Widely used catalysts in biodiesel production: a review

Bishwajit Changmai, a Chhangte Vanlalveni, b Avinash Prabhakar Ingle, c Rahul Bhagat d and Samuel Lalthazuala Rokhum a,e

An ever-increasing energy demand and environmental problems associated with exhaustible fossil fuels have led to the search for an alternative renewable source of energy. In this context, biodiesel has attracted attention worldwide as an eco-friendly alternative to fossil fuel for being renewable, non-toxic, biodegradable, and carbon-neutral. Although the homogeneous catalyst has its own merits, much attention is currently paid toward the chemical synthesis of heterogeneous catalysts for biodiesel production as it can be tuned as per specific requirement and easily recovered, thus enhancing reusability. Recently, biomass-derived heterogeneous catalysts have risen to the forefront of biodiesel productions because of their sustainable, economical and eco-friendly nature. Furthermore, nano and bifunctional catalysts have emerged as a powerful catalyst largely due to their high surface area, and potential to convert free fatty acids and triglycerides to biodiesel, respectively. This review highlights the latest synthesis routes of various types of catalysts (including acidic, basic, bifunctional and nanocatalysts) derived from different chemicals, as well as biomass. In addition, the impacts of different methods of preparation of catalysts on the yield of biodiesel are also discussed in details.

1. Introduction

The exponential growth of the world’s population coupled with the high standard of living has resulted in a steep increase in energy consumption. 1,2 The world’s total primary energy consumed (TPEC), which was over 150 000 000 GW h in the year 2015, is estimated to rise by a trigger 57% in 2050. 3 Currently, the transportation of goods and services, which is the major contributor to the global economy, primarily relies on non-renewable fossil fuels. In total primary energy consumption, 80% of the energy consumed is associated with petroleum resources. Amongst these, 54% is consumed in the transportation sector. 4 It has been predicted that the energy consumption in the transportation section will increase with an average rate of 1.1% per year. As a result, the high energy consumption of non-renewable petroleum-based fuel to fulfill the increasing energy demand of human society has led to an ecological imbalance, excess greenhouse gas emission, acid rain, global warming and drastic decline in fossil fuel reserves.

These negative factors associated with the excessive consumption and exhaustible nature of fossil fuels compel scientific communities to look for an alternative energy source. 5,6 Biofuels are an excellent source of energy and widely seen as a potential substitute for fossil fuels. They are prepared from renewable sources, such as plants, municipal wastes, agricultural crops, and agricultural and forestry by-products. 7 Over the last few decades, biofuels such as biodiesel have gained significant attention as an alternative fuel in the research field because of its sustainable and environment-friendly nature. Biodiesel has exhibited properties similar to conventional fossil fuels (petro-diesel), and has some properties that are better than petro-diesel, such as high combustion efficiency, high flash point, high cetane number, lower CO2 emission, lower sulfur content and better lubrication. 8,9 The high flash point of biodiesel (423 K), as compared to petrodiesel (337 K), makes it non-flammable and non-explosive, resulting in easy and safe handling, storage, and transportation. Additionally, it can be directly used in the automotive engine without any additional alteration. 10 It is estimated that biodiesel demand will increase to double or triple by the year 2020. 11 In light of this, in the last decades, much attention has been paid to research on biodiesel production with an intensification make it more sustainable and economical. An increasing interest in biodiesel is validated by the number of research paper publications in this area, as shown in Fig. 1. Statistical data analysis in Fig. 1 depicted the increasing trend of published research papers in the field of...
These data were collected in February 2020 from “SciFinder Database” using the keyword “biodiesel”. From a meager 157 publications in the year 1993, it has exponentially increased to 3725 publications during its peak in 2014.

2. (Trans)esterification

Transesterification or alcoholysis is a process to produce biodiesel in which edible/non-edible oils or triglyceride (TG) and alcohol have undergone nucleophilic reaction to form fatty acid methyl ester (FAME) and glycerol as a byproduct. The transesterification reaction is illustrated in Scheme 1. Three sequential reversible reactions occur in the transesterification process: (i) conversion of triglyceride to diglyceride, (ii) diglyceride conversion to monoglyceride, and finally, (iii) monoglyceride conversion to glycerol. An ester is formed in each conversion step; thus, one TG molecule produces three ester molecules. The transesterification reaction can efficiently convert a triglyceride of vegetable oil into FAME, also called biodiesel, as depicted in Scheme 1. However, the esterification reaction, a reaction between carboxylic acids and alcohols to afford esters, is essential to converting all free fatty acids (FFA) of vegetable oil into biodiesel, as shown in Scheme 2. These transesterification and esterification reactions are usually carried out in the two-pots procedure. Usually, the high FFA content of vegetable oil
is first converted to esters (FAME) via esterification reaction by employing an acid catalyst, followed by the transesterification reaction using a basic catalyst to convert triglycerides to FAME. However, (trans)esterification reactions (or simultaneous transesterification and esterification) in one-pot is highly desirable to convert both triglycerides and FFA of vegetable oil (with high FFAs) to FAME to reduce the time and cost of biodiesel production. The different routes to synthesize biodiesel are outlined in Fig. 2.

