We discuss a role of diproton correlation in two-proton emission from the ground state of a proton-rich nucleus, $^6$Be. Assuming the three-body structure of $\alpha+p+p$ configuration, we develop a time-dependent approach, in which the two-proton emission is described as a time-evolution of a three-body metastable state. With this method, the dynamics of the two-proton emission can be intuitively discussed by monitoring the time-dependence of the two-particle density distribution. With a model Hamiltonian which well reproduces the experimental two-proton decay width, we show that a strongly correlated diproton emission is a dominant process in the early stage of the two-proton emission. When the diproton correlation is absent, the sequential two-proton emission competes with the diproton emission, and the decay width is underestimated. These results suggest that the two-proton emission decays provide a good opportunity to probe the diproton correlation in proton-rich nuclei beyond the proton drip-line.

I. INTRODUCTION

The pairing correlation plays an essential role in many phenomena of atomic nuclei \cite{1,2}. In recent years, the dineutron and diproton correlations have particularly attracted a lot of interests in connection to the physics of unstable nuclei \cite{6-15}. These are correlations induced by the pairing interaction, with which two nucleons are spatially localized. Since the pairing gap in infinite nuclear matter takes a maximum at the density lower than the normal density \cite{5,12,16,17}, the dinucleon correlation is enhanced on the surface of nuclei. This property may also be related to the BCS-BEC crossover \cite{12,17,18}.

Although the dinucleon correlation has been theoretically predicted for some time, it is still an open issue to probe it experimentally. For this purpose, a pair-transfer reaction \cite{19-21} and the electro-magnetic excitations \cite{22-28} may be considered. However, even though there have been a few experimental indications \cite{22}, so far no direct experimental evidence for the dinucleon correlation has been found, mainly due to a difficulty to access the intrinsic structures in bound nuclei without disturbing with an external field.

This difficulty may be overcome by using two-proton ($2p$-) emission decays (these are referred to as two-proton radio-activities when the decay width is sufficiently small) of nuclei outside the proton drip-line \cite{29-31}. An attractive feature of the $2p$-emission is that two protons are emitted spontaneously from the ground state of unbound nuclei, and thus they are expected to carry information on the pairing correlations inside nuclei, including the diproton correlation \cite{32,33}.

The $2p$-radioactivity was predicted for the first time by Goldansky \cite{36,37}. He introduced the concept of the “true $2p$-decay”, which takes place in the situation where the emission of single proton is energetically forbidden. Although the dinucleon correlation has been theoretically predicted \cite{36-38}, this process should thus intimately be related to the diproton correlation.

Since the time of Goldansky, there has been an enormous progress in the problem of $2p$-decays, both experimentally and theoretically, and our understanding of the $2p$-decays has been considerably improved \cite{29,31}. It has been considered now that the actual $2p$-decays are often much more complicated than the simple diproton decays which Goldansky originally proposed \cite{36-47}. Moreover, it has not been completely clarified whether the diproton correlation can be actually probed by observing $2p$-decays.

The aim of this paper is to investigate the role of the diproton correlation in $2p$-emissions, and discuss a possibility of probing the diproton correlation through the $2p$-decays. For this purpose, one needs to handle a many-body meta-stable state, for which the theoretical frameworks can be categorized into two approaches: the time-independent framework \cite{48,50} and the time-dependent framework \cite{48,51,52}. In the time-independent approach, the decay state is regarded as a pure outgoing state with a complex energy, that is, the Gamow state. The real and the imaginary parts of the complex energy are related to the decay energy and width, respectively. An advantage of this method is that the decay width can be accurately calculated even when the width is extremely small \cite{31,53,55}. In the time-dependent framework, on the other hand, the quantum decay of a metastable state is treated as a time-evolution of a wave packet \cite{54,62}. An advantage of this method is that the decay dynamics can be intuitively understood by monitoring the time-evolution of the wave packet. These two
approaches are thus complementary to each other.

In this paper, we employ the time-dependent approach. This approach has been used in Refs. [56–59] to study one-proton emission decays of proton-rich nuclei. In our previous work [35], we extended this approach to \( \alpha \)-emission in one-dimension. We here apply this method to the \( \alpha \)-state of the ground state of the valence protons. As in Refs. [8, 13, 14, 27], we employ a realistic system, that is, the ground state of \( \alpha \)-emitter, where the \( \alpha \) consists of an \( \alpha \) particle as the spherical core nucleus and two valence protons. As in Refs. [8, 13, 14, 27], we employ the so called \( \alpha \)-coordinate indicated in Fig. 2 Subtracting the center of mass motion of the whole nucleus, the total Hamiltonian reads

\[
H_{3b} = h_1 + h_2 + \frac{p_1 \cdot p_2}{A_{c}m} + v_{pp}(r_1, r_2),
\]

\[
h_i = \frac{p_i^2}{2\mu} + V_{cp}(r_i) \quad (i = 1, 2),
\]

where \( h_i \) is the single particle (s.p.) Hamiltonian between the core and the \( \alpha \)-th proton. \( \mu \equiv m A_{c}/(A_{c} + 1) \) is the reduced mass where \( m \) and \( A_{c} \) are the nucleon mass and the mass number of the core nucleus, respectively. The interaction between \( \alpha \) and a valence proton, \( V_{cp} \), consists of the nuclear potential \( V_{WS} \) and the Coulomb potential \( V_{Coul} \),

\[
V_{cp}(r_i) = V_{WS}(r_i) + V_{Coul}(r_i).
\]

