently beamed in random directions. This produces a fine-scale anisotropy in the global momentum distribution, which can be manifest as highly variable radiative signatures. The beaming becomes weaker as the system size is increased, however, raising questions about beaming statistics in the limit of large system size.

(vi) The beamed high-energy particles are spatially correlated with intermittent current sheets, suggesting that magnetic reconnection may locally energize the nonthermal particles.

This work takes the first step in numerically investigating radiative turbulence in collisionless plasmas, but it is far from complete or comprehensive. Future directions include studying the effect of synchrotron cooling (which is self-consistently determined from the magnetic energy density rather than an external photon field), the weak cooling regime (which will not be in steady state, but may impose a high-energy cutoff to the particle energy distribution), and radiative cooling in electron-ion plasmas (which do not necessarily have a steady state due to ions being inefficient radiators). Although this work has established the existence of intermittent beaming in turbulence, the beam statistics and corresponding radiative signatures (especially in the large system limit) require a deeper investigation.

We can then write
\[ A \]
and
\[ \Gamma \]
where
\[ \partial \]
We now consider the steady state, the Fokker-Planck equation, along with a radiative cooling term, can be written as
\[ \frac{\partial}{\partial x} \left[ \tau \frac{\partial f}{\partial x} \right] = -\frac{\partial}{\partial \gamma} \left( \Gamma \frac{\partial f}{\partial \gamma} - \frac{\sigma}{\tau} \frac{\partial f}{\partial \gamma} \right) , \]

\[ f(x) \propto x^2 \left( \Gamma_0 + \Gamma_1 x + \Gamma_2 x^2 \right)^{(\Gamma_1 + \Gamma_2)/2} \exp \left( \frac{-x}{\Gamma_2} \right) \times \exp \left[ \frac{2 \Gamma_0 \Gamma_2 - \Gamma_1^2}{\Gamma_2^2} \tan^{-1} \left( \frac{\Gamma_1 + 2 \Gamma_2 x}{\sqrt{\Gamma_2^2 - \Gamma_1^2}} \right) \right] . \]

As \( x \to 0 \), as long as \( \Gamma_0 > 0 \), \( f(x) \sim x^2 \) as required by continuity. At intermediate values of \( x \), for nonzero \( \Gamma_0 > 0 \), if the ordering \( \Gamma_0 < \Gamma_1 x < \Gamma_2 x^2 \) is satisfied, there may be a power law with index \( 2 + (\Gamma_1 + \Gamma_2)/2 \Gamma_2^2 \) (which is thus increasing with energy unless \( \Gamma_0 \) is sufficiently negative). Finally, at large \( x \gtrsim \Gamma_2 \), there is an exponential cutoff. If all \( \Gamma_0 \) are zero except for \( \Gamma_2 \), then a Maxwell-Jüttner distribution is recovered, with temperature \( \Theta = \Gamma_2 \gamma_0 \). In general, adding the other \( \Gamma \) produces modest nonthermal corrections to the Maxwell-Jüttner distribution.

In this work, we restrict ourselves to \( \Gamma_1 = 0 \) and \( \Gamma_0 = 0 \) (anticipating that the diffusion process becomes independent of energy for particles with energies less than the mean energy). Thus, the advection and diffusion coefficients are
\[ A_p = \frac{\gamma_0}{\tau_e} (\Gamma_h + \Gamma_s x) , \]
\[ D_{pp} = \frac{\gamma_0}{\tau_e} \Gamma_2 \left( 1 + x^2 \right) . \]

Eq. A6 then becomes the three-parameter solution
\[ f(x) \propto x^2 \left( 1 + x^2 \right)^{\gamma_a/2} \exp \left( -\frac{x}{\Gamma_2} + \frac{\Gamma_1 + 1}{\Gamma_2} \tan^{-1} x \right) . \]

Note that since fitting to a physical distribution requires choosing \( \gamma_0 \), the actual number of fitting parameters is four \( (\gamma_0, \Gamma_h, \Gamma_s, \text{ and } \Gamma_2) \).

We choose the remaining parameters as follows. We set \( \gamma_0 = 300 \), approximately the mean energy measured in the simulations. We suppose that the diffusive acceleration timescale is given by (isotropic) second-order Fermi acceleration (Longair 2011) or gyrosorontal interactions with Alfvenic fluctuations (e.g., Schlickeiser 1989), which can be expressed by
\[ \tau_e \sim \frac{3 \lambda_{mfp} c}{v_A^2} \sim \frac{3 L}{\eta \sigma c} , \]

where \( \lambda_{mfp} = v_A (1 - v_A^2/c^2)^{-1/2} \) is the Alfven four-velocity, \( \lambda_{mfp} \) is the scattering mean free path, and \( \eta \) is the efficiency of scattering. Using the radiative steady-state condition (Eq. 5), assuming \( \theta_{ss} = \gamma_0/3 \), we also have
\[ \tau_e = \frac{4}{\eta_{mfp} \sigma v_A} . \]

Combining the two, we obtain
\[ \Gamma_2 = \frac{\tau_e}{\tau_2} \sim \frac{4 \eta_{mfp} c}{3 \eta_{mfp} v_A} \sim \frac{c}{v_A} . \]

We thus take \( \Gamma_2 \sim c/v_A \) when comparing different simulations with varying \( \sigma \). We then have two unconstrained parameters, \( \Gamma_h \) and \( \Gamma_s \), which we choose by hand. These two terms control the effect of heating processes and first-order acceleration processes, respectively, which have not (to our
best knowledge) been rigorously modeled by past analytic works.
