A W AIC: A WISE Astronomical Image Co-adder

Frank J. Masci and John W. Fowler
Infrared Processing and Analysis Center, Caltech 100-22, Pasadena, CA 91125, USA. Email: fmasci@caltech.edu

Abstract. We describe a new image co-addition tool, AWAIC, to support the creation of a digital Image Atlas from the multiple frame exposures acquired with the Wide-field Infrared Survey Explorer (WISE). AWAIC includes preparatory steps such as frame background matching and outlier detection using robust frame-stack statistics. Frame co-addition is based on using the detector’s Point Response Function (PRF) as an interpolation kernel. This kernel reduces the impact of prior-masked pixels; enables the creation of an optimal matched filtered product for point source detection; and most important, it allows for resolution enhancement (HiRes) to yield a model of the sky that is consistent with the observations to within measurement error. The HiRes functionality allows for non-isoplanatic PRFs, prior noise-variance weighting, uncertainty estimation, and includes a ringing-suppression algorithm. AWAIC also supports the popular overlap-area weighted interpolation method, and is generic enough for use on any astronomical image data that supports the FITS and WCS standards.

1. Introduction

The goal of image co-addition is to optimally combine a set of (usually dithered) exposures to create an accurate representation of the sky, given that all instrumental signatures, glitches, and cosmic-rays have been properly removed. By “optimally”, we mean a method which maximizes the signal-to-noise ratio (SNR) given prior knowledge of the statistical distribution of the input measurements.

The Wide-field Infrared Survey Explorer (WISE) mission will be generating over a million exposures (or frames) over the sky. WISE is a NASA Midex mission scheduled for launch in late 2009. It will survey the entire sky at 3.3, 4.7, 12, and 23µm with sensitivities up to three orders of magnitude beyond those achieved with previous all-sky surveys. For details on the scientific goals, requirements, instrument and mission design, see Mainzer et al. 2005. One of the primary products from WISE is a digital Image Atlas that combines the multiple 8.8 second, 47′ × 47′ frame exposures within predefined tiles over the sky. To support this, we have developed a suite of software modules collectively referred to as AWAIC for execution in the automated processing pipeline at the Infrared Processing and Analysis Center. The modules are written in ANSI-compliant C and wrapped into a Perl script, and will be made portable in the near future.

Here we review AWAIC’s co-addition algorithms, products, and extension to resolution enhancement (HiRes). It’s important to note that HiRes is not in the WISE baseline plan. It was implemented primarily to support offline research.
The statistical robustness and performance of algorithms will be addressed in more detail in future papers.

2. **WISE Frame Co-addition Pipeline**

Figure 1 gives an overview of the co-addition steps. It is assumed that the input science frames have been preprocessed to remove instrumental signatures and their pointing refined in some WCS using an astrometric catalog. Accompanying bad-pixel masks (in 32-bit integer format) and prior-uncertainty frames are optional. The frames are assumed to overlap with some predefined footprint (or tile) on the sky. This also defines the dimensions of the co-add products. The uncertainty frames store 1-σ values for each pixel. These are expected to be initiated upstream from a noise model specific to the detector and then propagated and updated as the instrumental calibrations are applied. The uncertainties are used for optional inverse-variance weighting of the input measurements, and for computing co-add flux uncertainties. If bad-pixel masks are specified, a bit-string template is used to select which conditions to flag against. The corresponding pixels in the science frames are then omitted from co-addition.

The first (optional) step is to scale the frame pixel values to a common photometric zero-point using calibration zero-point information in each FITS header. Currently, the software reads a zero-point in magnitudes stored in the “MAGZP” keyword. The common (or target) zero point is then written to the FITS headers of the co-add products to enable the calibration of photometric measurements. Frame overlap (or background-level) matching and outlier detection is then performed. These are described in §3. Since these initial steps modify the input frame and mask pixel values, local copies of the frames and masks are made to avoid overwriting the originals. After outliers have been flagged in the input masks, the frames are ready for co-addition. All “good”
(unmasked) pixels are reprojected and interpolated onto an upsampled output grid. Details are described in §4. The reprojection uses a fast input-to-output plane coordinate transformation that implicitly corrects for focal plane distortion if represented in the input FITS headers. The Simple Imaging Polynomial (SIP) convention for distortion is assumed (Shupe et al. 2005).

