Abstract

Background: CRISPR/Cas9 is widely used for precise genetic editing in various organisms. CRISPR/Cas9 editing may in many plants be hampered by the presence of complex and high ploidy genomes and inefficient or poorly controlled delivery of the CRISPR/Cas9 components to gamete cells or cells with regenerative potential. Optimized strategies and methods to overcome these challenges are therefore in demand.

Results: In this study we investigated the feasibility of improving CRISPR/Cas9 editing efficiency by Fluorescence Activated Cell Sorting (FACS) of protoplasts. We used Agrobacterium infiltration in leaves of Nicotiana benthamiana for delivery of viral replicons for high level expression of gRNAs designed to target two loci in the genome, NbPDS and NbRRA, together with the Cas9 nuclease in fusion with the 2A self-splicing sequence and GFP (Cas9-2A-GFP). Protoplasts isolated from the infiltrated leaves were then subjected to FACS for selection of GFP enriched protoplast populations. This procedure resulted in a 3–5 fold (from 20 to 30% in unsorted to more than 80% in sorted) increase in mutation frequencies as evidenced by restriction enzyme analysis and the Indel Detection by Amplicon Analysis, which allows for high throughput profiling and quantification of the generated mutations.

Conclusions: FACS of protoplasts expressing GFP tagged CRISPR/Cas9, delivered through A. tumefaciens leaf infiltration, facilitated clear CRISPR/Cas9 mediated mutation enrichment in selected protoplast populations.

polyethylene glycol (PEG) in combination with calcium ions or by electroporation (reviewed in [5]), where the latter requires elaborate tissue culturing for regeneration to fertile plants and may introduce genetic instability and resulting somaclonal variation. PEG-mediated transformation, in particular, has been used to deliver constructs encoding the PGE components, incl. Zinc Finger-Nucleases (ZFNs) [6], Transcription activator-like effector nucleases (TALENs) [7, 8] and CRISPR/Cas9 [8, 9] and lately also for delivery of the Cas9 enzyme and associated gRNA into plant cell protoplasts in vitro [10]. Excess DNA is regularly used for PEG mediated transformation of protoplasts (typically in molar ratios of 1: 1–2 × 10^7 (protoplast: plasmid DNA) [11]) and has been reported to confer unintended random integrations in the recipient genomes [12]. Agrobacterium-mediated transformation on the other hand is generally perceived to be an efficient and a more controlled way of delivering transgenes [13] and the use of strains, with putatively downregulated integration capacity [14], in combination with down-regulation of host factor integration genes may facilitate alternative ways of non-integrative delivery of PGE components. Also, Agrobacterium may in some cases be the only viable option for delivering of transgenes. In recent years, Agrobacterium-mediated delivered viral constructs has attracted increasing interest because of their high copy number and resulting expression capabilities [15, 16]. Deconstructed viral vectors (replicons) have proved extremely effective for rapid, high-yield production of a number of pharmaceutical proteins, of which some are currently undergoing clinical evaluation [16]. As efficient gene editing relies on PGE component expression, virus replicons have likewise attracted attention as delivery vehicles [17]. Deconstructed geminivirus type replicons (as delivery vehicles) have been shown to generate mutations in the solanaceous species Nicotiana benthamiana [17] and Solanum lycopersicum (tomato) [18] and recently in Triticum aestivum (wheat) [19]. N. benthamiana can be grown in high density and still produce large amounts of biomass in a matter of weeks [16], and has a track record for production of therapeutic glycoproteins in mg scale ([20–24]) through the use of leaf or leaf disc infiltration [25]. In addition, N. benthamiana may readily be subjected to protoplast transformation [26] and explant/protoplast regeneration [27, 28]. Several approaches have been reported to confer enrichment of PGE mutations in cells. Fluorescence Activated Cell Sorting (FACS) of edited cells, for example, is regularly used as means of PGE mutation enrichment in mammalian cell systems [29], and the present study addresses the feasibility of applying this strategy to plant cells.

So far reports on FACS and post FACS cultivation of plant protoplasts are relatively scarce [30], due to the removal of the rigid and structure providing cell wall, which otherwise stabilize the cell integrity [31–33]. The present study explores the combined use of Agrobacterium-mediated delivery of viral replicons for expression of GFP tagged gRNA/Cas9 in leaves of N. benthamiana with FACS in order to obtain protoplast populations with significantly increased gene editing.

**Results**

The overall strategy for Agrobacterium-mediated delivery of deconstructed replicons expressing gRNA/Cas9-2A-GFP in leaves of N. benthamiana combined with FACS of GFP expressing protoplasts is outlined in Fig. 1.