For the Coulomb part of the potential, \( V_{Coul} \), we use the one appropriate to a uniformly charged spherical particle of radius \( r_c = 1.68 \text{ fm} \). For the nuclear part, \( V_{WS} \), on the other hand, we use the Woods-Saxon parametrization given by

\[
V_{WS}(r) = V_0 f(r) + U_{ls}(l \cdot s) \frac{1}{r} \frac{df(r)}{dr},
\]

where

\[
f(r) = \frac{1}{1 + e^{r - R_0/a_0}}
\]

with \( R_0 = r_c \) and \( a_0 = 0.615 \text{ fm} \). We use the depth parameters of \( V_0 = -58.7 \text{ MeV} \) and \( U_{ls} = 46.3 \text{ MeV} \cdot \text{fm}^2 \). This potential yields the resonance energy and the width of the \( (p_{3/2}) \)-channel for \( \alpha - p \) scattering of \( E_r(p_{3/2}) = 1.96 \text{ MeV} \) and \( \Gamma_r(p_{3/2}) = 1.56 \text{ MeV} \), respectively. These values are compared with the experimental data, \( E_r(p_{3/2}) = 1.96(5) \text{ MeV} \) and \( \Gamma_r(p_{3/2}) \sim 1.5 \text{ MeV} \) (see Fig. 1) [63]. We note that this resonance state is quite broad and there has been some ambiguity in the observed decay width [63] [69].

\[ \text{Figure 2: (Color online) The } \text{coordinate for three-body system.} \]
| $S$ | $b_0$ (fm$^{-2}$) | $b_1$ (fm$^{-2}$) | $v_1$ (MeV) |
|-----|----------------|----------------|------------|
| 0   | 1.48           | 0.639          | -178.0     |
| 1   | 1.48           | 0.465          | -91.85     |

Table 1: The values of $b_0$, $b_1$ and $v_1$ in the Minnesota potential given by Eq. (6). $S$ indicates the combined spin of the two protons.

For the proton-proton interaction, $v_{pp}$, we use the Minnesota potential together with the Coulomb term for point charges:

$$v_{pp}(r_{12}) = v_0 e^{-b_0 r_{12}^2} + v_1 e^{-b_1 r_{12}^2} + \frac{e^2}{r_{12}},$$

where $r_{12} = |r_1 - r_2|$. For $b_0$, $b_1$ and $v_1$, we use the same parameters introduced in the original paper [68], as summarized in Table 1. On the other hand, the strength of the repulsive term, $v_0$, is adjusted so as to reproduce the empirical Q-value for the two-proton emission, as we will discuss in Sec. III.

B. Uncorrelated Two-proton Basis

Each s.p. state satisfying $h_i \phi_n(r_i)$ is labeled by $a = \{n_a, l_a, j_a, m_a\}$, that is, a combination of the radial quantum number $n$, the orbital angular momentum $l$, the spin-coupled angular momentum $j$ and its z-component $m$. Using these s.p. wave functions, one can construct the uncorrelated basis for the two protons coupled to an arbitrary spin-parity, $J^\pi$, where the coupled angular momentum $J$ is given by $J = j_a + j_b$ and the total parity $\pi$ is given by $\pi = (-)^{l_a + l_b}$. That is,

$$\Phi^{(J^\pi)}_{ab}(r_1, r_2) = \hat{A} [\phi_a(r_1) \otimes \phi_b(r_2)]^{(J^\pi)},$$

where $\hat{A}$ is the anti-symmetrization operator. In this work, we assume that the core nucleus always stays in the ground state with the spin-parity of $0^+$. Thus the uncorrelated basis given by Eq. (7) are reduced only to the $J^\pi = 0^+$ subspace, since the ground state of $^6$Be also has the spin-parity of $0^+$. That is,

$$\Phi^{(0^+)}_{ab}(r_1, r_2) = \Phi_{n_a n_b j_a j_b}(r_1, r_2)$$

$$= \frac{1}{\sqrt{2(1 + \delta_{n_a n_b})}} \sum_m C(j, m; j_a, m_a) \left[ \phi_{n_a l_a j_a m_a}(r_1) \phi_{n_b l_b j_b - m}(r_2) + \phi_{n_b l_b j_b m}(r_2) \phi_{n_a l_a j_a - m}(r_1) \right].$$

Notice $l_a = l_b$, $j_a = j_b$ for the $0^+$ state. In the following, for simplicity, we omit the superscript $(0^+)$ and use a simplified notation, $|\Phi_M\rangle$, for the uncorrelated basis given by Eq. (8), where $M = \{n_a, n_b, l, j\}$.

The eigen-states of the three-body Hamiltonian, $H_{3b}$, can be obtained by expanding the wave function on the uncorrelated basis,

$$|E_N\rangle = \sum_M U_{NM} |\Phi_M\rangle,$$

where the expansion coefficients, $U_{NM}$, are determined by diagonalizing the Hamiltonian matrix for $H_{3b}$. The state $|E_N\rangle$ then satisfies $H_{3b} |E_N\rangle = E_N |E_N\rangle$ in a truncated space.

All our calculations are performed in the truncated space defined by the energy-cutoff, $\epsilon_a + \epsilon_b \leq E_{cut} = 40$ MeV. The continuum s.p. states are discretized within the radial box of $R_{box} = 80$ fm (notice that the states $|E_N\rangle$ are also discretized). For the angular momentum channels, we include from $(s_{1/2})^2$ to $(h_{11/2})^2$ configurations. In order to take into account the effect of the Pauli principle, we exclude the bound $1s_{1/2}$ state from Eq. (10), that is given by the protons in the core nucleus. We have confirmed that our conclusions do not change even if we employ a larger value of $E_{cut}$ and/or include higher partial waves.