The outputs from AWAIC are the main intensity image, a depth-of-coverage map, a 1-σ uncertainty image based on input priors, an image of the outlier locations, and optionally if the overlap-area interpolation method was used, an image of the data-derived uncertainty computed from the standard deviation in each interpolated pixel stack and appropriately scaled by the depth-of-coverage. AWAIC also produces a wealth of Quality Assurance (QA) metrics and plots over pre-specified regions of the co-add footprint. These include background noise estimates, coverage and outlier statistics, and metrics to validate co-add flux uncertainties using χ² tests.

3. Preparatory Steps

3.1. Background Matching

Frame exposures taken at different times usually show variations in background levels due to, for example, instrumental transients, changing environments, scattered and stray light. The goal is to obtain seamless (and/or smooth) transitions between frames near their overlap regions prior to co-addition. We will want to equalize background levels from frame to frame, but at the same time preserve natural background variations and structures as much as possible. We have implemented the following simple method:

1. Fit a robust plane to each frame. By “robust”, we mean immune to the presence of bright sources and extended structure. Our goal is to capture the global underlying background level in a frame. There are of course cases where structure may span over most of a frame, and hence the background will be over-represented. The planar fit is parameterized by $z = f(x, y)$, where $z$ is the background level, and $x, y$ are frame-pixel coordinates.

2. The robust planar fits are subtracted from each respective frame. This effectively flattens the frames and places them on a zero-baseline.

3. Compute either: (i) the global median $M$ of all frame pixels contributing to the co-add footprint, or, (ii) a median plane from all the planar fits. The latter attempts to capture any natural background gradient over the co-add footprint.

4. Add this global median $M$ (a constant) to each of the “zero-level” frames (from 2), or, in the case of a median plane, extend it over the co-add region and then add it self-consistently to each input frame. The frames have now been matched to a common background level (or gradient). This will be more or less representative of the natural background over the co-add footprint region.

This method ensures continuity of the background across the footprint region after co-addition. This not only improves a co-add’s esthetic appearance (by minimizing frame level offsets between overlaps), but also makes it self-consistent.
Masci and Fowler

for scientific purposes. It’s important to note that instrumental transients or improper instrumental calibration (e.g., bad flat-fielding) can also manifest as gradients across frames. Therefore, one needs to be sure that any retained global gradient is purely astrophysical.

The above also includes a method to ameliorate biases from the possible presence of bright extended structure. Presence of extended structure (e.g., a galaxy) over a frame is first searched for by thresholding on the ratio of quantile differences in the pixel distribution, e.g., $Q_d = [q_{0.84} - q_{0.5}] / [q_{0.5} - q_{0.16}]$. Values of $Q_d \gtrsim 2$ usually indicate a highly skewed distribution and hence contamination from bright extended structure. If detected, a frame is partitioned into a grid and only those regions with the lowest median background value are used to perform the robust planar fitting. This method still has its limitations, but it extends the robustness of the algorithm.

3.2. Outlier Detection and Masking

The goal of outlier detection is to identify frame pixel measurements of the same location on the sky which appear inconsistent with the (bulk) remainder of the sample at that location. This assumes multiple frame exposures of the same region of sky are available. Potential outliers include cosmic rays, latents (image persistence), instrumental artifacts (including bad pixels), poorly registered frames from gross pointing errors, supernovae, asteroids, and basically anything that has moved or varied appreciably with respect to the inertial sky over the observation span of a set of overlapping frames.

In summary, the method involves first projecting and interpolating each input frame onto a common grid with user-specified pixel scale optimized for the detector’s Point Spread Function (PSF) size. The interpolation is performed using the overlap-area weighting method (analogous to using a top hat kernel). This accentuates and localizes the outliers for optimal detection (e.g., cosmic ray spikes). When all frames have been interpolated, robust estimates of the first and second moments are computed for each interpolated pixel stack $j$. We adopt the sample median ($\text{med}$), and the Median Absolute Deviation (MAD) as a proxy for the dispersion:

$$\sigma_j = 1.4826 \text{med} \{|p_i - \text{med}\{p_i\} |\},$$

where $p_i$ is the value of the $i^{th}$ interpolated pixel within stack $j$. The factor of 1.4826 is the correction necessary for consistency with the standard deviation of a Normal distribution in the large sample limit. The MAD estimator is relatively immune to the presence of outliers where it exhibits a breakdown point of 50%, i.e., more than half the measurements in a sample will need to be declared outliers before the MAD gives an arbitrarily large error.