**gRNA and replicon construct design**

In the present study we targeted the Nicotiana benthamiana PHYTOENE DESATURASE (NbPDS) and REDUCED RESIDUAL ARABINOSE arabinosyl transferase (NbRRA) loci, orthologous to the Arabidopsis thaliana arabinosyltransferase encoding genes involved arabinosylation of plant cell wall extensins (AtRRA1–3) [41, 42], which have a proven [43] and an untested CRISPR/Cas9 editing record, respectively (Fig. 2a). gRNA target sequences were confined to early exons and identified on the basis of in silico prediction analysis (http://portals.broadinstitute.org/gpp/public/analysis-tools/sgrna-design, [45]), and the presence of a Restriction Enzyme (RE) recognition sequence spanning the predicted cut site of SpCas9–3 bp upstream of the protospacer adjacent motif (PAM) [34] for RE-mediated mutation screening.

A deconstructed immobilized mild strain of the bean yellow dwarf virus (BeYDV), allowing for a high replicon copy number in the nucleus, has recently been used to construct an Agrobacterium T-DNA that integrates into the host cell chromosome and delivers a geminivirus replicon (GVR) [17, 46]. The minimal immobilized replicons are delivered by Agrobacterium infiltration (here to N. benthamiana leaves) along with co-infiltrated constructs for expression of replicon trans-acting replication initiation proteins (Rep or RepA) [47] (Fig. 1a). While the replicons are non-integrative and transiently expressed the initial Agrobacterium T-DNA (LB-RB) delivery of the replicon is integrative [17]. Lately, GVRs were constructed and used to propagate and express PGE components, such as ZFNs and TALENs and CRISPR/Cas9 [17]. In the present study, we inserted the Streptococcus pyogenes Cas9 enzyme (SpCas9) [48] in translational fusion with the 2A self-splicing sequence of the foot-and-mouth disease virus [37, 38] and GFP [49] (SpCas9-2A-GFP) under control of the CMV 35S promoter and the gRNAs under control of the AtU6 promoter [35, 36] in the BeYDV GVR replicon [17] as depicted in Fig. 1a and detailed in the Methods section.
In-leaf gRNA/Cas9 generated mutations

The SpCas9-2A-GFP/gRNA expressing GVR replicons (Fig. 1a) targeting the NbPDS and NbRRA loci (Fig. 2a) were electroporated into Agrobacterium tumefaciens and grown under selection overnight and re-suspended in infiltration buffer to a final total OD 600 of 0.2 where after the abaxial sides of young expanding leaves of N. benthamiana were subjected to Agrobacterium infiltration. The infiltrated plants were left for 2–4 days allowing for gRNA/Cas9 expression and mutation generation within the intact leaves. Western blot analysis of total proteinacious extracts, using anti-Flag and anti-GFP mAbs as primary antibodies against the Flag- and GFP-tagged SpCas9 revealed the presence of a distinct band at the expected MW (154 kDa) of mature SpCas9 with a faint band corresponding to the uncleaved fusion protein (SpCas9-2A-GFP, ca 180 kDa) in...
infiltrated leaves demonstrating expression and efficient 2A mediated auto cleavage of SpCas9-2A-GFP (Fig. 2b).

RE-mediated mutation analysis of PCR fragments, using primers flanking the gRNA target sites, revealed the presence of non-digestible bands indicative of mutated RE recognition/cleavage sequence for the two target sites (Fig. 2c and d). The RE resistant band of each locus was isolated, sub-cloned and sequenced with the presence of insertions or deletions (indels) demonstrated (Fig. 2c and d).

**Protoplast isolation and FACS-mediated mutation enrichment**

Protoplasts of WT and infiltrated leaves were essentially obtained using the protocol devised by Dovzhenko et al. 1998 [27] with minor modifications as outlined in the Methods section. Protoplast quality and yield varied significantly apparently influenced by growth conditions pre- and post-infiltration. Here a temperature of 22–24 °C, a 16 h/8 h (light/dark) regime of moderate sunlight (See ‘Growth conditions,’ Methods section) generally conferred a high amount of intact protoplasts. Protoplast integrity and transformation were assessed by comparative bright field and fluorescent microscopy frequently with varying estimated transformation rates of 20 - > 80% (Additional file 1: Figure S1). GFP fluorescence accumulated in particular in the cytoplasmic strands and the contours of the cell (Additional file 1: Figure S1), which is in agreement with a cytoplasmic 2A-mediated release of GFP. This was corroborated by the western blot analysis (Fig. 2b) showing presence of the mature SpCas9 with only traces un-cleaved product. Also, in agreement with soluble non-tagged GFP being able to pass into and accumulate in nuclei [50], some

![Fig. 2](image)
accumulation in nuclei structures was observed (Additional file 1: Figure S1).