C. Time-Dependent Method for Two-Proton Decay

Assuming the $2p$-emission as a time-dependent process, we carry out time-dependent calculations for the three-body system, $^6$Be. For this purpose, we first need to determine the initial state, $|\Psi(t = 0)\rangle$, for which the two valence protons are confined inside the potential barrier generated by the core nucleus. That is, the $2p$-density distribution at $t = 0$ has almost no amplitude outside the potential barrier. In order to construct such initial state, we employ the confining potential method, which will be detailed in the next section.

The initial state so obtained can be expanded with the eigen-states of $H_{3b}$, that is, $|E_N\rangle$ given by Eq. (10) as

$$|\Psi(0)\rangle = \sum_N F_N(0) |E_N\rangle.$$

After the time-evolution with the three-body Hamiltonian $H_{3b}$, this state is evolved to

$$|\Psi(t)\rangle = \exp \left[-i \frac{H_{3b}}{\hbar} t \right] |\Psi(0)\rangle = \sum_N F_N(t) |E_N\rangle,$$

where

$$F_N(t) = e^{-i E_N \hbar} F_N(0).$$

Notice that the state $|\Psi(t)\rangle$ can also be expanded on the uncorrelated basis as,

$$|\Psi(t)\rangle = \sum_M C_M(t) |\Phi_M\rangle,$$

with

$$C_M(t) = \sum_N F_N(t) U_{NM}.$$
We define the Q-value of the $2p$-emission as the expectation value of the total Hamiltonian, $H_{3b}$, with respect to the initial state, $|\Psi(0)\rangle$. Since the time-evolution operator, $\exp[-iH_{3b}/\hbar]$, in Eq. (12) commutes with $H_{3b}$, the Q-value is conserved during the time-evolution. That is,

$$Q = \langle \Psi(0) | H_{3b} | \Psi(0) \rangle = \langle \Psi(t) | H_{3b} | \Psi(t) \rangle.$$  \hspace{1cm} (16)

We also note that the wave function is normalized at any time: $\langle \Psi(t) | \Psi(t) \rangle = 1$.

In order to extract the information on the dynamics of two-proton emission, it is useful to introduce the decay state, $|\Psi_d(t)\rangle$, which is defined as the orthogonal component of $|\Psi(t)\rangle$ to the initial state [54]. That is,

$$|\Psi_d(t)\rangle = |\Psi(t)\rangle - \beta(t)|\Psi(0)\rangle,$$  \hspace{1cm} (17)

where $\beta(t) = \langle \Psi(0) | \Psi(t) \rangle$. While the initial state is almost confined inside the potential barrier, the main part of the decay state is located outside the barrier. We define the decay probability as the norm of the decay state,

$$N_d(t) = \langle \Psi_d(t) | \Psi_d(t) \rangle = 1 - |\beta(t)|^2.$$  \hspace{1cm} (18)

Notice that $N_d(0) = 0$ since $\beta(0) = 1$. Because $|\beta(t)|^2$ is identical to the survival probability for the decaying process, the decay width can be defined with $N_d(t)$ as [56–59],

$$\Gamma(t) \equiv -\hbar \frac{d}{dt} \ln[1 - N_d(t)] = \frac{\hbar}{1 - N_d(t)} \frac{d}{dt} N_d(t).$$  \hspace{1cm} (19)

It is worthwhile to mention that if the time-evolution follows the exponential decay law, such that

$$[1 - N_d(t)] = e^{-t/\tau},$$  \hspace{1cm} (20)

then $\Gamma(t)$ is related to the lifetime of the meta-stable state: $\Gamma = h/\tau$. This situation is realized when the energy spectrum, defined by $\{|E_N|\}$, is well approximated as a Breit-Wigner distribution [51, 52]. It is useful to define also the partial decay width $\Gamma_s(t)$ in order to understand the decay dynamics. This is defined as the width for the decay to a channel $s$, where the total decay width is given by

$$\Gamma(t) = \sum_s \Gamma_s(t).$$  \hspace{1cm} (21)

The partial decay width can be calculated with the expansion coefficient $a_s(t)$ of the decay state with the channel wave function,

$$|\Psi_d(t)\rangle = \sum_s a_s(t) |s\rangle,$$  \hspace{1cm} (22)

where $\langle s' | s \rangle = \delta_{s's}$. Since $N_d(t)$ in Eq. (18) is given as $N_d(t) = \sum_s |a_s(t)|^2$, the partial decay width reads

$$\Gamma_s(t) = \frac{\hbar}{1 - N_d(t)} \frac{d}{dt} N_{d,s}(t).$$  \hspace{1cm} (23)

where $N_{d,s} = |a_s(t)|^2$. In the next section, we will apply Eq. (23) in order to calculate the spin-singlet and spin-triplet widths for the $2p$-emission of $^6\text{Be}$.

Figure 3: (Color online) The original and confining potentials for the $s_{1/2}$, $p_{3/2}$ and $d_{5/2}$ channels in the $\alpha-p$ subsystem. $R_b$ in Eqs. (21) and (25) is taken to be 5.7 fm for all the channels.

