ABSTRACT

BACKGROUND AND PURPOSE: Juvenile xanthogranuloma is a non-Langerhans cell histiocytosis primarily affecting children. The purpose of this study was to characterize the imaging features of histologically confirmed pediatric head and neck juvenile xanthogranuloma.

MATERIALS AND METHODS: A retrospective review was performed of medical records and imaging of histologically confirmed head and neck juvenile xanthogranuloma.

RESULTS: Ten patients (6 girls, 4 boys) 1 month to 12 years of age were imaged with ultrasound only \((n = 1)\), CT only \((n = 2)\), CT and ultrasound \((n = 1)\), MR imaging only \((n = 3)\), or MR imaging and CT \((n = 3)\). Masses were solitary in 9 patients and multiple in 1. Solitary masses were located in the external auditory canal, infra-auricular region, infratemporal fossa with intracranial extension, frontal scalp, and subperiosteal space eroding the calvaria and along the dura. One patient with disseminated disease had scalp-, calvarial-, and dural-based masses. Clinical presentation included a mass or alteration in function. On sonography, juvenile xanthogranuloma appeared hypoechoic. On contrast-enhanced CT, masses appeared homogeneous and isoattenuating with muscle and sometimes eroded bone. On MR imaging, compared with the cerebral cortex, the masses appeared hyper- or isointense on T1 and hypointense on T2, had decreased diffusivity, and enhanced homogeneously. Juvenile xanthogranuloma was not included in the differential diagnosis in any case.

CONCLUSIONS: Head and neck juvenile xanthogranuloma has varied manifestations. Mild hyperintensity on T1, hypointensity on T2 compared with the cerebral cortex, decreased diffusivity, and homogeneous enhancement are characteristic. Awareness of these features should prompt radiologists to include juvenile xanthogranuloma in the differential diagnosis of pediatric head and neck masses.

ABBREVIATIONS: HN = head and neck; JXG = juvenile xanthogranuloma; LCH = Langerhans cell histiocytosis; US = ultrasound
because an infiltrative appearance may mimic malignancy.\(^2,22\) Previous reports detailing the radiographic features of JXG are limited to case reports and several small series or to a limited description of imaging within the context of a clinicopathologic report.\(^4-21\)

The purpose of this study was to provide detailed characterization of the ultrasound (US), CT, and MR imaging features of JXG in the HN region.

**MATERIALS AND METHODS**

Boston Children’s Hospital institutional review board approval was obtained for a retrospective review of pathologically confirmed pediatric cases of JXG. The pathology database at Boston Children’s Hospital was searched for all reports containing the text “xanthog” in patients younger than 19 years of age from December 1997 to December 2013. Cases were included only if the incisional or excisional biopsy met histologic criteria for JXG. The site of each biopsy was recorded. Patients with biopsies showing JXG involving the HN were studied further by review of their pathology and radiology records. Pathology was reviewed by a pediatric pathologist. Radiology examinations were reviewed by a pediatric neuroradiologist with approximately 20 years of experience and a neuroradiology fellow. For patients who were imaged with sonography, CT, and/or MR imaging, original images were reviewed in detail. The maximum lesion diameter on the presenting imaging examination was recorded. The attenuation of the ultrasound (US), CT, and MR imaging features of JXG are typically yellowish, due to their high lipid content.\(^5,8\) Hematoxylin-eosin stain, original magnification \(\times 600\). Microscopically, abundant variably lipidized histiocytes are present (arrow), usually with admixed Touton giant cells (star) and scattered inflammatory cells (not shown on this image).

The differential diagnosis provided on the original radiology reports was assessed for the 9 patients for whom the histopathologic diagnosis of JXG was not known at the time of imaging.

**RESULTS**

During a 16-year period, there were 114 children with a histologic diagnosis of JXG. Lesions involved the skin in 107 (94%) of these patients. Multiple lesions were present in 8 patients. Imaging was performed in 14 of 114 (12%) patients. Imaged lesions involved the skin and subcutaneous tissues (back, chest, neck, scalp, and groin), abdominal wall rectus sheath, paraspinal muscles, liver, neck, skull, and external auditory meatus. The HN was involved in 67 of 114 (59%) patients. Sites of cutaneous HN involvement included the forehead, cheek, nose, chin, ear, eyelid, lip, neck, and scalp. Review of pathologic features in all cases revealed diagnostic features of JXG (Fig 1). The features included an infiltrate of variably xanthomatized mononuclear histiocyte-like cells. Touton giant cells were seen in all except 1 case, and eosinophils and lymphocytes were seen in most cases.