FACS of fluorescent protoplasts were done using a FACSAria III (BD Biosciences) apparatus with settings to accommodate for the approximate size of *N. benthamiana* protoplasts [51] as described in the Methods section. Two fluorescent enriched populations, protoplasts with medium GFP intensity (P4) and with high intensity (P5), were selected for sorting corresponding to 17% & 10 and 14% & 5% of the total population for the *NbRRAall1-gRNA/SpCas9-2A-GFP* and *NbPDS2-gRNA/SpCas9-2A-GFP* infiltrations, respectively (Fig. 3b). RE analysis of PCR amplicons suggested an estimated indel frequency of unsorted, P4 and P5 sorted populations of 20–30, 50% and 70–80% for the *NbRRAall1-gRNA* and 40, 50 and > 80% for the *NbPDS2-gRNA* (Fig. 3c). This was corroborated by Indel Detection by Amplicon Analysis (IDAA) (Fig. 3d) and sequence analysis of the cloned PCR fragments of the two P5 populations (10 clones of each), which showed indel to WT ratio of 60 and 70%, respectively. The indel distributions obtained for the *NbRRAall1- and NbPDS2-gRNA* infiltrations −3(1), –1(2) & +1(4) and –1(3) & +1(3) (Fig. 3e), respectively, are in agreement with earlier findings for SpCas9 mediated mutations in plants [52].

Bright field microscopy suggested that 10–20% of a WT protoplast population was intact after FACS when using PBS buffer as sheath fluid and MMM550 as recipient buffer (Additional file 2: Figure S2). Viability of post FACS GFP

![Fig. 3](image_url)
positive protoplasts was assessed by bright field and fluorescence microscopy (Fig. 3f) and confirmed by propidium iodide exclusion assays (Additional file 2: Figure S2). Sorting into PBS as recipient buffer resulted in instant lysis as evidenced by bright field microscopy (data not shown). In agreement with ribonucleoprotein, i.e. in vitro transcribed gRNA and heterologous expressed Cas9, conferring nuclease activity in-vitro [10, 53], we tested (post FACS) for PBS lysis mediated editing activity and found an 2–3 fold increased editing when the PBS lysed protoplasts were left in PBS for 2 h at room temperature (Additional file 3: Figure S3). All post FACS protoplast samples were immediately incubated on ice accordingly. Potential continued editing in the time-span from FACS to further processing may on the other hand likewise increase the ‘in cell’ editing.

Embedment of GFP transformed protoplasts in alginate with initial callus formation (Additional file 4: Figure S4) demonstrated the feasibility of obtaining gene edited lines using an explant shoot regeneration systems as described in [40].

Discussion

The use of PGE in plants may be complicated by the presence of complex genomes and inefficient or poorly controlled delivery of PGE components to gamete cells or recipient pluripotent cells. DNA encoding PGE components may be delivered to the plant cell either directly, i.e. by biolistic transformation or protoplast transformation (reviewed by [5]), or indirectly, mainly via bacteria, usually Agrobacterium tumefaciens or (less commonly) Agrobacterium rhizogenes [54], which is generally perceived to be a controlled way of delivering transgenes [55]. Virus replicons provide high copy number of expression units and thus a means of significantly boosting PGE component expression levels [46, 56] and methods for increasing identification/selection of PGE-edited cells have been introduced and applied successfully e.g. for mammal cells [29].

In the present study we combined Agrobacterium-mediated delivery of a viral replicon expressing GFP labeled gRNA/SpCas9 for generation of in-leaf mutations with the use of FACS of GFP-fluorescent protoplasts for enrichment of mutated protoplast populations. BeYDV GVR replicons, expressing gRNAs targeting the NbPDS and the NbRRA locus in N. benthamiana, respectively, together with the SpCas9 nuclease, fused to the 2A self-splicing sequence and GFP (SpCas9-2A-GFP), were introduced into leaves of N. benthamiana by Agrobacte-rium-mediated infiltration and left for expression and mutation generation within the intact leaf. In leaf expression of the GFP- and Flag-tagged SpCas9 enzyme was readily verified by western blot analysis and generated mutations as evidenced by the presence of restriction enzyme (RE) resistant bands of PCR amplicons comprising the mutated recognition site were cooperated by cloning and sequence analysis of the RE resistant bands. Indel distribution was found to be in accordance with earlier studies for SpCas9 mediated genome editing in plants [52]. With the aim of selecting and concentrating edited cells GFP-expressing protoplasts were isolated and subjected to FACS. The two fluorescence-enriched populations were selected for FACS with the most stringently sorted population yielding a 3–5 fold enrichment in mutations as evidenced by RE-mediated mutation analysis of PCR amplicons and sequence analysis.