III. RESULTS

A. Initial State

Let us now numerically solve the three-body model and discuss the $2p$-decay of $^6\text{Be}$. As we mentioned in the previous section, we construct the initial state for the two protons such that the $2p$-density distribution is localized around the core nucleus and thus has almost no amplitude outside the core-proton potential barrier. To this end, we employ the confining potential method [69–71]. Within this method, we modify the core-proton potential, $V_{cp}$, so as to make a meta-stable two-proton state be bound. We generate the confining potential for the present problem as follows. Because the $\alpha-p$ subsystem has a resonance at $E_0 = 1.96$ MeV in the $p_{3/2}$-channel, the two protons in $^4\text{Be}$ are expected to have a large component of the $(p_{3/2})^2$ configuration. Thus, we first modify the core-proton potential for the $p_{3/2}$-channel in order to generate a bound state as follows:

$$V_{cp}^{conf}(r) = V_{cp}(r) \quad (r \leq R_b),$$

$$V_{cp}(R_b) \quad (r > R_b),$$  \hspace{1cm} (24)

with $R_b = 5.7$ fm. Here we have followed Ref. [71] and taken $R_b$ to be outside the potential barrier rather than the barrier position. For the other s.p. channels, we define the confining potential as

$$V_{cp}^{conf}(r) = \begin{cases} V_{cp}(r) & (r \leq R_b), \\ V_{cp}(r) + \Delta V_{p_{3/2}}(r) & (r > R_b), \end{cases}$$  \hspace{1cm} (25)

where $\Delta V_{p_{3/2}}(r) = V_{cp}(R_b) - V_{cp}(r)$ for the $s_{1/2}$-channel. The original and confining potentials for the $s_{1/2}$, $p_{3/2}$ and $d_{5/2}$ channels are shown in Fig. 3. We note that, for this system, the core-proton barrier is mainly due to the centrifugal potential rather than the Coulomb potential.
This situation is quite different from heavy 2p-emitters with a large proton-number, such as $^{45}$Fe.

The initial state for the 2p-emission is obtained by diagonalizing the modified Hamiltonian including $V_{\text{cp}}(r)$. The empirical Q-value for the two-proton emission is 1.37 MeV for $^{6}$Be [63, 64]. However, the Minnesota potential with the original parameters overestimates this value by about 50%. Thus we have modified the parameter $\nu_0$ in Eq. (9) from the original value, $\nu_0 = 200.0$ MeV [63], to $\nu_0 = 156.0$ MeV so as to yield $Q = 1.37$ MeV when it is calculated by Eq. (10).

In Fig. 4 we show the density distribution of the initial state obtained in this way. By integrating the spin coordinates, the density distribution becomes a function of the radial distances, $r_1$ and $r_2$, as well as the opening angle between the two valence protons, $\theta_{12}$. That is,

$$\tilde{\rho}_{2p}(t=0; r_1, r_2, \theta_{12}) = 8\pi r_1^2 r_2^2 \sin \theta_{12} \cdot \rho_{2p}(t=0; r_1, r_2, \theta_{12}), \quad (26)$$

with

$$\rho_{2p}(t=0; r_1, r_2, \theta_{12}) = |\Psi(t=0; r_1, r_2, \theta_{12})|^2. \quad (27)$$

Here $\tilde{\rho}_{2p}$ is normalized as

$$\int_0^{R_{\text{max}}} dr_1 \int_0^{R_{\text{max}}} dr_2 \int_0^\pi d\theta_{12} \tilde{\rho}_{2p} = 1. \quad (28)$$

In the left panel of Fig. 4, $\tilde{\rho}_{2p}$ is plotted as a function of the distance between the core and the center of mass of the two protons: $r_{c-pp} = \sqrt{r_1^2 + r_2^2 + 2r_1 r_2 \cos \theta_{12}/2}$, and the relative distance between the two protons: $r_{p-p} = \sqrt{r_1^2 + r_2^2 - 2r_1 r_2 \cos \theta_{12}}$. In the right panel of Fig. 4, we also display the angular distributions obtained by integrating $\tilde{\rho}_{2p}$ for the radial distances.

It is clearly seen that the initial wave function is confined inside the potential barrier at $r \cong 4$ fm (see Fig. 4). Furthermore, the 2p-density is concentrated near $r_{p-p} = 2$ fm, corresponding to the diproton correlation in bound nuclei [14]. The corresponding angular distribution becomes asymmetric and has the higher peak at the opening angle $\theta_{12} \cong \pi/6$. This peak is almost due to the spin-singlet configuration, being analogous to the dinucleon correlation. This suggests the existence of the diproton correlation in the meta-stable ground state of $^{6}$Be due to the pairing correlation.

As is well known, the mixture of configurations with
s.p. states with opposite parity plays an essential role in generating the dinucleon correlation \([7]\). In order to study the effect of the diproton correlation in the 2p-emission, we have also performed the same calculation but only with odd-\(l\) partial waves, that is, \(p^2, f^2\), and \(h^2\). In the following, we call this case as the \((l = \text{odd})^2\) case. In this case, the pairing correlations are taken into account only among the s.p. states with the same parity, while the mixture of opposite parity configurations is entirely ignored. In Fig. 5 we show the initial configuration obtained only with the odd-\(l\) partial waves. We have used \(v_0 = 88.98\) MeV in order to reproduce the empirical Q-value in this case. In the left panel of Fig. 5 there are two comparable peaks at \(r_{\text{p-p}} = 2\) and \(5\) fm whereas, in the right panel, the corresponding angular distribution has a symmetric form. This result is in contrast with that in the case with all the configurations from \((s_{1/2})^2\) to \((h_{11/2})^2\), shown in Fig. 4 where the pairing correlations are fully taken into account.

In Table 2 properties of the initial state are summarized. It is clearly seen that, in the case of the full configuration-mixture of the main component is \((p_{3/2})^2\), reflecting the fact that the \(p_{3/2}\) channel has a resonance in the \(\alpha\)-p subsystem. The mixture of different partial waves are due to the off-diagonal matrix elements of \(H_{3b}\), corresponding to the pairing correlations. A comparable enhancement of the spin-singlet configuration exists also in the case with the \((l = \text{odd})^2\) bases, even though there is no localization of the two protons as shown in Fig. 5.

