Jammed packings of 3D superellipsoids with tunable packing fraction, contact number, and ordering

Ye Yuan, Kyle VanderWerf, Mark D. Shattuck, and Corey S. O’Hern

1 Introduction

Athermal particulate materials, such as granular media, foams, and emulsion droplets, typically jam, or become solid-like with a non-zero static shear modulus when they are compressed to sufficiently large packing fractions. Unwanted jamming occurs in many industrial processes, such as clogging in hopper flows, and controlled jamming and unjamming has been used in robotics to grip soft, sharp, or fragile objects. Further, unjamming in geological systems, such as landslides and earthquakes, causes significant financial and human loss.

Many prior studies have focused on jamming in model systems composed of frictionless, spherical particles. Disordered packings of frictionless, monodisperse spherical particles are isostatic at jamming onset with \( z_J = z_{\text{iso}} \) contacts per particle, where \( z_{\text{iso}} = 2d_J = 6 \) and \( d_J = 3 \) is the number of translational degrees of freedom for spheres, and with packing fraction at jamming onset \( \phi_J \approx 0.64 \). Previous work has characterized the critical scaling of the structural and mechanical properties of jammed packings of spherical particles.

However, most athermal, particulate systems in industrial processes and in nature are composed of highly non-spherical particles. In general, disordered jammed packings of non-spherical particles are hypostatic with \( z_J < z_{\text{iso}} \), where \( z_{\text{iso}} = 10 \). Thus, disordered jammed packings can possess a range of contact numbers, \( 6 \leq z_J \leq 12 \), and packing fractions at jamming onset that depend on the shape of the constituent particles. In two spatial dimensions (2D), we showed recently that disordered packings generated via athermal, quasi-static compression for a wide variety of non-spherical shapes are mechanically stable, despite the fact that \( z_J < z_{\text{iso}} \). We found that certain types of contacts between nonspherical particles can constrain multiple degrees of freedom and that the number of missing contacts below the isostatic value matches the number of quartic eigenmodes of the dynamical matrix. At jamming onset, perturbing the system along a quartic eigenmode causes the total potential energy to increase as the fourth power (not quadratically) in the perturbation...
Given that jammed packings of non-spherical particles can occur over a wide range of contact numbers and packing fractions, is it possible to a priori determine whether a system is jammed if we are only given its \( z \) and \( \phi \)? For disordered packings of monodisperse spheres, we know that if \( \phi > 0.64 \) and \( z > 6 \), the packing is jammed. For disordered packings of convex-shaped particles in 2D, we found that the packing fraction at jamming onset can be collapsed approximately onto a master curve that depends only on the shape parameter \( A = p^2 / 4 \pi a \), where \( p \) is the perimeter and \( a \) is the area of the particle.\(^{19}\) In 2D, \( \phi_f \approx 0.84 \) for \( A = 1 \), \( \phi_f \) increases with \( A \), reaching a peak near \( A \approx 1.1 \), and then decreases continuously with further increases in \( A \). Results for \( \phi_f \) have also been reported for packings of nonspherical particles in 3D, but separately for each family of shapes, e.g., ellipsoids,\(^{19}\) spherocylinders,\(^{17}\) spheropolyhedra.\(^{24}\) Here, we will address the question of whether there is a general relationship between the packing fraction at jamming onset and one or more particle shape parameters in packings of non-spherical particles in 3D.

Further, few studies have attempted to connect the contact number to mechanical stability for ordered packings of non-spherical particles,\(^{23,28}\) despite the fact that packings of monodisperse particles that deviate by less than 20% from perfect sphericity can possess significant translational and orientational order. In particular, does the relationship between the number of missing contacts below the isostatic value and number of quartic modes hold for ordered or partially ordered packings of non-spherical particles? One might expect that some of the “extra” contacts that occur in ordered packings, may be mechanically redundant\(^{22}\) and therefore will not contribute to the packing’s stability, resulting in a mismatch between the number of missing contacts and the number of quartic modes.