The IDAA method allows for fast and direct assessment of indel prevalence and distribution [39]. In the current study, IDAA was combined with RE analysis for visualization of the isolated mutation population, where potential single nucleotide substitutions within the RE recognition site will otherwise co-migrate with the WT peak. While the observed > 50% reduction of FAM-fluorescence signal in IDAA analyses of overnight RE digests may complicate absolute peak quantification between samples, quantification of the WT peak and indel peak(s) within single samples, provides a means of estimating relative mutation efficacies between samples. The combined use of the RE analysis and the IDAA technique adds an extra analytical layer to the versatile IDAA technique. 10–20% of the protoplasts appeared to be intact in post FACS populations, when PBS and the MMM550 buffer were used as sheath fluid and recipient buffer, respectively. This ratio may, however, be increased by replacing the sheath fluid PBS buffer with a more osmotically favorable buffer and, if feasible on the FACS apparatus used, decrease shearing forces by lowering the psi. Here FACS on a Sony SH3800S cell sorter yielded ample intact protoplasts post FACS probably due to the available 130 µm sorting chip with accordingly lower psi. Isolation of non-ruptured protoplasts through the use of a sucrose gradient significantly aids the identification of protoplast populations with and without GFP-expression. Once an initial delineation of the protoplast populations on the cell sorter has been established, this step may potentially be omitted.

Extracellular gRNA/Cas9 activity from lysed protoplasts, e.g. mediated by FACS sorting, was significant and this residual activity, which may lead to an over estimated indel frequency, was abolished by incubation on ice or FACS sorting into an RNase containing or protein denaturing buffer.

Also, in this study protoplast yields were generally highly variable. A recent study on Agrobacterium infiltration-mediated expression of a reporter in leaves of N. benthamiana recommended infiltration of more plants but less leaves and sample more positions on the leaf as opposed to run a high number of technical
replicates [57]. In addition, it is conceivable that Agrobacterium infection/pathogenesis may affect intact protoplasts yield.

Recently, an unexpected high level of integrations in the recipient genomes associated with PEG-mediated plasmid transformation of protoplasts was reported [12]. Further optimization of the here devised PGE approach may include exploring the use of integration deficient Agrobacterium strains [58] or Virus Induced Gene Silencing (VIGS) mediated down-regulation of host plant factors [59] also important for T-DNA integration, as means of non-integrative delivery of the PGE components [60]. The obtained mutation enrichment may facilitate mutation detection e.g. in situations where the activity of a particular gRNA is weak and reduce laborious explant generation and screening steps. Alternatively, the protoplast based PGE system may be used e.g. in promoter-reporter editing test-screens.

Conclusions
The present study outlines a strategy for enrichment of CRISPR/Cas9 editing in leaf protoplasts. GFP tagged gRNA/Cas9 (gRNA/Cas9-2A-GFP) was delivered by Agrobacterium-infiltration to leaves of N. benthamiana and protoplasts isolated. Subsequent FACS of GFP expressing protoplasts resulted in several fold mutation enrichment in the selected fluorescence enriched protoplast populations.

Methods
Growth conditions
Seeds of wild-type Nicotiana benthamiana were sown and grown in soil (Pindstrup substrate number 2) for 4 weeks in greenhouse with a 16/8 h light/dark cycle, app. 70% relative humidity and a day/night temperature cycle of 24 and 17 °C.

2 days prior to infiltration plants were subjected to regular sunlight at a photosynthetic flux of 20–40 μmol photons m⁻² s⁻¹, Photosynthetic Active Radiation (PAR): 20.5 μE.m⁻² s⁻¹, Red – Far Red ratio (R:FR): 1.69), 22–24 °C temperature, an app. 16 h/8 h (light/dark) diurnal rhythm and 70% relative humidity, which were also imposed in the post-infiltration period.