Ten patients had imaging of HN lesions. The 6 female and 4 male patients ranged in age from 1 month to 12 years at the time of imaging, with 8 children younger than 1 year of age. Their clinical presentations and initial radiologic diagnoses based on the imaging findings are summarized in Table 1. US only was performed in 1 patient; US and CT, in 1 patient; CT only, in 2 patients; MR imaging only, in 3; and both MR imaging and CT, in 3. Imaging characteristics are summarized in Table 2. Lesions were solitary in 9 children and multiple in 1 patient who had disseminated disease. Maximum diameters of the lesions in the 10 patients ranged from 2 to 60 mm.

Doppler US examinations performed for evaluation of each of the superficial lesions, one adjacent to the coronal suture and the other in the infra-auricular region (Fig 2), revealed sharply defined, ovoid, slightly heterogeneous, hypoechogenic masses without demonstrable internal blood flow.

On contrast-enhanced CT, the lesions appeared as homogeneous, solid soft-tissue masses without calcifications and isointense, or hyperintense with respect to the signal intensity of the cerebral cortex, based on visual inspection. The presence of enhancement on postcontrast T1-weighted sequences within the lesions was characterized as homogeneous versus heterogeneous. ADC maps were generated from diffusion-weighted images, and whole-lesion average ADC measurements were obtained by using a freehand ROI. The differential diagnosis provided on the original radiology reports was assessed for the 9 patients for whom the histopathologic diagnosis of JXG was not known at the time of imaging.
in a third patient showed lytic destruction of the temporal bone affecting the floor of the middle ear space, the tegmen tympani, and the lateral retroauricular mastoid cortex. There was also erosion of the ossicles and otic capsule region of the petrous bone (Fig 3). Bony erosion was not identified in 3 of 6 children. All of these children had small, nonspecific, enhancing soft-tissue masses projecting into the external auditory canal or involving the skin and subcutaneous tissues beneath the ear (Fig 2).

As suggested by the range of technical parameters, the MR imaging technique has evolved considerably during the study period, with a more recent trend toward imaging on 3T systems using multichannel phased array coils with an FOV optimized for the ROI and higher resolution imaging. Neverthe-

**Table 1: Patient age and sex, clinical presentation, lesion location, and radiographic diagnosis**

| Case | Age, Sex | Clinical Presentation | Location | Radiographic Diagnosis |
|------|----------|-----------------------|----------|------------------------|
| 1    | 10 yr, F | Mass and bloody ototympanoma for 10 days | External auditory canal, polyploid mass | Polyp |
| 2    | 4 mo, M  | Mass and bloody discharge for 1 month | External auditory canal, subcutaneous tissues | Sebaceous cyst, dermoid or branchial cleft cyst |
| 3    | 3 mo, M  | Reddish-blue nodule for 2 days | Infra-auricular, subcutaneous, and cutaneous | Lymph node, pilomatrixoma, nontuberculous mycobacterial infection |
| 4    | 1 mo, M  | Facial weakness, otorrhea for 1 month | Infratemporal fossa, middle ear space, bony erosion, intracranial, temporal lobe edema | LCH, neuroblastoma |
| 5    | 7 mo, F  | Scalp mass for 2 weeks | Subperiosteal with outer table erosion, parietal bone | Neuroblastoma metastasis, LCH, fibromatosis, other malignant tumor |
| 6    | 4 mo, F  | Enlarging scalp mass for 6 weeks | Cutaneous edema, subcutaneous scalp mass over coronal suture | Dermoid |
| 7    | 1 mo, F  | Mass over nose since birth | Subcutaneous tissue, midline nasofrontal | Neuroglial heterotopia |
| 8    | 10 mo, F | Enlarging mass over nose for 3 weeks | Subperiosteal with outer table erosion, parietal frontal | LCH, metastasis such as neuroblastoma, other malignant tumor |
| 9    | 12 yr, F | Tremor for 6 months, recent seizure | Intracranial, extra-axial; frontal lobe edema | Tumor not otherwise specified |
| 10   | 9 mo, M  | Multiple skin lesions since birth, occipital lesion for 4 weeks | Innumerable scalp lesions; occipital calvarial, epidural; intracranial parietal dural-based | Referred for imaging with known diagnosis of JXG |