We investigate these questions by generating static packings of monodisperse frictionless, superellipsoidal-shaped particles in 3D using numerical simulations.\(^{23,23}\) We consider more than 200 different particle shapes by changing the shape parameters that define superellipsoids. For each packing, we determine \( \phi_f, z_f \), the orientational order, and the eigenvalues and eigenmodes of the dynamical matrix. We carry out two packing-generation protocols. In Protocol 1, we jam the packing via athermal quasistatic compression,\(^{12,21}\) starting from a random, dilute initial configuration of particles. In Protocol 2, we thermalize an unjammed configuration at an intermediate packing fraction before applying the same athermal quasistatic compression protocol (Protocol 1). We find that Protocol 1 generates globally disordered packings with a narrow distribution of jammed packing fractions and contact numbers. Protocol 2, on the other hand, is able to generate packings of superellipsoidal particles with a wide range of orientational order.

We find several key results. First, for disordered packings of superellipsoidal particles in 3D generated via Protocol 1, we find that the jammed packing fraction can be collapsed onto a master curve using two shape parameters instead of only one as we found for 2D.\(^{19}\) In addition, we find that the number of contacts, even in ordered packings of superellipsoids, determines their mechanical stability. In particular, the number of quartic eigenmodes of the dynamical matrix matches the number of missing contacts relative to the isostatic value in ordered superellipsoid packings, as well as in disordered packings.

The article is divided into several sections. In Sec. 2, we review the definition of superellipsoids, describe the two packing-generation protocols we implement, and define the orientational order parameters we use to measure the degree of order in jammed packings. In Sec. 3, we present our key results. Finally, in Section 4, we summarize our results and discuss directions for future research. We also include three Appendices. In Appendix A,
we show that we widely sample the two shape parameters that characterize the shape of superellipsoids. In Appendix B, we examine the local orientational order in superellipsoid packings. Finally, in Appendix C, we show the correlation between the average curvature of the particles at interparticle contacts and the average contact number for packings of superellipsoids.

## 2 Methods

In this section, we begin by defining the shape parameters for superellipsoids, and explain the wide variation in particle shape that is possible by tuning these parameters. Next, we describe our two protocols, the athermal protocol 1, and the thermal protocol 2, which we use to generate disordered and ordered jammed packings of these shapes, respectively. We then discuss calculations of the global and local order parameters that we use to quantify the mechanical response.

### 2.1 Model of superellipsoidal particles

The surface of a superellipsoidal particle located at the origin is defined by

\[ |x/a|^{2p} + |y/b|^{2p} + |z/c|^{2p} = 1, \]

where \(a, b, c\) \((a \leq b \leq c)\) are the lengths of the semi-major axes, and \(p\) is the deformation parameter. For superellipsoids, there are three independent parameters that control the particle shape, i.e., \(p\) and the two aspect ratios \(w_1 = a/b\) and \(w_2 = c/b\). If \(a = b\), there is only one relevant aspect ratio \(w = c/a\) and if \(b = c\), \(w = a/c\). Note that the particle shape reduces to a superball when \(a = b = c\). By tuning \(p\), we can vary the superellipsoid shape from ellipsoidal \((p = 1)\) to octahedral \((p < 1)\) and cuboidal \((p > 1)\). We focus our studies on five specific \(p\)-values: \(p = 0.75, 0.85, 1, 1.5,\) and 2.

Instead of \(p\) and the aspect ratios, \(w_1\) and \(w_2\), the shape of superellipsoids can also be characterized by \(p\), the reduced aspect ratio \(\beta = ac/b^2\), and asphericity,

\[ \zeta = 1 - (4\pi)^{1/3} (3V_p)^{2/3}/A_p, \]

where \(V_p\) and \(A_p\) give the particle volume and surface area. The shape parameter \(\beta\) allows us to distinguish “flattened” \((\beta < 1)\) versus “elongated” \((\beta > 1)\) shapes. The shape with \(\beta = 1\) is termed a self-dual ellipsoid, which shows anomalous properties in disordered \(\omega\) and dense \(\omega\) packings. The asphericity satisfies \(0 < \zeta < 1\), and \(\zeta = 1\) for spheres. For the \(p\) values studied, the superellipsoid particle shape in the \(\beta-\zeta\) plane is roughly bounded by the values for prolate \(\beta_{\text{max}}(\zeta)\) and oblate ellipsoids \(\beta_{\text{max}}(\zeta)\) as shown in Fig. 12 in Appendix A. We focus on \(\zeta\) values from 0 to ~0.35 and sample \(\beta_{\text{min}}(\zeta) < \beta < \beta_{\text{max}}(\zeta)\).