Vectors and construct designs
Descriptive naming of vectors, primers and primer sequences are provided in Additional file 5: Table S1. The vector pLSLGFP-R (V82), described in [17], containing GFP insert in front of the CMV35S promoter and Gateway destination site in front of CMV 35S promoter-LIR, respectively, was kindly provided by Nicholas Baltes, Michigan University, US. The gRNA Gateway entry vector V26 (pUC57_attl1-AtU6-BbsI-BbsI-tracr-TT_AttL2) was synthesized by Genscript. To obtain insertion of NbRRAall1- or NbPDS2 gRNAs V26 was linearized with BbsI and gRNA targets NbRRAall1 and NbPDS2 were inserted by ligation of the annealed oligonucleotides P042 & P043 and P149 & P150, respectively, yielding V207 (attl1-AtU6: NbPDS2-tracr-TT_AttL2) and V208 (attl1-AtU6: NbRRAall1-tracr-TT_AttL2). V207 and V208 were linearized using EcoRI and cloned together with the Streptococcus pyogenes Cas9 (SpCas9) fragment [11], which was PCR amplified from HBT-Cas9 (Gift from Jen Sheen, Harvard Medical School) using the primer-set P077 & P212, the GFP-Nos fragment amplified from pLSLGFP. R using the primer set L1 & L2, all together using the In-fusion cloning kit (Clontech), yielding V197 (pUC57_AttL1-SpCas9-2A-GFP-Nos; AtU6-NbRRAall1-gRNA-TT_AttL2) and V198 (pUC57_AttL1-SpCas9-2A-GFP-Nos; AtU6-NbPDS2-gRNA-TT_AttL2). V197 & V198 was gateway cloned using pLSL_v2 as destination vector yielding V199 (pSL_v2_LIR-AttB1-SpCas9-2A-GFP-Nos; AtU6-NbRRAall1-gRNA-TT-AttB2_SIR-35S-LIR) and V200 (pLSL_v2_LIR-AttB1-SpCas9-2A-GFP-Nos; AtU6-NbPDS2-gRNA-TT-AttB2_SIR-35S-LIR), respectively. V199 & V200 will, when co-expressed with pREP, express SpCas9 in fusion with the 2A self-splicing sequence of the foot-and-mouth disease virus (FMDV) [37, 38] and GFP [49] (SpCas9-2A-GFP) under control of the CMV35S promoter.

For GFP expression only V82 (pLSLGFP-R_v2) was used.

PDS (NbPDS) and RRA (NbRRA) target loci in the N. benthamiana chromosome
N. benthamiana genes were obtained from https://solgenomics.net/tools/blast/?db_id=266 [61] based on homology with the Arabidopsis thaliana genes. As N. benthamiana is allotetraploid both chromosome variations of a gene in the given locus are obtained. In contrast to e.g. the presence of 1 and 3 isogenes of AtPDS [62] and AtRR4 [41, 42] in diploid Arabidopsis, respectively, NbPDS and NbRRA appear to be single gene loci in allotetraploid N. benthamiana.

The NbRRA gene SolGenomics: Niben101Scf18348 with exons (33526..33687, 35895..36708 & 36767..37113) and Niben101Scf09172 with exons (198006..198228, 198317..199449, 199413..199501, 200074..200127, 200369..200501, 200792..200940, 201104..201223, 201388..201601..201694..201796, 202066..202113 & 202983..203028) and with the NbPDS-gRNA situated in Exon 3 (15409..15428, 199476..199945).
Agrobacterium mediated leaf infiltration and expression in Nicotiana benthamiana

Agrobacterium tumefaciens pGV3850, harboring constructs (pREP, p19 and (pLSL_V2__LIR-AttB1-SpCas9-2A-GFP-Nos; AttL6-NbRRAaII1-gRNA-TT- AttB2 SIR-35S-LIR (V199) or pLSL_V2__LIR-AttB1-SpCas9-2A-GFP-Nos; AttL6-NbPDS2-gRNA-TT-AttB2 SIR-35S-LIR (V200) and empty vector control were inoculated in 5 ml YEP media with kanamycin (50 mg/L) and incubated at 28 °C, 250 rpm for 24 h. Cells were harvested by centrifugation for 20 min at 4000×g and re-suspended in infiltration buffer (10 mM MES-KOH, pH 5.8, buffer, containing pellet was re-suspended in 3 ml of 10 mM MES-KOH, pH 5.7, 20 mM KCl, supplemented with 1% Cellulase R10 (w/v) (Duchefa Biochemie, C8001), heated to 55 °C, 10 min, then supplemented with 10 mM CaCl2 and 0.1% BSA) and incubated 2–3 h at room temperature.

The abaxial side of 3–5 young expanding leaves (4–6 × 6–8 cm (Width, Length)) of N. benthamiana was infiltrated with A. tumefaciens pGV3850 containing the various constructs and co-infiltrated with the p19 construct [63] (Final OD600 = 0.2) essentially as described by Sainsbury and Lomonossoff (2008) [64], and left for 2–4 days depending on the experimental setting.