From the point of view of the isobaric symmetry in nuclei, it is interesting to compare the initial state of \(^6\text{Be}\) with the ground state of its mirror nucleus, \(^6\text{He}\). Assuming the \(\alpha\)-n+n structure, we perform the similar calculation for the ground state of \(^6\text{He}\). For the \(\alpha\)-n system, there is an observed resonance of \(p_{3/2}\) at \(E_r = 0.735(20)\) MeV with its width, \(\Gamma_r = 0.600(20)\) MeV \([63, 72]\). In order to reproduce this resonance, we exclude the Coulomb term from \(V_{\text{cp}}\) and modify the depth parameter to \(V_0 = -61.25\) MeV in the Woods-Saxon potential. The pairing interaction is adjusted to reproduce the empirical two-neutron separation energy, \(\langle H_{3b}\rangle = -S_{2n} = -0.975\) MeV \([72]\), by using \(v_0 = 212.2\) MeV in Eq. (6). Notice that we deal with the bound state of the three-body system in this case, and thus the confining potential is not necessary. In Fig. 6 the two-neutron density distribution is shown in the same manner as in Fig. 4. Its properties are also summarized in the last column of Table 2. Obviously, the two-neutron wave function in \(^6\text{He}\) has a similar distribution to the 2p-wave function in \(^6\text{Be}\). The dinucleon correlation is present also in \(^6\text{He}\), characterized as the spatial localization with the enhanced spin-singlet component \([13]\). Consequently, the confining potential which we employ provides such initial state of \(^6\text{Be}\) that can be interpreted as the isobaric analogue state of \(^6\text{He}\).

| \(\langle H_{3b}\rangle\) (MeV) | \(^6\text{Be}\) \((l = 0)\) | \(^6\text{He}\) (g.s.) |
|-----------------|-----------------|-----------------|
| \(p_{3/2})^2\) (%) | 88.9 | 97.1 | 92.7 |
| \(p_{1/2})^2\) (%) | 3.1 | 2.8 | 1.6 |
| \(s_{1/2})^2\) (%) | 2.2 | 0.0 | 1.3 |
| other \((l = \text{even})^2\) (%) | 5.2 | 0.0 | 4.2 |
| other \((l = \text{odd})^2\) (%) | 0.6 | 0.1 | 0.2 |
| \(P(S = 0)\) (%) | 82.2 | 80.6 | 78.1 |

Table 2: Calculated properties for the initial state of \(^6\text{Be}\) and the bound ground state of \(^6\text{He}\). The results with all the configurations from \((s_{1/2})^2\) to \((h_{11/2})^2\) are labeled by “full”. Those obtained only with the odd-\(l\) partial waves for \(^6\text{Be}\) are also shown.
Figure 7: The decay probability and the decay width of the 2p-emission from $^6$Be, obtained with the time-dependent method. The result in the case of the full configuration-mixture is plotted by the solid line, whereas that in the \((l=\text{odd})^2\) case is plotted by the dashed line. The experimental value, $\Gamma_{\text{exp}} = 92 \pm 6$ keV \[63, 64\], is marked by the shaded area.

B. Decay Width

In order to describe the decay process of $^6$Be, we suddenly change the potential at $t = 0$ from the confining potential, $V_{\text{conf}}$, to the original one, $V_{\text{cp}}$. The initial state constructed in the previous subsection then evolves in time. We first show the results of the decay probability, $N_d(t)$, and the decay width, $\Gamma(t)$, defined by Eqs.\[18\] and \[19\], respectively.

In Fig. 7 the calculation is carried out up to $ct = 1400$ fm. We have confirmed that the artifact due to the reflection at $r = R_{\text{box}}$ is negligible in this time-interval. One can clearly see that, after a sufficient time-evolution, the decay width converges to a constant value for all the cases, and the exponential decay-rule is realized. Furthermore, the result in the case of full configuration-mixture yields the saturated value of $\Gamma(t) \approx 88.2$ keV, which reproduces the experimental decay width, $\Gamma = 92 \pm 6$ keV \[63, 64\].

On the other hand, the decay width is significantly underestimated when the partial waves are limited only to odd-$l$ partial waves (Note that we exclude even-$l$ partial waves not only at $t = 0$ but also for $t > 0$ in this case). The underestimation of the decay width is caused by an increase of the pairing attraction: with the odd-$l$ partial waves only, to reproduce the empirical Q-value, we needed a stronger pairing attraction. The two protons are then strongly bound to each other and are difficult to go outside, even they have a similar energy release to that in the case of full configuration-mixture. From this result, we can conclude that the mixing of opposite parity configurations is indispensable in order to reproduce simultaneously the Q-value and the decay width of the 2p-emission, supporting the assumption of the diproton correlation.

For the above two cases, we also calculate the par-
tial decay widths for the spin-singlet and the spin-triplet configurations. The corresponding formula to Eq. (23) is given as
\[ \Gamma_S(t) = \frac{\hbar}{1 - N_{d}(t)} \frac{d}{dt} N_{d,S}(t), \]

with
\[ N_{d,S}(t) \equiv \langle \Psi_{d,S}(t) | \Psi_{d,S}(t) \rangle \]
\[ = \int_{0}^{r_{\text{box}}} dr_{1} \int_{0}^{r_{\text{box}}} dr_{2} \int_{0}^{\pi} d\theta_{12} \times 8\pi^{2}r_{1}^{2}r_{2}^{2}\sin\theta_{12} |\Psi_{d,S}(t; r_{1}, r_{2}, \theta_{12})|^{2}. \]

where \( S \) indicates the combined spin of the two protons. The results are shown in Fig. 8. Clearly, the spin-singlet configuration almost exhausts the decay width in the case of full configuration-mixture shown in the upper panel of Fig. 8. This suggests that the emitted two protons from the ground state of \(^{6}\text{He}\) have mostly the \( S = 0 \) configuration like a diproton. On the other hand, in the lower panel of Fig. 8 one can see that the spin-triplet configuration occupies a considerable amount of the total decay width when we exclude even-\( l \) partial waves.