We consider pairwise, purely repulsive interactions between superellipsoids using the Perram and Wertheim formulation. For each pair of overlapping superellipsoids \(i\) and \(j\), we calculate the volume scaling factor \(\eta_{ij}\) that brings the two superellipsoids to exact tangency. The potential energy for particles \(i\) and \(j\) is then defined by \(U_{ij} = \epsilon \zeta_{ij}^2 / 2\), where \(\epsilon\) is the characteristic energy scale, \(\zeta_{ij} = \eta_{ij}^{1/2} - 1\), and \(\eta_{ij} \leq 1\). The total potential energy is given by \(U = \sum_{i<j} U_{ij}\). The repulsive force on particle \(i\) from \(j\) is \(f_{ij} = -\nabla U\) is given by

\[ f_{ij} = 2\epsilon \zeta_{ij} \eta_{ij} \hat{r}_{ij} / (\hat{r}_{ij} \hat{r}_{ij}) \]

The shape parameter \(\beta\) allows us to distinguish “flattened” \((\beta < 1)\) versus “elongated” \((\beta > 1)\) shapes. The shape with \(\beta = 1\) is termed a self-dual ellipsoid, which shows anomalous properties in disordered \(\omega\) and dense \(\omega\) packings. The asphericity satisfies \(0 < \zeta < 1\), and \(\zeta = 1\) for spheres. For the \(p\) values studied, the superellipsoid particle shape in the \(\beta-\zeta\) plane is roughly bounded by the values for prolate \(\beta_{\text{max}}(\zeta)\) and oblate ellipsoids \(\beta_{\text{max}}(\zeta)\) as shown in Fig. 12 in Appendix A. We focus on \(\zeta\) values from 0 to ~0.35 and sample \(\beta_{\text{min}}(\zeta) < \beta < \beta_{\text{max}}(\zeta)\).

We consider pairwise, purely repulsive interactions between superellipsoids using the Perram and Wertheim formulation. For each pair of overlapping superellipsoids \(i\) and \(j\), we calculate the volume scaling factor \(\eta_{ij}\) that brings the two superellipsoids to exact tangency. The potential energy for particles \(i\) and \(j\) is then defined by \(U_{ij} = \epsilon \zeta_{ij}^2 / 2\), where \(\epsilon\) is the characteristic energy scale, \(\zeta_{ij} = \eta_{ij}^{1/2} - 1\), and \(\eta_{ij} \leq 1\). The total potential energy is given by \(U = \sum_{i<j} U_{ij}\). The repulsive force on particle \(i\) from \(j\) is \(f_{ij} = -\nabla U\) is given by

\[ f_{ij} = 2\epsilon \zeta_{ij} \eta_{ij} \hat{r}_{ij} / (\hat{r}_{ij} \hat{r}_{ij}) \]
where \( \hat{n}_{ij} \) is unit normal of the tangent plane between just-touching superellipsoids pointing toward \( i \) and \( \hat{r}_{ij} \) is the center-to-center vector pointing from superellipsoid \( j \) to \( i \). The torque \( \hat{\tau}_{ij} \) on particle \( i \) from \( j \) is calculated using

\[
\hat{\tau}_{ij} = \hat{n}_{ij} \times \hat{r}_{ij},
\]

where \( \hat{r}_{ij} \) is the vector from the center of particle \( i \) to the point of adjacency between superellipsoids \( i \) and \( j \). See Fig. 1 for an illustration of \( \hat{n}_{ij}, \hat{r}_{ij}, \) and \( \hat{l}_{ij} \) for two contacting superellipsoids. We will measure lengths, energies, and forces in terms of \( a, \varepsilon, \) and \( \varepsilon/a. \)