Protoplast isolation

Protoplasts were obtained using the protocol devised by Dovzhenko et al. 1998 [27]. Inoculated N. benthamiana leaves for subsequent protoplast-alginate embedding were sterilized by dipping in 96% ethanol and floating in 1.5% hypochlorite solution for 15 min. 3–5 leaves were cut into 0.5–1 mm strips with a scalpel and submerged in 10 ml enzyme solution (400 mM mannitol, 20 mM MES-KOH, pH 5.7, 20 mM KCl, supplemented with 1% Cellulase R10 (w/v) (Duchefa Biochemie, C8001), 0.25% Macerozyme (Duchefa Biochemie, C8002), heated to 55 °C, 10 min, then supplemented with 10 mM CaCl2 and 0.1% BSA) and incubated 2–5 h at 26 °C, 100 rpm, then filtered through a 100 μm filter into a 50 ml Falcon tube, centrifuged for 5 min at 100хg, where after the supernatant was poured off and the protoplast-containing pellet was re-suspended in 3 ml of 10 mM MgSO4, 10 mM MgCl2, 10 mM MES-KOH, pH 5.8, buffer, 0.5 M mannitol (MMM550) which was carefully layered on top on 8 ml 0.6 M sucrose cushion and spun down at 100хg, 2 min, at room temperature. Intact protoplasts at the interface were collected and spun down at 100хg for 2 mins then re-suspended in MMM550 — if used for alginate imbedding this step was repeated three times. For viability test the protoplast-containing pellet was re-suspended in 5 ml 2.5 mM MES-KOH, pH 5.7, 125 mM CaCl2, 154 mM NaCl, 5 mM KCl, 0.5 mM glucose (W5), centrifuged for 5 min at 100хg, the supernatant poured off, and the pellet re suspended in 0.5 ml W5 and placed on ice until FACS, which was initiated immediately after the wash step.

Embedment of GFP-fluorescent protoplast in alginate

Protoplast embdenment in alginate was essentially done as described in [27] except the thin alginate layer was formed using the ‘droplet on Ca-agar’ method as described in [65]. Briefly, protoplasts re-suspended in 200 μl MMM550 were mixed with 200 μl alginate solution (MMM550 + 2.8% alginate (low viscosity)). A 300 μl droplet was left on a Ca-Agar plate (0.4 M mannitol, 50 mM CaCl2, 1% plant agar (Duchefa 1001.5000)) which was tilted to spread out the droplet, and after 30 min a floating solution (0.4 M mannitol, 50 mM CaCl2) was added to the plates to allow for movement of the layer. The layer was taken up by a spatula and moved to small Petri dishes containing F-PCN (described in [8]).

gDNA extraction

A single fully infiltrated leaf was thoroughly ground in liquid nitrogen and DNA was extracted using DNeasy Plant Mini Kit (Qiagen).

PCR of genome target NbRRA and NbPDS loci

PCR-amplicons containing the NbRRA & NbPDS targets were amplified using nested PCR: First 5 μl of protoplast suspension (obtained as described in ‘Protoplast isolation’) was used in a 50 μl PCR reaction using Phire Plant Direct PCR Master Mix (ThermoFisher F160S) with the cycle parameters: 5 min at 98 °C followed by 40 cycles of 10 s at 98 °C, 10 s at (65 °C for RRA and 62 °C for PDS) and 40 s at 72 °C followed by 7 min at 72 °C using the primers P348 & P232 and P346 & P342 for genome target PCR was performed in a 50 μl reaction using X7 polymerase [66] with 1:100 diluted 1’th PCR reaction as template and the cycle parameters: 5 min at 94 °C followed by 25 cycles of 30 s at 94 °C, 30 s at 58 °C and 30 s at 72 °C followed by 7 min at 72 °C and the primers P319 and P320.

Nested PCR of NbPDS2 was done in a 25 μl reaction using ClonAMP HiFi master mix 2x (Takara 639,298) with the cycle parameters: 5 min at 98 °C followed by 20 cycles of 30 s at 98 °C, 30 s at 65 °C and temperature dropping 0.5 °C per cycle and 30 s at 72 °C followed by 20 cycles of 30 s at 98 °C, 30 s at 58 °C and 30 s at 72 °C followed by 3 min at 72 °C and the primers P321 and P320.

Primers for scoring in leaf mutations were P321 & P322 (NbRRAalI1) and P324 & P326 (NbPDS2).