**Table 2: Lesion characteristics on CT and MR imaging**

| Case | Size (mm) | US | CT Attenuation a without Contrast | CT Attenuation b with Contrast | Bony Erosion | Relative Signal Intensity on T1b | Relative Signal Intensity on T2b | Enhancement Postgadolinium | ADC (×10⁻³ mm²/s) |

a Compared with muscle.

b Compared with gray matter.

**FIG 2.** A 3-month-old boy with a reddish-blue infra-auricular nodule that had been noticed for 2 days (patient 3). A, Transverse sonographic image reveals a hypoechoic solid mass. The mass was mistaken for adenopathy. B, Axial contrast-enhanced CT image shows a sharply circumscribed subcutaneous mass (arrow) that also involves the skin. The mass is isoattenuating with muscle and has no distinguishing characteristics other than its location. The lack of calcification is unusual for pilomatrixoma, which is the most common tumor in this location. The lack of necrosis or parotid space adenopathy is atypical for nontuberculous mycobacterial infection, which is the most common infection in this location.
less, on T2-weighted MR images, the JXG ranged from hypointense (3 of 6 patients) to isointense (3 of 6 patients) relative to gray matter (Figs 3–5), while on T1-weighted sequences before administration of contrast, the lesions ranged from isointense (3 of 6 patients) to hyperintense (3 of 6 patients) relative to gray matter (Figs 4 and 5). Diffusion-weighted imaging was available in 4 cases, and the lesions demonstrated decreased diffusivity (Figs 3 and 5), appearing hypointense relative to the cortex on ADC maps, with average ADC values of the lesions ranging from 0.53 to 0.78×10⁻³s/mm². Enhancement on postcontrast T1-weighted MR imaging was homogeneous in all patients (Figs 3–7).

Two patients had extra-axial lesions associated with edema in the adjacent brain parenchyma with seizures in one of these children (Figs 3 and 6). The other child presented a few weeks after birth with left facial weakness, and imaging revealed temporal bone erosion, as detailed earlier, with progressive enlargement in the soft-tissue components extending inferiorly into the infratemporal fossa and superiorly into the middle cranial fossa on serial imaging (Fig 3). One patient had disseminated disease with innumerable cutaneous and subcutaneous lesions; a calvarial mass; and lobulated, plaquelike dural-based lesions (Fig 7). This patient also had abdominal visceral involvement.

A diagnosis of JXG before head and neck imaging was known in only 1 patient who had cutaneous lesions and disseminated disease. For the remaining 9 patients, the radiologic differential diagnosis provided for the tumor varied depending on the location of the tumor (Table 1). Proposed differential diagnoses included Langerhans cell histiocytosis (LCH) or neuroblastoma (masses with bony erosion), neuronal heterotopia (midline nasofrontal mass), granulomatous inflammation, lymph node or nonmineralized pilomatrixoma (subcutaneous infra-auricular lesion), epidermoid or dermoid (lesion over a coronal suture and external auditory canal lesion), and first branchial cleft cyst or polyp (external auditory canal lesion). Most interesting, JXG was not included in the initial radiologic differential diagnosis for any of these 9 patients.

FIG 3. A 1-month-old boy with a 1-month history of left facial weakness and otorrhea (patient 4). A, Coronal T2-weighted MR image shows a mass that is hypointense compared with the cortex. Tumor involves the infratemporal fossa (long arrow), erodes the skull base and tegmen tympani, and involves the middle ear space (arrowhead) and epidural space in the middle cranial fossa. There is edema of the adjacent temporal lobe (short arrow). Scalp swelling is due to recent surgical debulking of the intracranial component at another institution. B, Coronal contrast-enhanced, fat-suppressed T1-weighted MR imaging shows the homogeneously enhancing mass extending into the middle ear space and the epidural space (arrow). C, On this axial DWI ADC image, the lesion (arrows) demonstrates decreased diffusivity. Axial CT image (D) shows lytic destruction of the mastoid temporal bone retroauricular cortex (short arrow). Tumor extends into the left middle ear space with erosion of the short process of the incus (long arrow) along its medial aspect and erosion of the otic capsule bone around the oval window and lateral semicircular canal (arrowhead).