### 2.2 Packing-generation protocols

We generate jammed packings of \( N = 400 \) frictionless, monodisperse superellipsoidal particles in cubic simulation cells with periodic boundary conditions using two compression protocols: 1) an athermal protocol and 2) a thermal protocol. For protocol 1, we first initialize an overlap-free, dilute configuration of particles with random positions and orientations. We then compress the configuration in small increments of packing fraction, \( \Delta \phi = 10^{-3} \), minimizing the total potential energy \( U \) using the L-BFGS method after each compression step. We terminate the energy minimization procedure when the average normalized force on a particle is below a small threshold, \( \langle |\sum_j \hat{n}_{ij}| \rangle / \langle |f_{ij}| \rangle < \Delta \), where \( \Delta = 10^{-4} \). We stop compressing the system when the total potential energy per particle first satisfies \( U/N > U_{\text{tol}} \), where \( U_{\text{tol}} = 10^{-10} \). We then measure the packing fraction \( \phi_f \), contact number \( z_J \), and other quantities of the first jammed packing with \( U/N > U_{\text{tol}} \) that is closest to \( U_{\text{tol}} \). We find that the results presented here do not depend on the thresholds \( \Delta \) and \( U_{\text{tol}} \). Examples of nine static packings of superellipsoids with different shapes generated via protocol 1 are shown in Fig. 2.

For protocol 2, we first thermalize unjammed configurations at intermediate packing fractions \( \phi_i \sim 0.55 \), between the freezing and melting packing fractions for hard superellipsoids using Monte Carlo methods that do not allow particle overlaps for \( N_t \) steps. We then input these configurations into the compression and energy minimization procedure described in protocol 1. By varying \( N_t \) and \( \phi_i \), we can obtain jammed packings of superellipsoids with tunable \( \phi_f \), contact number \( z_J \), and degree of orientational order.

To calculate average quantities for the packing fraction, contact number, and other quantities at jamming onset, we average over 5 to 10 independent initial conditions. We validated our methods for generating jammed packings of superellipsoids by comparing our results for \( \phi_J \) from protocol 1 to those from recent studies of packings of spheroids and superballs by Donev, et al. (See Fig. 3.)

### 2.3 Dynamical matrix

The dynamical matrix, which provides all possible second derivatives of the total potential energy with respect to the rotational and translational degrees of freedom of the system, determines the linear mechanical response of jammed particle packings. We define the dynamical matrix as

\[
M_{kl} = \partial^2 U / \partial \xi_k \partial \xi_l,
\]

where \( \xi = \{x_1, y_1, z_1, \theta_{1x}, \theta_{1y}, \theta_{1z}, \ldots, x_N, y_N, z_N, \theta_{Nx}, \theta_{Ny}, \theta_{Nz}, \alpha N, \beta N, \gamma N \} \), \( (x_i, y_i, z_i) \) is the location of the center of particle \( i \), and \( (\theta_i, \phi, \psi) \)
are the rotation angles about the x-, y-, and z-axes used to define the orientation of particle i. Thus, the dimension of the dynamical matrix is $6N \times 6N$. For jammed superellipsoid packings (in cubic simulation cells with periodic boundary conditions), the dynamical matrix possesses $6N' - 3$ nonzero eigenvalues $\lambda_i$ (with corresponding unit eigenvectors $\hat{e}_i$), where $N' = N - N_f$ and $N_f$ is the number of rattler particles with unconstrained translational or rotational degrees of freedom.

To determine $M_{ij}$, we calculated the first-order derivatives of the dynamical matrix, $\partial U / \partial \xi_k$, analytically, and calculated all of the second-order derivatives numerically. We find that the eigenvalues of the dynamical matrix do not depend sensitively on the numerical derivatives for displacements $<10^{-3}$.

### 2.4 Order parameters

In packings of non-spherical particles, one can measure the degree of order in the translational (i.e. positions of the particle centers) and rotational (i.e. orientations of the particles) degrees of freedom. In the systems we study, when the particle orientations are ordered, the particle positions also contain significant order. Thus, in these studies, we will focus on quantifying the orientational order.

We measure the global nematic $S_2^{\perp \parallel}$ and cubatic $C_4$ order parameters. $S_2$ is defined as the largest eigenvalue of the $3 \times 3$ matrix:

$$S_{\alpha \beta} = \frac{3}{2} \langle \delta_{\alpha \beta} \rangle - \frac{\delta_{\alpha \beta}}{2},$$

where $\delta_{\alpha \beta}$ is the Kronecker delta, $\alpha, \beta = x, y,$ and $z$, $\delta_{\alpha \beta}$ is the $\alpha$-component of the unit vector that characterizes the orientation of particle $i$, and $\langle \rangle$ indicates an average over all pairs of particles $i$ and $j$. $\hat{s}_i$ is chosen as the shortest (longest) axis of the particle when $\beta < 1$ ($\beta > 1$). With this definition of $\hat{s}_i$, $S_2$ can capture stacking order that can occur in packings of flat shapes, as well as nematic order that can occur in packings of elongated shapes. $S_2 = 0$ for systems without orientational order and 1 for systems with complete particle alignment.