3. Biodiesel

The American Society for Testing and Materials (ASTM) described biodiesel as a mono-alkyl ester produced from edible/non-edible oils or animal fats. Vegetable oils or animal fats comprise mainly triacylglycerol (TAG), which is an ester of fatty acids (FA) and glycerol. The physicochemical properties of vegetable oils and animal fats are greatly influenced by the compositions of the TAG, which further often dictates the quality of biodiesel produced from these resources. FA are classified broadly into two groups: (i) saturated FA, which has carbon–carbon single bonds, and (ii) unsaturated FA, which comprises at least one carbon–carbon double bond. The FA most widely found in vegetable oils are oleic acid (18 : 1), palmitic acid (16 : 0), linoleic acid (18 : 2), linolenic acid (18 : 3), stearic acid (18 : 0), palmitoleic acid (16 : 1), myristic acid (14 : 0), and arachidic acid (20 : 0). Besides these FA, a trace amount of phospholipids, tocopherols, carotenes, sulphur compounds, and water are also found in vegetable oils.17,18

4. Feedstocks for biodiesel production

The feedstocks for the production of biodiesel are mainly edible18–20 and non-edible vegetable oils,21–23 waste cooking oils,24,25 and animal fats, including tallow,25 yellow grease,26 lard,27 chicken fat28–30 and by-products from the production of omega-3 fatty acids from fish oil.31,32 Algae are another promising feedstock for biodiesel, which have a high potential to replace edible oil due to their availability in a pond, sewage water or in shallow ocean water without dislodging land used for food production.33–34 Worldwide, 31% biodiesel is produced from palm oil, 27% from soybean oil and 20% from rapeseed oil.35 Different countries use various feedstocks based on their local availability. The major feedstocks used in various countries are listed in Table 1. The feedstock cost alone contributed to 75% of the biodiesel cost.36 Thus, the proper selection of feedstocks for biodiesel is necessary to reduce the overall cost of biodiesel production. Ironically, the utilization of edible oils (e.g., sunflower, rape, soy) as feedstocks for biodiesel, called the first-generation biofuels, resulted in a food-versus-fuel problem, and also disturbed the agricultural farmland allocation.37 In Malaysia, the edible palm oil price has increased by 70% due to its uses as feedstock in the biodiesel industry.38 In this regard, to mitigate the problem associated with the food-versus-fuel nexus and high cost of first-generation biodiesel, non-edible oils are currently largely targeted as a biodiesel feedstock. Another problem associated with first-generation biofuels is their remarkably higher cost than fossil fuels. Hence, to bring down the cost of biodiesel, the utilization of non-edible oil as biodiesel feedstocks is highly relevant. Non-edible oils of more than 300 species are available in South Asia. India has an abundant amount (approximately 1 million tons per year) of such non-edible oils. Pongamia pinnata (karanja) and Jatropha curcas oils (JCO) were identified as the most promising oil.39

![Fig. 2 Catalyst classification for biodiesel synthesis.](image-url)
feedstocks by the Government of India. However, in India’s biodiesel program, *Jatropha* has prominence over karanja due to its lower gestation period. If properly managed, non-edible crops planted in different parts of the world have the potential to reduce our dependence on fossil fuels for energy sources and edible oils as biodiesel feedstocks.

Biodiesel has been widely used as biofuels in the European Union (EU), and 49% of biodiesel was produced from rapeseed oil in 2015 in EU. With the increasing uses of waste cooking oil (WCO), recycled vegetable oils and palm oils, the share of rapeseed oil in biodiesel production decreased from 72% in 2008. To reduce our dependency on edible oil and reduce the price of biodiesel, EU has raised the share of WCO to the 2nd position after rapeseed oil in 2015. The top five biodiesel producers in EU are Germany, France, Spain, Netherlands, and Poland. Germany is the largest biodiesel producer in EU, and its production capacity increased from 3.2 billion litres in 2010 to 3.8 billion litres in 2014.