DISCUSSION

Our study confirmed that the HN is a favored location for both cutaneous and extracutaneous JXG; the latter included the calvaria, midline nasofrontal region, periauricular region, and temporal bone. Intracranial disease in our series manifested as a dural-based mass or masses. Multifocal disease is rarely encountered. A small but important proportion of all pediatric JXG cases (12%) of this classic pediatric disease undergo preoperative imaging. Our study demonstrated the range of US, CT, and MR imaging findings in primarily extracutaneous JXG of the pediatric HN. We also showed that while only a small fraction of all pediatric JXGs were imaged, this entity was seldom included by the radiologist in the differential diagnosis for any of these 9 patients. Our findings, based on the evaluation of a very limited number of patients, suggest that on US, the presence of a solid, sharply circumscribed, superficial, nonmineralized mass should prompt consideration of JXG in the differential diagnosis. Hypoechoic and relatively avascular sonographic characteristics help distinguish JXG from lymph nodes. Bone erosion associated with JXG was not an uncommon finding in this series and could be depicted on both CT and MR imaging. Indeed, the presence of bone involvement has been described as a feature of JXG, but not of adult xanthogranuloma.17 Tumors that demonstrated punched-out lytic destruction resembled LCH most closely. However, 1 tumor demonstrated irreg-
ular calvarial destruction simulating a higher grade primary or metastatic tumor.

On CT, JXGs have been described as masses of soft-tissue attenuation with central areas of hypoattenuation in the muscles, lungs, kidney, liver, and adrenal glands and as small hypoattenuating nodules in the spleen. In this series, the cases for which contrast-enhanced CT was performed were homogeneously isoattenuating compared with muscle, without central areas of hypoattenuation. Because the examination protocol did not include precontrast imaging, the true determination of enhancement could not be made with certainty.

The MR imaging appearance of JXGs involving the extremities and CNS has been previously described. Intramuscular JXG may have slightly high signal intensity on T2-weighted images and isointense with muscle on T1-weighted images. Likewise, the MR signal intensity of intracranial and spinal JXG has been reported as similar to that of neural tissue with faint homogeneous enhancement after gadolinium administration. The higher signal intensity on T1-weighted images compared with the cortex in many of the JXGs in our series is presumably attributable to the presence of lipid within these lesions. Lipid-rich zones correspond to xanthomatized areas that are seen histologically, characterized by abundant intracellular fat within histiocytes, and they occur as a variably prominent component of JXG. The low signal intensity compared with the cortex on T2-weighted images may be attributable to attenuated cellularity, which is a common histologic feature, or collagenous matrix, which is thought to develop with time in JXG. Decreased diffusivity is also likely attributable to attenuated cellularity and/or collagenous matrix, a feature that simulates higher grade lesions such as neuroblastomas or atypical teratoid/rhabdoid tumors. Ultimately, imaging is useful for delineating the extent of disease and for narrowing the differential diagnosis.

Our review of radiology reports for differential diagnoses provided at the time of imaging highlighted some of the diagnostic pitfalls that can be posed by JXG. The size and location of the JXG

**FIG 4.** A 7-month-old girl with a 2-week history of a right frontal scalp mass that was clinically thought to represent a dermoid cyst (patient 5). A. Axial CT image shows a semilunar mass with irregular erosion of the calvarial outer table (short arrow) and periosteal reaction (long arrow). B. Axial T2-weighted MR image demonstrates that the mass is hypointense relative to the cerebral cortex. C. On this sagittal T1-weighted MR image, the mass is hyperintense relative to cerebral cortex. D. Sagittal gadolinium-enhanced T1-weighted MR image shows that the lesion enhances homogeneously.