The final step involves re-projecting and re-interpolating each input pixel again, but now testing each for outlier status against other values in its stack using the pre-computed robust metrics. A pixel with value $p_i$ is declared an outlier if for given “upper” ($u_{\text{thres}}$) and “lower” ($l_{\text{thres}}$) tail thresholds, either of the following is satisfied:

$$p_i > \text{med}\{p_i\} + u_{\text{thres}}\sigma_j$$
$$p_i < \text{med}\{p_i\} - l_{\text{thres}}\sigma_j$$

(2)
If declared an outlier, a bit is set in the accompanying frame mask for use downstream. The algorithm also includes an adaptive thresholding method in that if a pixel is likely to contain “real” signal (e.g., from a source), the upper threshold is automatically inflated by a specified amount to avoid (or reduce the incidence of) outlier flagging at that location. To distinguish between what’s real or not, we generate a background subtracted median-SNR co-add using all the input pixels. The background and local noise are computed using spatial median filtering and quantile differencing: \( \sigma \approx q_{0.5} \cdot q_{0.16} \) respectively. The idea here is that since these metrics are relatively outlier resistant, a large median pixel value in the co-add (or SNR derived therefrom) is likely to contain signal associated with a source. Therefore, when flagging outliers using Eq. 2 we also threshold on the SNR co-add to determine if \( u_{\text{thres}} \) should be inflated.

We require typically at least five samples (overlapping pixels) in a stack for the above method to be reliable. This is because the MAD measure for \( \sigma \), even though robust, can itself be noisy when the sample size is small. Simulations show that for the MAD to achieve the same accuracy as the most optimal estimator of \( \sigma \) for a normal distribution (i.e., the sample standard deviation), the sample size needs be \( \approx 2.74 \times \) larger. A noisy \( \sigma \) will adversely affect the ability to perform reliable outlier detection. Another requirement to ensure good reliability is to have good sampling of the instrumental PSF, i.e., at the Nyquist rate or better. When well sampled, more detector pixels in a stack can be made to align within the span of the PSF, and any pixel variations due to PSF shape are minimized. On the other hand, a PSF which is grossly under-sampled can artificially increase the scatter in a stack, with the consequence of erroneously flagging pixels containing true source signal. Figure 2 illustrates these concepts. The WISE detectors are all slightly better than critically sampled. Simulations
have shown that for depths-of-coverage of eight or more, (where eight is the median depth for WISE when scanning across the ecliptic), we expect to detect outliers to completeness and reliability levels of $\gtrsim 80\%$ for a nominal threshold of $\sim 5\sigma$.

4. Co-addition using PRF Interpolation

One of the interpolation methods in AWAIC involves using the detector’s Point Response Function (PRF) as the interpolation kernel. The PRF is simply the instrumental PSF convolved with the pixel response. When knowledge of the intra-pixel responsivity is absent, the pixel response is assumed to be uniform, i.e., a top hat. The PRF is what one usually measures off an image using the profiles of point sources. Each pixel can be thought as collecting light from its vicinity with an efficiency described by the PRF.

The PRF can be used to estimate the flux at any point in space as follows. In general, the flux in an output pixel $j$ is estimated by combining the input detector pixel measurements $D_i$ using PRF-weighted averaging:

$$f_j = \frac{\sum_i (r_{ij}/\sigma_i^2) D_i}{\sum_i r_{ij}/\sigma_i^2},$$

(3)

where $r_{ij}$ is the value of the PRF from input pixel $i$ at the location of output pixel $j$. The $r_{ij}$ are volume normalized to unity, i.e., for each $i$, $\sum_j r_{ij} = 1$. This will ensure flux is conserved. The inverse-variance weights $(1/\sigma_i^2)$ are optional and default to 1. The $\sigma_i$ can be fed into AWAIC as $1\sigma$ uncertainty frames, e.g., as propagated from a prior noise model. The sums in Eq. 3 are over all input pixels in all input frames. With multiple overlapping input frames, this will result in a co-add. The $1\sigma$ uncertainty in the co-add pixel flux $f_j$, as derived from Eq. 3 is given by

$$\sigma_j = \left[ \sum_i w_{ij}^2 \sigma_i^2 \right]^{1/2},$$

(4)