The cubatic order parameter $C_4$ is obtained by first calculating the fourth-order Legendre polynomial,

$$P_4(\hat{t}, \hat{u}) = \frac{1}{8} \left( 35[\hat{t} \cdot \hat{u}]^4 - 30[\hat{t} \cdot \hat{u}]^2 + 3 \right),$$

where $\hat{t}$ is the unit vector aligned with one of the $3N$ orientations of the semi-major axes of each of the particles and $\hat{u}$ is a unit vector aligned with one of the three of the semi-major axes for particle $i$. For each particle $i$ in a given jammed packing, we select the $\hat{u}_i$ that maximizes $P_4(\hat{t}, \hat{u}_i)$ for a given $\hat{t}$. We then average $P_4(\hat{t}, \hat{u}_i)$ over all particles for a given $\hat{t}$ and define $C_4$ as the maximum over all $3N$ orientations $\hat{t}$. For $C_4 \sim 1$, packings possess large cubatic order, which can occur in packings of cube-like particles with $p > 1$. In Appendix B, we show results for the local nematic and cubatic order in packings of superellipsoids.

### 3 Results and Discussion

Our results are divided into two subsections. In Sec. 3.1, we present our results for disordered packings of superellipsoids generated via protocol 1. We show the global nematic and cubatic order parameters for packings containing a wide variety of superellipsoidal shapes. We find that the packing fraction at jamming onset for disordered packings of superellipsoids can be collapsed as a function of the two shape parameters, $\alpha$ and $\beta$. In Sec. 3.2, we show that we can tune the packing fraction and contact number at jamming onset by increasing the orientational order of the packings generated via protocol 2. We also show that, even for ordered packings, the number of quartic modes of the dynamical matrix is equal to the isostatic number of contacts minus the number of contacts in the packing. Thus, we find a direct link between the contact number and mechanical properties even for ordered packings of superellipsoids.

#### 3.1 Disordered packings of superellipsoids

In this section, we focus on the structural properties of superellipsoid packings generated via protocol 1. In Fig. 7(a), we show a scatter plot of the global nematic $S_2$ and cubatic $C_4$ order parameters for all jammed packings generated using protocol 1.

![Fig. 7](image_url)
We find that many of the packings are disordered with $S_2$ and $C_4 \sim 1/\sqrt{N} \sim 0.07$. However, as demonstrated in the inset to Fig. 4 (a), $S_2$ increases as $\beta$ decreases below 1 and the particle shape flattens. For more elongated shapes with $\beta > 1$, $S_2$ is roughly independent of $\beta$. We also find that the cubic order increases as the particles become more cube-shaped with $\beta > 1$, even though the packings were generated using the athermal protocol. In Fig. 4 (b) and (c), we show example packings of flattened and cube-like superellipsoids generated via protocol 1 with elevated values of $S_2$ and $C_4$. In (b), we show the local nematic order of the particles for a packing of flattened superellipsoids with $p = 0.75$ and $w = 0.3$. In (c), we show the local cubic order of the particles for a packing of superballs with $p = 2$. These packings possess local nematic and cubic order. (See Appendix B.)

In Fig. 5, we show the packing fraction at jamming onset $\phi_J$ as a function of the asphericity $\mathcal{A}$ for a variety of superellipsoid shapes. The relation between $\phi_J$ and $\mathcal{A}$ is similar to that for packings of noncircular particles in 2D. $\phi_J$ starts at a relatively low value for spherical particles (i.e., random close packing for monodisperse spheres with $\phi_J(0) \approx 0.64$), $\phi_J$ grows with increasing asphericity, reaching a peak $\phi_J \sim 0.70-0.74$ near $\mathcal{A} \sim 0.05$, and then $\phi_J$ begins decreasing, falling below $\phi_J(0)$ for $\mathcal{A} > 0.1$. We also note that the data for $\phi_J(\mathcal{A})$ does not collapse as well onto a single curve in 3D, compared to the collapse of $\phi_J(\mathcal{A})$ for packings of 2D noncircular particles.