**FIG 5.** A male infant with a mass over the nose that had been present since birth (patient 7). A. A clinical photograph at 18 days of age demonstrates a raised, yellowish mass with surrounding erythema over the right side of the nasal bridge. Clinically, this was thought to represent a dermoid, neuroglial heterotopia, or cephalocele. B. Axial T2-weighted MR image at 1 month of age demonstrates that the mass (arrow) is isointense with the cerebral cortex with no intracranial connection. C. DWI ADC image shows that the mass has decreased diffusivity compared with the cortex. D. Axial T1-weighted image without contrast demonstrates that the tumor is hyperintense relative to cerebral cortex. E. On the gadolinium-enhanced, fat-suppressed T1-weighted image, there is mild homogeneous enhancement, which is difficult to appreciate given the intrinsic hyperintensity on the nonenhanced T1-weighted images. Appreciation of the enhancement is helpful in excluding dermoid and cephalocele.
affected the radiographic differential diagnosis. For example, the small, nonerosive lesions projecting into the external auditory meatus simulated polyps or dermoids. The cutaneous and subcutaneous infra-auricular lesion was mistaken for a benign tumor of hair follicles or possibly a granulomatous infection. Two cases of midline nasal region JXGs mimicked neuropigial heterotopia, encephalocele, or dermoid/epidermoid on physical examination. One of these lesions was thought to be a neuropial heterotopia at the time of imaging by virtue of the midline nasofrontal location and similar signal characteristics compared with the cortex. In retrospect, a clue as to the correct diagnosis lay in the relative high signal on T1-weighted imaging before contrast, the relatively low signal intensity on T2, and homogeneous enhancement following the administration of contrast. Three lesions (midline frontal, parietal, and infratemporal fossa eroding temporal bone) that demonstrated bony erosion were originally interpreted at the time of imaging as LCH, metastasis (eg, neuroblastoma), fibrous tumor, or other malignant tumor. Reinterpretation of the imaging for this study revealed intrinsic T1 shortening in 2 of 3 of these lesions that again would have been atypical for entities mentioned in the differential diagnosis. Thus, imaging provides information for surgical planning and can be useful in differentiating JXG from other lesions in the clinical differential diagnosis or at least should prompt inclusion of JXG in the differential diagnosis.

Histologic misclassification can be a pitfall in studies requiring histologic-radiologic correlation. In the current study, we believe the histologic diagnoses to have been ascertained with a high level of certainty. When classic histologic features including Touton giant cells are observed, the microscopic findings in JXG are quite distinctive. When Touton giant cells are lacking, the histologic differential may sometimes expand to include other lesions that can show histiocytic differentiation, as can be observed in a subset of inflammatory myofibroblastic tumors and fibrous histiocytomas; however, immunohistologic and sometimes genetic information can be discriminating in these more difficult cases.

Intracranial involvement in JXG is uncommon and, in our limited experience, includes solitary or multiple dural-based lesions and secondary extension from extracranial sites, as demonstrated in the present series. In some cases, there may be parenchymal edema adjacent to the lesions, which can be associated with seizure activity. Multiple intraparenchymal and subarachnoid foci of JXG are rare but are also described in the literature. Intracranial involvement in JXG is associated with increased mortality and morbidity. The intracranial lesions tend to grow and require follow-up imaging. While cutaneous lesions usually resolve spontaneously, extracutaneous lesions may require medical or surgical intervention. Optimal treatment for unresectable, systemic disease is currently
undefined; however, treatment regimens similar to those used for LCH have been used successfully. 27-29

CONCLUSIONS

JXG of the HN has a variety of manifestations and can simulate LCH, fibrous tumors, and high-grade, highly cellular lesions such as neuroblastoma or other malignant neoplasms. The presence of a soft-tissue mass with intrinsically high signal intensity on T1-weighted images and relatively low signal intensity on T2-weighted MR images relative to the cerebral cortex, homogeneous enhancement, and decreased diffusivity may suggest the diagnosis of JXG. Familiarity with the common locations, typical imaging appearances, and recognized diagnostic pitfalls outlined herein may prompt radiologists to include JXG in the radiographic differential diagnosis for head and neck masses.