where $w_{ij} = (r_{ij}/\sigma_i^2)/\sum_i r_{ij}/\sigma_i^2$. Equation 4 assumes the measurement errors (in the $D_i$) are uncorrelated. Note that this represents the co-add flux uncertainty based on priors. With $N_f$ overlapping input frames and assuming $\sigma_i = \text{constant}$ throughout, it’s not difficult to show that Eq. 4 scales as: $\sigma_j \simeq \sigma_i / \sqrt{N_f P_j}$, where $P_j = 1/\sum_i r_{ij}^2$ is a characteristic of the detector’s PRF, usually referred to as the effective number of “noise pixels”. This scaling also assumes that the PRF is isoplanatic (has fixed shape over the focal plane) so that $P_j = \text{constant}$. Furthermore, the depth-of-coverage at co-add pixel $j$ is given by the sum of all overlapping PRF contributions at that location: $N_j = \sum_i r_{ij}$. This effectively indicates how many times a point on the sky was visited by the PRF of a “good” detector pixel $i$, i.e., not rejected due to prior-masking. If no input pixels were masked, this reduces to the number of frame overlaps, $N_f$.

In general, the PRF is usually non-isoplanatic, especially for large detector arrays. AWAIC allows for a list of spatially varying PRFs to be specified, where each PRF corresponds to some pre-determined region (e.g., a partition of a square grid) on the detector focal plane.
Equation 3 can be compared to the popular pixel overlap-area weighting method, e.g., as implemented in the \texttt{Montage} tool. In fact if the PSF is grossly under-sampled, then the PRF is effectively a top hat spanning one detector pixel. The interpolation as described above then reduces to overlap-area weighted averaging where the interpolation weights $r_{ij}$ become the input($i$)-to-output($j$) pixel overlap areas $a_{ij}$. Incidentally, AWAIC also implements the overlap-area weighting method, in case detector PRFs are not available.

Figure 3 shows a schematic of a detector PRF mapped onto the co-add output grid. The PRF boundary is shown as the dashed circle and is centered on the detector pixel. To ensure accurate mapping of PRF pixels and interpolation onto the co-add grid, a finer cell-grid composed of “pixel cells” is set up internally. The cell size can be selected according to the accuracy to which the PRF can be positioned. The PRF is subject to thermal fluctuations in the optical system as well as pointing errors if multiple frames are being combined. Therefore, it does not make sense to have a cell-grid finer than the measured positional accuracy of the PRF. The PRF pixels are mapped onto the cell-grid frame by first projecting the center of the detector pixel with distortion correction if necessary, and then using a local transformation with rotation to determine the positions of the PRF pixels in the cell-grid. The value of a PRF-weighted detector pixel flux $r_{ij}D_i$ in a co-add cell pixel $j$ is then computed using either a nearest-neighbor match, or, the overlap-area weighting method. The latter is more accurate but slower.

After all the input pixels with their PRFs have been mapped, the internal co-add cells are down-sampled to the desired output co-add pixel sizes.

There are three advantages to using the PRF as an interpolation kernel. First, it reduces the impact of masked (missing) input pixels if the data are well sampled, even close to Nyquist. This is because the PRF tails of neighboring

\footnote{http://montage.ipac.caltech.edu/}
“good” pixels can overlap and stretch into the bad pixel locations to effectively give a non-zero coverage and signal there in the co-add. Second, Eqs 3 and 4 can be used to define a linear matched filter optimized for point source detection. This effectively represents a cross-covariance of a point source template (the PRF) with the input data. It leads to smoothing of the high-frequency noise without affecting the point source signal sought. In other words, the SNR per pixel in the co-add is maximized for detecting point source peaks. The inclusion of inverse-variance weighting further ensures that the SNR is maximized since it implies the co-add fluxes will be maximum likelihood estimates for normally distributed data. The creation of co-adds which are also optimized for source-detection will benefit projects (e.g., WISE) where a source catalog is also a release product. The third advantage is that the PRF allows for resolution enhancement by “deconvolving” its effects from the input data.