In the first and the second rows of Table 8 we tabulate the total and partial widths in the case of full configuration-mixture and in the \( (l = \text{odd})^{2} \) cases, respectively. The values are evaluated at \( ct = 1200 \) fm, where the total widths sufficiently converge. Clearly, there is a significant increase of the spin-singlet width in the case of full configuration-mixture, by about one order of magnitude larger than that in the case of \( (l = \text{odd})^{2} \) waves.

On the other hand, we get similar values of the spin-triplet width in these two cases. From this result, we can conclude that the mixture of the odd-\( l \) and even-\( l \) s.p. states is responsible for the enhancement of the spin-singlet emission, although the dominance of the spin-singlet configuration in the initial state is apparent in both the two cases.

A qualitative reason for the dominance of the spin-singlet configuration is due to the \((s_{1/2})^{2}\) channel. Notice that the \((s_{1/2})^{2}\)-channel is allowed only for \( S = 0 \). Because there is no centrifugal barrier in this channel, the spin-singlet emission can be dominant. On the other hand, for the spin-triplet configuration, only \( L = 1 \) is permitted. Thus the \((s_{1/2})^{2}\) configuration does not contribute to it, and there is a centrifugal barrier for all the channels in the spin-triplet configuration. Consequently, apart from the reduction due to the stronger pairing attraction, the spin-triplet widths are similar in both the two cases.

\section{C. Time-Evolution of Decay State}

In order to discuss the dynamics of the emission process, we show the density distribution of the decay state,
\[ \tilde{\rho}_{d}(t) = 8\pi^{2}r_{1}^{2}r_{2}^{2}\sin\theta_{12}\rho_{d}(t), \]
\[ \rho_{d}(t) = |\Psi_{d}(t; r_{1}, r_{2}, \theta_{12})|^{2}. \]

The decay state, which is orthogonal to the initial state confined inside the potential barrier, has the most of its...
amplitude outside the potential barrier. In the following, we adopt three sets of radial coordinates: (i) The first set includes \( r_{c-pp} \) and \( r_{p-p} \), similarly to the left panel of Fig. 9. (ii) In the second set, we integrate \( \bar{\rho}_d \) with respect to the opening angle, \( \theta_{12} \), and plot it as a function of \( r_1 \) and \( r_2 \). In order to see the peak-structure clearly, we omit the radial weight \( r_1^2 r_2^2 \) in \( \bar{\rho}_d \) in the second set. (iii) Within the third set, on the other hand, we integrate \( \bar{\rho}_d(t) \) over the radial distances, and plot it as a function of \( \theta_{12} \). We will use in Figs. 10, 11 and 13 these sets of coordinates in order to present the amplitude of the decay state in actual calculations.

Before we show the results of the actual calculations, we schematically illustrate the dynamic of the 2p-emissions in Fig. 9. From the geometry, the emission modes are classified into two categories: “simultaneous two-proton” and “one-proton” emissions. The diproton emission is a special case of the first category. The second category corresponds to the case where only one proton penetrates the barrier.

Figs. 9(a), (b) and (c) correspond to the simultaneous 2p-emissions with \( \theta_{12} = 0, \pi \) and \( \pi/2 \), respectively, where \( \theta_{12} = 0 \) (Fig. 9(a)) corresponds to the diproton emission. In these three cases, the density in the \((r_1, r_2)\)-
Figure 11: (Color online) The same as Fig.10 but for the case with only \((l = \text{odd})^2\) waves. Notice a different scale in the left column from that in Fig.10.

plane shows the same patterns, and is concentrated along \(r_1 \cong r_2\). The simultaneous emissions with different opening angles can be distinguished only in the \((r_{\text{pp}}, r_{c-\text{pp}})\)-plane: for instance, in the diproton emission, the probability shows mainly along the line with \(r_{c-\text{pp}} \gg r_{\text{pp}}\), while it is along the line with \(r_{c-\text{pp}} = 0\) for \(\theta_{12} = \pi\). In the one-proton emission shown in Fig.9(d), only one of the two protons goes through the barrier while the other proton remains inside the core nucleus. This is seen as the increment along \(r_{c-\text{pp}} \cong r_{\text{pp}}/2\) and \(r_1\) or \(r_2\) \(\cong 0\) lines.

In Fig. 10(e) and (f), we illustrate two hybrid processes. The first one is a “correlated emission”, shown in Fig. 10(e). In the correlated emission, the two protons are emitted simultaneously to almost the same direction, holding the diproton-like configuration. In this mode, in the early stage of tunneling, the density distribution has a larger amplitude in the region with \(r_1 \cong r_2\) and small \(\theta_{12}\). In the \((r_{\text{pp}}, r_{c-\text{pp}})\)-plane, it corresponds to the increment of the probability in the region of \(r_{\text{pp}} \ll r_{c-\text{pp}}\). After the barrier penetration, the two protons separate from each other mainly due to the Coulomb repulsion. The second hybrid process is a “sequential emission”, which is shown in Fig. 10(f). In this mode, there is a large possibility in which one proton is emitted whereas the other proton remains around the core. The density distribution shows high peaks along \(r_1 \gg r_2\) and \(r_1 \ll r_2\). In the \((r_{\text{pp}}, r_{c-\text{pp}})\)-plane, it corresponds to the increment along the line of \(r_{c-\text{pp}} \cong r_{\text{pp}}/2\). In contrast to the pure one-proton emission, the remaining proton eventually goes through the barrier when the core-proton subsystem is unbound.
1. case of full configuration-mixture

We now show the results of the time-dependent calculations for the 2p-emission of $^6$Be. We first discuss the case of full configuration-mixture, where the odd-$l$ and even-$l$ single particle states are fully mixed by the pairing correlation. The density distribution for the decay state along the time-evolution is shown in Fig. 11. The left, middle and right columns correspond to the coordinate sets (i), (ii) and (iii) defined before, respectively. The first to the fourth panels in each column show the decay-density at $ct = 100, 200, 600$ and $1000$ fm, respectively. For a presentation purpose, we normalize $\bar{\rho}_d$ at each step of time.