In Fig. 6, we show the contact number at jamming onset $z_J$ versus the asphericity $\mathcal{A}$ for (a) spheroids with an axis of symmetry and $z_{\text{iso}} = 12$. $z_J = 6$ for isostatic packings of spherical particles in the limit $\mathcal{A} \to 0$. As found previously, $z_J$ for packings of nonspherical particles does not jump discontinuously from 6 to $z_{\text{iso}}$ when $\mathcal{A}$ increases above zero. Instead, $z_J$ increases continuously with $\mathcal{A}$.

$z_J$ for some of the particle shapes reaches $z_{\text{iso}}$ for $\mathcal{A} < 0.35$, e.g., oblate, prolate, self-dual, and general ellipsoids, but others, such as superellipsoids with $p = 0.75$, 0.85, 1.5, and 2.0 do not. Note that $z_{\text{iso}}$ is smaller for spheroids, compared to $z_{\text{iso}}$ for other non-axisymmetric particle shapes, and thus the maximum packing fraction for spheroids is smaller than that for the other shapes we studied. We correlate values of $z_J < z_{\text{iso}}$ for superellipsoids with the curvature at interparticle contacts in Appendix C.

The packing fraction at jamming onset $\phi_J$ for packings of superellipsoids does not completely collapse when plotted versus a single shape parameter, e.g., the asphericity $\mathcal{A}$. (See Fig. 5) This result suggests that $\phi_J$ for packings of nonspherical particles in 3D depends on two or more shape parameters. In Fig. 7 (a), we show $\phi_J$ versus the reduced aspect ratio $\beta$ for several values of the asphericity $\mathcal{A} = 0.1$, 0.15, 0.2, and 0.25, excluding cube-like superellipsoids with $p > 1$. All of the curves $\phi_J(\beta)$ are concave down for the different values of $\mathcal{A}$. In Fig. 7 (b), we show a contour plot of $\phi_J$ as a function of both $\beta$ and $\mathcal{A}$. We find that at small $\mathcal{A}$, the largest $\phi_J$, $\phi_J^{\text{max}}$, occurs near $\beta = 1$, however, $\phi_J^{\text{max}}$ shifts to $\beta > 1$ when $\mathcal{A} > 0.2$. Thus, $\phi_J$ depends on both shape parameters $\mathcal{A}$ and $\beta$.

3.2 Tunable hypostaticity

In this section, we show that we can increase the nematic or cubic order in packings of superellipsoids using protocol 2 to generate the packings. We compare the packing fraction and contact number at jamming onset for packings generated via protocols 1 and 2. We focus on packings of superballs with $p = 1.25$ and 1.5 and packings of oblate ellipsoids with $w = 0.3$.

In Fig. 8 (a), we show the global nematic $S_2$ and cubic $C_4$ order parameters versus the packing fraction at jamming onset $\phi_J$ for single packings of oblate ellipsoids (with $w = 0.3$) and sup-
balls (with $p = 1.25$ and 1.5) generated via protocol 2. We also compare these results to those for packings of the same shapes, but generated using protocol 1. Example packings are displayed in Fig. 8(b). We find that $S_2$ and $C_4 < 0.1-0.2$ for packings generated via protocol 1. However, $S_2$ and $C_4$ can become larger than 0.7 for packings generated using protocol 2. For all shapes studied, $\phi_J$ increases with increasing orientational order.

In Fig. 9(a), we show the eigenvalue spectrum of the dynamical matrix (Eq. 5) sorted from smallest to largest for packings of 6 different types of superellipsoids. As found in previous studies of packings of ellipsoids, the eigenvalue spectrum has three distinct regimes. For nearly spherical shapes, in regimes 2 and 3, the eigenmodes are purely rotational and translational, respectively. Regimes 2 and 3 merge for systems with sufficiently large asphericity $\delta$. “Quartic” modes occur in regime 1. When the system is perturbed along an eigenmode in this regime, the change in the total potential energy $\Delta U$ between the unperturbed and perturbed packings first increases quadratically with the perturbation amplitude $\delta$, but then scales as $\delta^4$ beyond a characteristic amplitude $\delta^*$ that scales to zero with decreasing pressure. (See Fig. 10(a).) We found in previous studies of nonspherical particles that the number of quartic modes $N_q$ matches the deviation in the number of contacts at jamming onset from the isostatic value, i.e. $N_c = N_{iso}^c - N_q$, where $N_{iso}^c = d_f(N - N_t) - 2$. We show this result for packings of superellipsoids generated via protocol 1 in Fig. 9(b). This result shows that even though $N_c < N_{iso}^c$, disordered packings of superellipsoids generated via protocol 1 are mechanically stable.