Cloning in pJet and sequencing

10 μl of PCR product was digested ON in a 50 μl reaction with Bgl (NbRRAalI1 amplicon) and AtrII (NbPDS amplicon). Enzyme Resistant bands were isolated from agarose gels using Nucleospin® Gel and Monarch® DNA
Gel Extraction Kit (New England Biolabs) and cloned into pJet1.2 using CloneJET PCR Cloning Kit #K1232. Sequences were aligned using CLC Workbench.

**Indel detection by amplicon analysis (IDAA) and semi quantification of IDAA peaks**

Indel Detection by Amplicon Analysis (IDAA) was done essentially as described in and outlined in [39] and in the Method section ‘PCR of genome target NbRRA and NbPDS loci’. Briefly A tri-primer PCR setup which relies of the incorporation of a fluorescent universal 6-FAM 5’-labelled primer (FamF), with the corresponding non-labeled primer in a 1:10 diluted concentration, was used for FAM labeling of PCR amplicons. PCR amplification of the NbRRAall1 and NbPDS2 regions were done using the ClonAMP HiFi master mix 2x (Takara 639,298) in a 25 μl reaction with the cycle parameters: 5 min at 95°C followed by 30 cycles of 30 s at 95°C, 30 s at 58°C and 30 s at 72°C followed by 3 min at 72°C. Primers were P230 & P231 (NbRRAall1) and P232 & P233 (NbPDS2), where bold designates FAM primer overhang (Additional file 5: Table S1).

Mutation frequencies, as identified by quantification of peak area in IDAA chromatograms, were estimated using the Open Source Software program Imagej (https://imagej.nih.gov/ij/) from and with areas identified as described (http://www.openwetware.org/wiki/Protein_Quantification_Using_Imagel).

**Fluorescence microscopy**

Fluorescence imaging (presence GFP) was carried out with an epifluorescence microscope Olympus BX41 equipped with a CCD camera (FITC filter for GFP fluorescence and DAPI filter for FDA staining) or a laser scanning confocal microscope Leica SP5 equipped with an Argon (488 nm) and a Argon laser (448 nm).

**Western blot analysis**

App. 50 μl of seedling powder, crushed in liquid N₂, was boiled in 50 μl 2 × SDS-PAGE loading buffer (280 mM SDS, 400 mM Tris, 40% glycerol, 1.4 M mercaptoethanol, 0.6 mM Bromophenol Blue) for 15 min and separated (200 V, 50 min) on 12% Criterion XT Bis-Tris gels (Bio-rad). Proteins were electrotransferred onto polyvinylidene difluoride (PVDF) membranes (Bio-rad) using a Trans-Blot® TurboTM Blotting instrument (Bio-rad). The membrane was blocked in blocking solution (PBS pH 7.5, 5% non-fat dry milk) overnight at 4°C under mild shaking. The membrane was probed with anti-GFP mouse IgG (Roche) and Anti-Flag M2 mouse IgG (Sigma) at 1 : 1000 dilution in blocking solution overnight at 4°C, followed by 3 × 5’ wash in PBS buffer (PBS pH 7.5). The membrane was then incubated with goat anti-mouse IgG conjugated to Alkaline Phosphatase (AP) (Sigma) (1 : 1000 dilution in blocking solution) for 1 h at room temperature, and rinsed 3 × 5’ with PBST. Pre-mixed NBT/BCIP AP solution (UCPH, DK) was added to the blot and incubated for color development.

**Post FACS residual gRNA activity of lysed protoplasts**

20 μl of protoplasts expressing gRNA-NbPDS2/SpCas9 were added to 80 μl PBS, briefly vortexed and left at room temperature for 2 h; 20 μl of protoplasts were added to PBS buffer with 5 μl RNaseA/T1 (Thermo fisher #EN0551), briefly vortexed and left at room temperature for 2 h; and 20 μl of protoplasts was flash frozen with immediately addition of 80 μl PBS which were then heated for 3 min at 95°C. Flanking primers used were P233 and P232.