Use of the PRF as an interpolation kernel also has its pitfalls, at least for the process of co-add generation. The operation defined by Eq. 3 leads to a “smoothing” of the input data in the co-add grid. This smoothing is minimized for a top-hat PRF spanning one detector pixel (equivalent to overlap-area weighting). This leads to smearing of the input pixel signals and one consequence is that cosmic rays can masquerade as point sources (albeit with narrower width) if not properly masked. For point sources with Gaussian profiles, their effective width will increase by a factor of \( \sim \sqrt{2} \). Furthermore, a broad kernel will cause the noise to be spatially correlated in the co-add, typically on scales (correlation lengths) approaching the PRF size. Correlations are minimized for top-hat kernels. Both the effects of flux smearing and correlated noise must be accounted for in photometric measurements off the co-add, both in profile fitting and aperture photometry. The compensation for flux smearing can be handled through an appropriate aperture correction. Ignorance of correlated noise will cause photometric uncertainties to be underestimated. Methods on how to account for correlated noise in photometry will be discussed in a future paper.

5. Extension to Resolution Enhancement

We now describe a generic framework for co-addition with optional resolution enhancement (HiRes). Above we referred to the concept of combining frames to create a co-add. The HiRes problem asks the reverse: what model or representation of the sky propagates through the measurement process to yield the observations within measurement error? As a reminder, the measurement process is a filtering operation performed by the instrument’s PRF:

\[
\text{sky (truth)} \otimes \underbrace{\text{PSF} \otimes \text{sampling}}_{\text{PRF}} \rightarrow \text{measurements}. \tag{5}
\]

Our goal is to infer a plausible model of the sky or “truth” given the instrumental effects.

5.1. The Maximum Correlation Method

The HiRes algorithm in AWAIC is based on the Maximum Correlation Method (MCM). This was originally implemented to boost the scientific return of data
from IRAS approximately 20 years ago (Aumann et al. 1990; Fowler & Aumann 1994), and is still provided as an online service to users. We have now implemented MCM in a form which is suitable for use on any imaging data that are compatible with the FITS and WCS standards, and the SIP convention for distortion. The versatility of MCM is that it implicitly generates, as its very first step (or first iteration), a PRF-interpolated co-add as described above. The algorithm is as follows.

1. First we begin with a flat model image of ones, i.e., a “maximally correlated” image:

   \[ f^{n=0}_j = 1 \forall j, \]  

   where the subscript \( j \) refers to a pixel in the upsampled output grid, and \( n \) refers to the iteration number. This starting image is a first guess at the “truth” that we plan to reconstruct. Obviously this is a bad approximation, since it represents what we know without any measurements having been used yet. We could instead have used prior information as the starting model if it was available.

2. Next, we use the detector PRF(s) to “observe” this model image, or predict the input detector measurements. Starting with \( n = 1 \), the predicted flux in each detector pixel \( i \) is obtained by a “convolution”:

   \[ F^n_i = \sum_j r_{ij} f^{n-1}_j, \]  

   where \( r_{ij} \) is the response (PRF value) of pixel \( i \) at the location of output model pixel \( j \). Eq. 7 is a tensor inner product of the model image with the flipped PRF (see below for why we need to flip the PRF). It may not be a true convolution since the kernel \( r_{ij} \) may be non-isoplanatic.

3. Correction factors are computed for each detector pixel \( i \) by dividing their measured flux, \( D_i \), by those predicted from the model (Eq. 7):

   \[ K_i^n = \frac{D_i}{F^n_i}. \]  

4. For each model pixel \( j \), all “contributing” correction factors, i.e., contributed by the overlapping PRFs of all neighboring detector pixels \( i \) are averaged using response-weighted averaging (with optional \( 1/\sigma_i^2 \) weighting):

   \[ C^n_j = \frac{\sum_i (r_{ij}/\sigma_i^2) K_i^n}{\sum_i r_{ij}/\sigma_i^2}, \]  

5. Finally, the model image pixels are multiplied by their respective averaged correction factors (Eq. 9) to obtain new refined estimates of the model fluxes:

   \[ f^n_j = f^{n-1}_j C^n_j. \]
after the first \((n = 1)\) iteration of MCM, \textit{co-add} fluxes will automatically result:
\[ f_1^j = f_0^j C_1^j = f_j. \]