Is the relationship between the number of contacts and number of quartic modes the same for packings of nonspherical particles with significant orientational order? For example, in ordered systems, it is possible that some of the $N_c$ contacts are redundant and therefore do not provide independent constraints to block the degrees of freedom in the packings. In Fig. 11(a), we show the contact number for packings of three types of superellipsoids generated via protocol 2 that possess significant global nematic and cubic order (cf. Fig. 4(a).) The contact number in these systems ($z_f \to 10$) is much larger than that for packings generated using protocol 1.

In Fig. 11(b), we show the eigenvalue spectrum of the dynamical matrix for three packings of superballs with $p = 1.5$ generated using protocol 2. As shown previously, the spectrum includes three regimes with a regime of quartic eigenmodes at the lowest values. Further, the crossover in behavior from $\Delta U \sim \delta^2$ to $\sim \delta^4$ occurs at a similar value of $\delta^*$ that scales to zero with decreasing pressure. (See Fig. 10(b).) In the inset of Fig. 11(b), we show the number of contacts $N_c$ versus the number of quartic modes $N_q$ for all of the packings generated using protocol 2. We find that even with significant orientational order, the number of quartic modes matches the deviation in the number of contacts from the isostatic value. Thus, we find that there are no redundant contacts for hypostatic packings of superellipsoids with $z_f < z_{iso}$, and $z_f$ determines their mechanical stability.

4 Conclusions and Future Directions

In this article, we carried out computational studies of jammed packings of frictionless superellipsoids for more than 200 different particles shapes in three spatial dimensions. We implemented two protocols to generate static packings: protocol 1, which uses athermal quasistatic compression, and protocol 2, which includes thermal fluctuations and compression. Protocol 1 typically generates packings with small values of the global nematic and cu-
any geometrically redundant contacts, and thus the contact number \( z_J < z_{iso} \) directly determines their mechanical stability.

Our work opens up several new avenues of future research. First, in this work, we were able to generate packings of superellipsoids with tunable orientational order, \( \phi_J \), and \( z_J \). However, we only considered packings with \( z_J < z_{iso} \). It will be interesting to generate packings of nonspherical particles with even more order, where \( z_J > z_{iso} \). In this case, do quartic modes still occur and if so, what determines their number? Another future research direction involves packings of frictional non-spherical particles. \(^{48-49}\)

Packings of frictional spherical particles can occur with contact numbers that satisfy \( d_J + 1 < z_J < 2d_J \) where, \( d_J = 3 \) for spherical particles. \(^{48-49}\) Prior studies have shown that packings of frictional nonspherical particles can possess \( z_J < d_J + 1 \) \(^{46}\) where for example \( d_J = 5 \) for axisymmetric particles. Do these packings possess quartic modes, and if so, how many? It is clear that much more work is needed to understand the number of contacts that are required to determine the mechanical stability of packings of frictional, nonspherical particles.

**Conflicts of interest**

There are no conflicts to declare.

**Appendix A: Variation of the shape parameters \( \beta \) and \( \mathcal{A} \)**

In this Appendix, we show the range of reduced aspect ratio \( \beta \) and asphericity \( \mathcal{A} \) that can be achieved for superellipsoidal particle shapes. For oblate and prolate ellipsoids, the asphericity \( \mathcal{A}(\beta) \) can be written explicitly. For oblate ellipsoids, we find

\[
\mathcal{A}(\beta) = \frac{2\beta^{2/3}}{1 + \frac{\beta^2}{4\pi^2} \ln \left( \frac{1 + \sin \gamma}{\cos \gamma} \right)},
\]

---

**Fig. 11** (a) The contact number at jamming onset \( z_J \) versus the packing fraction at jamming onset \( \phi_J \) for packings of superellipsoidal shapes considered in Fig. 8 generated via protocol 2. Results for packings generated using protocol 1 are represented by crosses. (b) Eigenvalues \( \lambda_i \) of the dynamical matrix sorted from smallest to largest for three packings of superballs with \( p = 1.5 \) marked by the solid symbols in (a). The packings possess \( z_J = 8.20, 9.1, \) and 9.8. The inset shows \( N_i \) versus \( N_i^{iso} - N_i \) for all packings of superellipsoids generated via protocol 2. The dashed line has unit slope and passes through the origin.