**Flow cytometry and fluorescence activated cell sorting (FACS) of N. benthamiana protoplasts**

The protoplast solution was first passed through 50-μm filcons (BD Biosciences) to achieve a single-cell suspension. Protoplast suspensions were cytometrically analyzed and sorted with a FACSaria III (BD Biosciences) fitted with a 100-μm nozzle and using phosphate-buffered saline (PBS) as a sheath fluid. The procedure and setting used were as described in [29] with a large nozzle size (100 μm) to provide optimal survival for most cell types and sorting based on ~10,000 events. Briefly, the sheath pressure was set at 20 psi, and the deflection plate voltage was set at 5000 V (default “low” setting). A 488 nm Coherent Sapphire Solid State laser was used for excitation, and emission was measured at 530 nm for GFP. The photomultiplier tube voltage was set at 183 V for forward scatter, 286 V for side scatter, 308 V for GFP, and 518 V for Allophycocyanin. The threshold value for event detection was set at 8835 on forward scattering. The drop drive frequency was set to approximately 30 kHz, and the amplitude was set to approximately 45 V; the drop delay value was approximately 26 (these settings will vary slightly with day-to-day operation of the FACSaria III). Identification of viable, single protoplasts through the use of forward scatter (FSC) and side scatter (SSC) as a first gating strategy, which is routinely used for gating mammalian cells, was not attempted due to the high variability of protoplast size. Instead, the FITC and DAPI intensities were recorded as represented in dot plots. 10,000 events are displayed in each plot. Gates were set to separate and thus enable enrichment of WT and GFP transfected protoplasts, using the WT sample to define non-transfected wild type populations in the transfected samples. Transfected protoplasts were defined as FITC-positive events. Data were processed using the FACSDivA 8.0.1 software (BD Biosciences).
Viability test was done on a Sony SH800S Cell sorter, with automated setup for 130 μm microfluidics sorting chips, psi 9. PBS was used as sheath fluid, with samples sorted into flat-bottom 96 well microtitre-plates containing 200 μl W5 buffer. For visualization purposes protoplasts were layered at the bottom of the microtiter plate by a brief centrifugation step, 100×g, 5 min.

Gating strategy on Sony SH800S cell sorter was similar to those used on the BD FACSAria III sorter.

Additional files

**Additional file 1:** Figure S1. Localized GFP-fluorescence of SpCas9-2A-GFP/NbPD2-gRNA from Agrobacterium infiltrated in leaves of N. benthamiana 3 days post infiltration was evident in the contours epidermis cells of intact leaves (A). Overlay of bright field and fluorescence (FITC filter) microscopy of isolated SpCas9-2A-GFP/NbPD2-gRNA transformed protoplasts regularly showed 60 – > 80% transformation efficiency (B). GFP fluorescence was seen in cytoplasmic strands with some nuclei accumulation (A and C), which both are in accordance with a primarily cytoplasmic localization of the GFP. (PDF 5243 kb)

**Additional file 2:** Figure S2. WT N. benthamiana protoplasts pre and post FAC. Protoplasts were isolated as described in the Methods section, stored in buffer MMMS50 on ice and immediately FAC sorted (total population sorted) into the MMMS50 buffer and stored on ice. An estimated survival rate of ca 10–20% (concentric intact protoplast) was observed as evidenced by bright field (A) microscopy. (B, C) GFP expression analysis using confocal microscopy and viability test using propidium iodide (PI). Left panels are scan of the protoplasts expressing SpCas9-2A-GFP construct. Right panels non-transformed control. (B) Distinctable GFP signal can be observed in transformed protoplasts (arrowhead). (C) Viability analysis using propidium iodide (PI). Non PI stained protoplast expressing GFP were observed. (PDF 7907 kb)

**Additional file 3:** Figure S3. Post FACs residual gRNA/Cas9 activity of lysed protoplasts. Ribonucleaseprotein, i.e. in vitro transcribed gRNA mixed with heterologous expressed SpCas9 enzyme, delivered by PEG transformation, have been shown to confer efficient nuclease activity in Agrobacterium thaliana, tobacco, lettuce and rice protoplasts [10, 53]. We tested whether PBS mediated protoplast lysis could mediate additional extra-cellular derived indel formation in resultting in an over-expressing gRNA/SpCas9 activity. Incubation 2 h at room temperature in PBS buffer resulted in a 2–3 fold increased indel formation, compared to immediate activity abolishment through flash freezing/boiling or RNAse addition, as judged by resistant RE band intensities. Lanes: Pos Ctrl (NbPD2-2gRNA/SpCas9 positive from leaves), Neg ctrl (WT without NbPD2-gRNA/SpCas9), RT 2 h (PBS mediated lysis followed by 2 h incubation at room temperature), flash freezing (flash freezing in liquid N2 followed by boiling), +RNAse (RNAse addition). For experimental setup see Method section (PDF 191 kb)

**Additional file 4:** Figure S4. GFP-fluorescent protoplasts embedded in alginate. Single fluorescent protoplasts are visible by fluorescence (FITC filter) microscopy before (A) and after alginate embedment (B). Calli formation (C) of a single protoplast as evidenced by bright field microscopy. Protoplast embedment in alginate is described in the Methods section. (PDF 4381 kb)