If we desire resolution enhancement, the above process is iterated, where the model image from step 5 is used to re-predict the measurements in step 2. This process of iteratively refining the model continues until the model reproduces the measurements to within the noise, i.e., the predictions from Eq. 7 are consistent with the measurements \(D_i\). If input prior uncertainties \((\sigma_i)\) are available, this convergence can be formally checked using a global \(\chi^2\) test that uses all the input detector pixels:
\[
\chi^2_n = \sum_{i=1}^{N} \frac{(D_i - F^n_i)^2}{\sigma_i^2},
\]
where we expect \(\chi^2_n \approx N\) (the number of degrees of freedom, \(= \) the number of input pixels). Alternatively, convergence can also be checked by examining the correction factors for each detector pixel (Eq. 8), where we expect \(K^n_i \approx 1\) within the noise, or, via the averaged correction factors (Eq. 10), where \(C_j^0 \rightarrow 1\) after many iterations. An image of the latter can be generated by the software at each iteration. Iterating much further beyond the initial signs of convergence has the potential of introducing unnecessary (and usually unaesthetic) detail in the model. This is important to ensure a parsimonious HiRes solution.

Therefore, it is an algorithmic property of MCM that it only modifies (or de-correlates) a \textit{flat} starting model image to the extent necessary to make it reproduce the measurements within the noise. A PRF-interpolated co-add (from the first MCM iteration) will generally not satisfy the measurements after it is “convolved” with the detector PRFs, i.e., when subject to the measurement process (Eq. 5).

As a detail, the input PRFs are first flipped in \(x\) and \(y\) (or equivalently rotated by \(180^\circ\)) when HiRes’m is performed \((n > 1)\). This is to conform to the usual rules of convolution and assumes the input PRFs were made by combining images of point sources observed with the same detector in the same native \(x\)-\(y\) pixel frame. For PRF-interpolated co-adds however (that terminate at \(n = 1\)), the PRFs are not flipped since a cross-covariance with the input data is instead needed. The PRFs here are used as matched filters to generate products optimized for point source detection (see §4).

It is also worth noting that MCM reduces to the classic Richardson-Lucy (RL) method if the following are assumed: (i) the PRF is isoplanatic so that a constant kernel allows for Fourier-based deconvolution methods to be used; (ii) the inverse-variance weighting of measurement correction factors is disabled from the PRF-weighted averaging (Eq. 9), or equivalently if all the input variances \(\sigma^2_i\) are assumed equal. This implies the solution will converge to the maximum likelihood estimate for data that are Poisson distributed. With inverse-variance weighting included, the solution converges to the maximum likelihood estimate for Gaussian distributed data. This is usually always satisfied for astronomical image data in the limit of high photon counts; (iii) there is no explicit testing for global convergence at each iteration by checking, for example, that the solution reproduces the data within measurement error (Eqs 7 and 11). This criterion was indeed suggested by Lucy (1974), although it is seldom used in modern implementations of the RL method.
In the absence of prior information for the starting model, MCM implicitly gives a solution which is the “smoothest” possible, i.e., has maximal entropy. This should be compared to maximum entropy methods (e.g., Cornwell & Evans 1985) which attempt to minimize the $\chi^2$ of the differences between the data and the convolved model, with an additional constraint imposing smoothness of the solution. MCM requires no explicit smoothness constraint. MCM can indeed use a regularizing constraint in the form of non-flat starting model, (e.g., an image of the sky from another detector or wavelength), but this jettisons the idea of an image with maximally correlated pixels, and the refined model image will not be the smoothest possible. Smoothness is important because it can be used to convey fidelity in a model. In general, the solution to a deconvolution problem is not unique, especially in the presence of noise. Many models can be made to fit the data, and many methods invoke regularization techniques in order to select a plausible solution. A consequence is that some methods give more structure or detail than necessary to satisfy the data, and there is no guarantee that this structure is genuine. MCM adopts the Occam’s razor approach. Given no prior constraints (apart from satisfying the input data), MCM will always converge on the simplest solution. This will be the smoothest possible.

5.2. The CFV Diagnostic

A powerful diagnostic from MCM is the Correction Factor Variance (CFV). This represents the variance about the PRF-weighted average correction factor (Eq. 9) at a location in the output grid for iteration $n$: $V^n_j = \langle K^n_i \rangle_j - \langle K^n_i \rangle^2_j$, or

\[
V^n_j = \sum_i w_{ij} [K^n_i]^2 - \left[ \sum_i w_{ij} K^n_i \right]^2,
\]