---

**Fig. 12** The reduced aspect ratio \( \beta \) versus the asphericity \( \mathcal{A} \) for all of the particle shapes studied. The solid and dashed lines correspond to Eqs. 8 and 9 for oblate and prolate ellipsoids, respectively.
where $\gamma = \cos^{-1} \beta$. For prolate ellipsoids, $\mathcal{A}(\beta)$ can be expressed as

$$\mathcal{A}(\beta) = \frac{2\beta^{2/3}}{1 + \frac{\beta}{\sin \beta}}, \quad (9)$$

where $\alpha = \cos^{-1} \beta$. In Fig. 12 we plot the relations between $\beta$ and $\mathcal{A}$ for oblate and prolate ellipsoids, as well as $\beta(\mathcal{A})$ for superellipsoids with $p = 2$. We find that these curves serve as upper and lower bounds for the shape parameters of all other shapes that we study for $\mathcal{A} < 0.35$.

**Appendix B: Local nematic and cubic order parameters**

In the main text, for example in Figs. 4(a) and 8(a), we showed results for the global nematic $S_2$ and cubic $C_4$ order parameters for packings of superellipsoids. In these figures, we also show example packings from the simulations with the particles colored according to the value of the local nematic and cubic order parameters. The local nematic order parameter $S_{2}^{\text{loc}}$ is defined analogously to Eq. (6) as the largest eigenvalue of the $3 \times 3$ matrix:

$$S_{2}^{\text{loc}} = \frac{3}{2} \left\langle \hat{s}_{i} \cdot \hat{s}_{j} \right\rangle_{j} - \frac{\delta_{i j}}{2}, \quad (10)$$

where $\langle \rangle_{j}$ averages over particles $j$ that overlap particle $i$.

To define the local cubic order parameter $C_{4}^{\text{loc}}$ for particle $i$, we first calculate

$$P_{4}(\hat{a}_{i}, \hat{a}_{j}) = \frac{1}{8} \left(35[\hat{a}_{j} \cdot \hat{u}_{i}]^{4} - 30[\hat{a}_{j} \cdot \hat{u}_{i}]^{2} + 3 \right), \quad (11)$$

where $\hat{u}_{i}$ is a unit vector aligned with one of the three orientations of the semi-major axes for particle $j$ that overlaps particle $i$. We first select the $\hat{u}_{i}$ orientation along one of the three semi-major axes that maximizes $P_{4}(\hat{u}_{i}, \hat{u}_{i})$ for a given $\hat{u}_{i}$. We then average $P_{4}^{\text{max}}(\hat{a}_{i}, \hat{a}_{j})$ over all particles $j$ that overlap $i$. The local cubic order parameter $C_{4}^{\text{loc}}$ is defined as the maximum over the three orientations for $\hat{u}_{i}$. We plot the global versus the local orientational order parameters in Fig. 13. For the nematic and cubic order, the global and local order grow proportionately.

**Appendix C: Gaussian curvature at contact points**

In this Appendix, we show that for packings of superellipsoids with small contact numbers at jamming onset, the Gaussian curvature $K_{G}$ at the points of contact are typically small, suggesting that two flat contacting surfaces can constrain multiple rotational degrees of freedom. In Fig. 14 we show the probability distribution $P(K_{G})$, where $K_{G} = K_{G}(abc)^{2/3}$, for superellipsoid packings generated via protocol 1. (Note that each contact point contributes two $K_{G}$ values.) We find that $P(K_{G})$ for packings of cube-like superellipsoids, e.g. with $p = 2$ and small $z$, possess a wide tail that extends to small values of $K_{G}$. For other particle shapes, such as oblate and prolate ellipsoids, $P(K_{G})$ is much narrower and does not extend to small values of $K_{G}$.

**Acknowledgements**

We acknowledge support from NSF Grants Nos. CBET-1605178 (K. V. and C. O.) and CMMI-1463455 (M. S.) and the China Scholarship Council Grant No. 201806010289 (Y. Y.). This work was also supported by the High Performance Computing facilities operated by Yale’s Center for Research Computing. In addition, we acknowledge the High-performance Computing Platform of Peking University. We also thank S. Li at Peking University for helpful discussions.