In the left and middle columns of Fig. 11, it can be seen that the process in this case is likely the correlated emission shown in Fig. 9(c). Contributions from the other modes shown in Fig. 9 are small. In the middle column of Fig. 11 during the time-evolution, there is a significant increment of $\bar{\rho}_d$ along the line with $r_1 \cong r_2$. The corresponding peak in the left column is at $r_{pp} \ll r_{cep} \cong 10$ fm, which means a small value of $\theta_{12}$. It should also be noted that, after the barrier penetration, the two protons lose their diproton-like configuration due to the Coulomb repulsion, which results in the increase of $r_{pp}$. Thus, for $r_{cep} \geq 10$ fm which is a typical position of the potential barrier from the core, the density distribution extends around the $r_{cep} \cong r_{pp}$ region. In this process, the pairing correlation plays an important role to generate the significant diproton-like configuration before the end of the barrier penetration. In the right column of Fig. 11, the distributions are also displayed as a function of the opening angle, $\theta_{12}$. We can clearly see that the decay state has a high peak at $\theta_{12} \cong \pi/6$ in this time-region.

These results imply that the two protons are emitted almost in the same direction, at least in the early stage of the emission process. Intuitively, from the uncertainty principle, this would correspond to a large opening angle in the momentum space. Indeed, such component has been experimentally observed to be dominant for the 2p-decay of $^6$Be [40, 41]. It would be an interesting future work to carry out the Fourier transformation of the decay state and compare our calculations with the experimental data.

2. $(l = odd)^2$ case

We next discuss the case only with $(l = odd)^2$ bases. In Fig. 11 the decay density shows a strong pattern of the sequential emission demonstrated in Fig. 9(f): significant increments occur along the lines with $r_{cep} \cong r_{pp}/2$ and $r_1 \gg r_2$ or $r_1 \ll r_2$. Notice that the contribution from the simultaneous emissions also exists, especially in the early time-region. As a result, the decay state has widely spread amplitudes as a mixture of these emission modes. However, the simultaneous mode is minor compared with the case of full configuration-mixture. Notice that the condition for a true 2p-emitter is satisfied also in this case: the core-proton resonance is located at 1.96 MeV which is above $Q_{2p} = 1.37$ MeV. However, even with the strong pairing attraction and the energy condition for the true 2p-emitter, the process hardly becomes the correlated emission when the parity-mixing is forbidden or extensively suppressed. The angular distribution shows exactly the symmetric form, and is almost invariant during the time-evolution. This is because we exclude the pairing correlation between the positive and negative parity states in the core-proton system, not only at $t = 0$ but also during the time-evolution.

3. no-pairing case

Finally, for a comparison with the above two cases, we also perform similar calculations but by completely neglecting the pairing correlation. In this case, we only consider the uncorrelated Hamiltonian, $h_1 + h_2$. Because of the absence of the non-diagonal components in the Hamiltonian matrix, it can be proved that, if the s.p. resonance is at an energy $\epsilon_0$ with its width $\Gamma_0$, the 2p-resonance is at $2\epsilon_0$ with its width $2\Gamma_0$. The 2p-wave function is expanded on the uncorrelated basis with a single set of angular quantum numbers. Namely,

$$\Psi_{l(\ell)}(t) = \sum_{n_\lambda n_\beta} C_{n_\lambda n_\beta}(t) \Phi_{n_\lambda n_\beta}(ij),$$

where $(ij) = p_{3/2}$ for $^6$Be. In order to reproduce the empirical Q-value of $^6$Be, we inevitably modify the core-proton potential. We employ $V_0 = -68.65$ MeV to yield the s.p. resonance at $\epsilon_0(p_{3/2}) = 1.37/2 = 0.685$ MeV, although the scattering data for the core-proton subsystem are not reproduced and the character of a true 2p-emitter disappears. With this potential, we obtain the s.p. resonance with a broad width: $\Gamma_0(p_{3/2}) \cong 170$ keV. Because of the broad decay width, we need to increase the radial box to $R_{box} = 200$ fm in order to neglect the artifact due to the reflection at $R_{box}$ in the long time-evolution.

Figure 12: (Color online) The same as Fig. 8 but for the case without pairing correlations.
The result for the decay width is shown in Fig. 12 and in the last row of Table 3. To get the saturated result, we somewhat need a relatively longer time-evolution than that in the case of full configuration-mixture. Thus, in Table 3, we evaluate the decay width at $ct = 3000$ fm. By this time, the total decay width, $\Gamma(t)$, converges to about 340 keV which is consistent to that expected from the s.p. resonance, $\gamma_0(p_{3/2})$. During the time-interval shown in Fig. 12, there still remain some oscillations in $\Gamma(t)$. This is a characteristic behavior of the broad resonance, namely an oscillatory deviation from the exponential decay-rule. For the spin-singlet and triplet configurations, their contributions have exactly the ratio of $2 : 1$. This result is simply due to the re-coupling of the angular momentum for the $(p_{3/2})^2$ configuration.