where $w_{ij} = (r_{ij}/\sigma^2_i)/\sum_i r_{ij}/\sigma^2_i$, and the detector-pixel correction factors $K^n_i$ were defined in Eq. 8. At early iterations, the CFV is generally high everywhere because spatial structure has not yet been resolved, and the model contradicts the measurements when subject to the measurement process. If after convergence, all the detector-pixel measurements contributing a non-zero response at some location $j$ agreed exactly with their predicted fluxes (Eq. 7), then all the $K^n_i$ would be $\approx 1$ and the CFV ($V^n_j$) at that location would be zero. Areas with a relatively large CFV indicate the presence of input pixel measurements which do not agree with the majority of the other measurements (e.g., outliers). It could also indicate noisy data, saturated data, regions where the PRF is not a good match (e.g., erroneously broad), or that a field has not yet converged and would benefit from further iteration. By thresholding the CFV, one can therefore create a mask for a HiRes image to assist in photometry, e.g., to avoid outliers and unreliable detections from amplified noise fluctuations (see below).

Example CFVs for the M51 galaxy are shown in Figure 6. The corresponding co-add and HiRes’d images appear in Figure 5. To illustrate the above concepts, outlying input measurements were not masked in the left and middle images of Figure 6. These refer to iteration levels $n = 1$ and $n = 40$ respectively, with the latter corresponding to convergence. The CFV image on the far right was created from data with outliers detected and masked a priori using the algorithm described in § 3.2.
Apart from providing a qualitative diagnostic, the CFV can also be used to compute a posteriori (data-derived) uncertainties in the pixel fluxes $f^n_j$ in a HiRes image. In general, the 1-σ uncertainty at iteration $n$ can be written in terms of the CFV as:

$$\sigma^n_j = c^n f^n_j \sqrt{V^n_j / \sum_i r_{ij}}, \quad (13)$$

where the sum is over the responses from all measurements $i$ at output pixel $j$, i.e., the effective depth-of-coverage. $c^n$ is a correction factor to account for re-distribution of noise power across spatial frequencies from one iteration to the next. At low iterations, power is relatively high at low frequencies, i.e., the noise is correlated across pixels. As iterations increase, noise is de-correlated and power migrates to high frequencies. The spectrum approaches that of white noise, provided the input measurement noise was spectrally white. For $n = 1$ (giving a co-add), $c^1 \equiv 1/\sqrt{P_j}$, where $P_j$ is the effective number of noise pixels defined in §4. With $c^1$ written this way, Eq. (13) becomes equivalent to the co-add pixel uncertainty defined in Eq. 4. In general, the $c^n$ at any iteration $n \geq 1$ can be approximated from the output image products as:

$$c^n \sim \frac{\sigma_{RMS}[f^n_j]}{\langle \sigma^n_j [c^n = 1] \rangle}, \quad (14)$$

where $\sigma_{RMS}$ is the standard-deviation (or some robust equivalent) of the pixel noise fluctuations within a “source-free” stationary background region with ≈uniform depth-of-coverage in the $f^n_j$ image. The denominator is the mean (or median) of Eq. (13) with $c^n = 1$ in the same region. At the time of writing, AWAIC only computes an image of $\sigma^n_j [c^n = 1]$, since it can be quite subjective on how the source-free stationary background is chosen. If such doesn’t exist, background fitting may be required with $\sigma_{RMS}$ computed from the fit residuals. The user can then rescale the $\sigma^n_j [c^n = 1]$ image using the estimate of $c^n$ from Eq. (14). This will give pixel uncertainties which are more or less statistically compatible with noise fluctuations in the HiRes’d image. Pixel SNRs will also be the maximum possible since MCM would have converged to the maximum likelihood estimate for data that were Gaussian distributed. With the correct value of $c^n$, a user then has an estimate of the flux uncertainty anywhere in the HiRes’d image, including at the location of sources. This will allow one to estimate uncertainties in source photometry. Noise correlations are also expected to be minimal in a converged HiRes image, or negligible if products were created with ringing suppression turned on (see below).

5.3. Ringing Suppression

Like most deconvolution methods, MCM can lead to ringing artifacts in the model image. This limits super-resolution, i.e., when attempting to go well beyond the diffraction limit of an imaging system. In general, ringing occurs because the reconstruction process tries to make the model image agree with the “true” scene with access to only the low spatial frequency components comprising the data. The input data are usually band-limited, and information beyond some high spatial frequency cutoff can never be recovered. The best we can ever reconstruct is a “low-pass filtered” version of the truth, with the filter
determined by the maximum spatial frequency the observations provide. This includes the finite sampling by pixels. A hard high frequency cutoff will lead to sinc-like oscillations in real image space. The magnitude of the ringing depends on the strength of a source relative to the local background intensity level.

It is no accident that a solution with ringing is the smoothest (and simplest) solution possible with MCM. Anything smoother (with more low frequency power) will not satisfy the measurements when subject to the measurement process (Eq. 5). However, since a large number of less-smooth solutions can reproduce the observations, those without ringing are generally more desirable. Therefore, we relax our request for the smoothest image and use prior knowledge that the background and (desired) source fluxes are physically distinct and separable. There have been numerous approaches that have used this philosophy (e.g., Lucy 1994). In brief, the ringing suppression algorithm in AWAIC first generates an image of the slowly varying background for each input frame on some specific scale using median filtering; this is subtracted from the respective input frames to create the “source” images; negative noise fluctuations are set to zero, and a tiny positive offset added; MCM is then run on the background-subtracted images until convergence; the background images are combined and then added to the HiRes’d source-image product. This operation enforces a positivity constraint for reconstruction of the source signals. It ensures that source flux won’t ring against an essentially zero background level so power can be forced into high spatial frequencies. After the background has been added to the HiRes’d source-only product, MCM is re-executed for several iterations using this as the starting model image and the original frames as input. This step re-adjusts the solution and attempts to restore the intrinsic noise properties of the HiRes process, i.e., what one would have obtained if no background were removed or positivity constraint enforced. It ensures that photometric uncer-

Figure 5 gives an overview of the above steps.

5.4. HiRes in Practice

Like most deconvolution methods, MCM does not alter the information content of the input image data. The signal and noise at a given frequency are scaled approximately together, keeping the SNR fixed. The process just re-emphasizes different parts of the frequency spectrum to make images more amenable to a certain kind of examination, e.g., for detecting previously unresolved objects and thereby increasing the completeness of surveys.

For optimal HiRes’ing, the input data will have to adequately sample the instrumental PSF to at least better than the Nyquist sampling frequency $2\nu_c$, where $\nu_c$ is the maximum frequency cutoff inherent in the PSF. For a simple diffraction-limited system with aperture diameter $D$, $\nu_c \propto D/\lambda$ and corresponds to the full width at half maximum (FWHM) of an Airy beam. Even if the detector pixels undersample the PSF (below Nyquist), redundant coverage with $N$ randomly dithered frames can help recover the high spatial frequencies, since the average sampling will scale as $\approx 1/N$ of an input pixel. The better the sampling, the better the HiRes algorithm is at improving spatial resolution. For imaging data from the Spitzer IRAC and MIPS detectors with typically $\text{SNR} \gtrsim 5/\text{pixel}$ and 10 frame overlaps, our HiRes algorithm reduces the FWHM of the effective PRF to $\approx 0.35\lambda/D$ - a factor of almost 3 below the diffraction limit. This corresponds to almost an order of magnitude increase in flux per solid angle for a Gaussian profile. This enhancement assumes accurate knowledge of the PRF over the focal plane.

An example output from AWAIC at three MCM iteration levels is shown in Figure 5. At high iterations, point source ringing starts to appear. The ringing around the satellite dwarf galaxy at the bottom is aggravated because the core is saturated in the data, and the PRF used for HiRes’ing (which is derived from unsaturated data) is not a good match. “Flat” core profiles in the data, due
6. Summary and Future Work

We have given a broad overview of the algorithms implemented in a new generic co-addition/HiRes’ing tool. The goal is to produce high fidelity science quality products with uncertainty estimates and metrics for validation thereof. The HiRes (MCM) algorithm contains considerable improvement over previous methods in that it includes \textit{a posteriori} uncertainty estimation, statistically motivated convergence criteria, a powerful diagnostic (the CFV) to locate inconsistencies in the input data and assess the overall quality of HiRes solutions, and the ability to handle non-isoplanatic PRFs. Algorithms will be discussed in more detail in future papers. Future work will explore methods to accelerate convergence in MCM, the ability to handle time-dependent PRFs (e.g., adapted to variable seeing), and an analysis of the completeness, reliability, and photometric accuracy of sources detected in HiRes’d images, especially in confused fields. More
examples, analyses, user-interface details, and animations of MCM can be found at [http://web.ipac.caltech.edu/staff/fmasci/home/wise/awaic.html](http://web.ipac.caltech.edu/staff/fmasci/home/wise/awaic.html)