By comparing these results with those in the case of the full configuration-mixing, we can clearly see a decisive role of the pairing correlations in $2p$-emissions. Assuming the empirical Q-value, if we explicitly consider the pairing correlations, the decay width becomes narrow and agrees with the experimental data. On the other hand, in the no-pairing case, we need a modified core-proton interaction to reproduce the empirical Q-value, and the properties of the core-proton resonance state become inconsistent with the experimental data. Even though the Q-value is adjusted in this way, the calculated $2p$-decay width is significantly overestimated in this case. Namely, we cannot simultaneously reproduce the experimental Q-value and the decay width with the no-pairing assumption. If one is forced to reproduce them simultaneously, one may need an unphysical core-proton interactions.

In Fig. 13, we show the density distribution of the decay state during the time-evolution. Obviously, in this case, the process is the sequential or, moreover, like the...
one-proton emission. There is a significant increase of the density along the lines with \( r_{c-pp} \approx r_{p-p}/2 \) and, consistently, with \( r_1 \gg r_2 \) and \( r_1 \ll r_2 \) (see Fig. 9). On the other hand, the probability for the simultaneous and correlated emissions are negligibly small. This is quite different from that in the case of full configuration-mixture, where the correlated emission is apparent.

D. Role of Pairing Correlation in Decay Width

In this subsection, we discuss a general role of the pairing correlation in the 2\( p \)-emission. To this end, we calculate the 2\( p \)-decay width for different Q-values in the case of full configuration-mixture and the no-pairing case. The variation of the Q-value is done by changing the parameter \( V_0 \) in the core-proton potential (Eq. (3)), while the pairing interaction used in the case of full configuration mixture is kept unchanged. Notice that for the no-pairing case, the s.p. resonance appears at \( \epsilon_0(p_{3/2}) = Q/2 \).

In Fig. 14, the decay width is plotted as a function of the decay Q-value. We note that the calculated decay widths are well converged after a sufficient time-evolution in all the cases. The decay width is evaluated at \( ct = 1200 \) and 3000 fm in the full-correlation and the no-pairing cases, respectively. Clearly, the no-pairing calculations overestimate the decay width, in all the region of \( Q_{2p} \). Namely, the three-body system becomes easier to decay without the pairing correlation, for the same value of the total energy release (Q-value). In other words, the pairing correlation plays an essential role in the meta-stable state, stabilizing it against particle emissions. We note that a similar effect has been predicted also for a one-neutron resonance, that is, the width of a one-neutron resonance becomes narrow when one considers the pairing correlations [74].

Also, as we have confirmed in the previous section, the emission dynamics with and without the pairing correlations are essentially different to each other: the correlated emission becomes dominant if the pairing correlation is fully considered, whereas the sequential emission plays a major role in the no-pairing case. Consequently, the pairing correlation must be treated explicitly in the metastable states, otherwise one would miss the essential effect on both the decay-rule and the dynamical phenomena.

IV. SUMMARY

We have investigated the 2\( p \)-emission of the \( ^6\)Be nucleus by employing a three-body model consisting of an \( \alpha \) particle and two valence protons. We have applied the time-dependent method and discussed the decay dynamics of many-body meta-stable states, particularly in connection to the diproton correlation. An advantage of the time-dependent method is that it provides not only a way to evaluate the decay width, but also an intuitive way to understand the decay dynamics.

By using the confining potential method, we first obtained the initial state of \( ^6\)Be, in which the two protons are confined inside the potential barrier. Because of the pairing correlation between the two protons, the initial configuration includes the diproton correlation, similarly to the dineutron correlation in the ground states of Borromean nuclei such as \( ^4\)He. At time \( t = 0 \), the confinement is removed so that the 2\( p \)-state evolves in space and time. In this calculation, the decay width can be read off by plotting the survival probability as a function of time. We have found that our Hamiltonian well reproduces simultaneously the experimental Q-value and decay width of \( ^6\)Be. We have also shown that the decay state predominantly has the spin-singlet configuration.

By monitoring the time-evolution of the density distribution of the decay state, we have confirmed that the decay process in the early stage is mainly the correlated emission, in which the two protons tend to be emitted in a similar direction, reflecting the diproton correlation in the initial state. Thus, the 2\( p \)-emission can be a promising tool to probe experimentally the diproton correlation. We have also performed the calculations by including only odd-\( l \) partial waves in order to switch off the diproton correlation. In this case, even though we use the model parameters which reproduce the empirical Q-value, the decay width is significantly underestimated. The decay process shows a large component of the sequential emission, in contrast to the case of full configuration-mixture. From these results, we can conclude that the diproton correlation plays an important role in the 2\( p \)-emission, providing an opportunity to probe it by observing the 2\( p \)-emission.

We have also checked that, if the pairing correlation is completely neglected, the decay width is largely overes-
timated, partly because the proton-core potential has to be made deeper in order to yield the empirical Q-value. By monitoring the time-evolution of the density distribution of the decay state, it has been clarified that the emission is mostly a sequential decay with the no-pairing assumption. Namely, the pairing correlation is critically important to determine not only the decay width but also the dynamical phenomena.

In order to compare quantitatively the calculated results with the experimental data, we would need a more careful treatment of the final-state interactions (FSIs). In this work, we mainly treat the early stage of the time-evolution, terminating the calculations at \( ct \sim 1400 \text{ fm} \) in order to avoid the artifact due to the reflection at the edge of the box, \( R_{\text{box}} \). On the other hand, the two protons are detected in the actual experiments at a much later time after being significantly affected by the FSIs. In order to fully take into account the FSIs, we would have to use an extremely large box even though the computational costs would increase severely.

The time-dependent method which we employed in this paper can be applied also to a decay of other many-body meta-stable states. It provides a novel and intuitive point of view to the decay process. It would be an interesting future problem to apply this method to other problems of many-particle quantum decays, such as the two-neutron emission and the two-electron auto-ionization of atoms.