Various types of feedstocks (such as edible plant oils, non-edible oils, waste cooking oils, animal fats, and algal oil) have been considered for the synthesis of biodiesel, and are discussed below.

### 4.1 Edible plant oils

Soybean oil, sunflower oil, rapeseed oil, and palm oil are widely utilized as a biodiesel feedstock in numerous nations, for example, Argentina, Brazil, Indonesia, Europe, US, and Malaysia. At present, an estimated 95% of the world’s total biodiesel is produced from sunflower oil, rapeseed oil, and palm oil. Various types of edible oils exploited as feedstocks for the production of biodiesel are recorded in Table 2.

### 4.2 Non-edible plant oils

Recently, non-edible plant oils have been increasingly considered as another promising potential feedstock for biodiesel, which is attributable to their high oil content and low cost. In addition, unlike edible oils, it does not pose a ‘food versus fuel’ problem as they can be grown in barren and arid regions, which are not suitable for agriculture. Furthermore, non-edible oil plants can grow under harsh conditions and hardly need any attention. Thus, this reduces the cost involved in cultivation, and potentially reduces the cost of biodiesel.

Some of the commonly investigated non-edible plant oils for biodiesel production include *Jatropha curcas*, *Pongamia glabra* (Karanja), *Madhuca indica* (Mauha), *Azadirachta indica* (neem), *Moringa oleifera* (moringa seed), *Calophyllum inophyllum*, *Salvadora oleoides* (Pili), *Nicotiana tabacum* (tobacco), cottonseed oil, *Eruca sativa* Gars, terebinth, rubber seed oil, desert date, *Acrocomia aculeata* (macaúba), *Crambe abyssinica* (hochst), linseed oil, rubber seed oil, *Sapium sebiferum* (chinese tallow), *Sapindus mukorossi* (soapnut), *Euphorbia tirucalli* (milky bush), *Calophyllum inophyllum* (polanga oil), jojoba, leather pre-fleshings, apricot seed, *Pistacia chinensis* (bunge seed), sal oil and *Croton megalocarpus*. Among all these oil plants, *Jatropha curcas*, *Pongamia glabra* (Karanja), *Madhuca indica* (Mauha), *Azadirachta indica* (neem) are commercially available and most largely used in biodiesel production.

### 4.3 Waste cooking oil

Biodiesel production from WCO can partially substitute fossil fuels as well as can solve the energy crisis and environmental pollution. Moreover, WCO is cheaper than fresh vegetable oils, consequently, lessening the expense incurred for biodiesel synthesis. WCO can be grouped into two classifications based on their FFA content if the FFA content is >15%. It is then called brown grease; otherwise, it is named ‘yellow grease’. Annually, 1 billion tons of WCO is generated throughout the world. In EU, it is estimated that around 0.7–1 MT WCO were collected per year. Among 80 000 tons of WCO, around 65 000 tons were collected from the UK alone, basically originating from commercial restaurants and food processing industries. Therefore, the disposal of WCO is a major concern, which otherwise contaminates water and the environment at large. Although some portions of WCO oil were used in the production of soap, major parts of WCO were usually dumped into the river and landfills. In light of this, the production of biodiesel from WCO not only reduced the cost of biodiesel, but also resolved the disposal problem of WCO and minimized environmental pollution.

### 4.4 Animal fats

Animal fats are another feedstock for biodiesel production with the potential to reduce the cost of biodiesel. This type of feedstock includes lard, tallow and chicken fat. However, due to the presence of a high quantity of saturated fatty acids, it has some shortcomings both in chemical and physical properties, such as poor cloud point, poor pour point, and so forth. At the same time, its high saturation level has various advantages, such as a high cetane number and high oxidation stability. Moreover,
animal fats are more favourable biodiesel feedstocks, as compared to vegetable oils due to their low price.

4.5 Algal oil

Currently, microalgae are viewed as one of the most promising feedstocks for the industrial-scale synthesis of biodiesel. Biodiesel production from algal oil is highly sustainable, as several strains of microalgae can double in size within hours. Thus, they have the capacity to create a large number of litres of biodiesel per hectare every year. Additionally, several microalgal strains can be grown on non-arable land in a saline water medium, their mass cultivation does not compete with food production.

5. Characterization of catalysts and biodiesel

Several analytical techniques are employed to characterize both catalysts and FAME produced. Each analytical technique will be discussed in the upcoming sections as and when relevant. As a preliminary study, Fourier transform infrared spectroscopy (FT-IR) is usually employed to detect the presence of various functional groups in the catalyst, while X-ray diffraction (XRD) can be employed to investigate the crystallinity and qualitative detection of elements present in the catalyst. The surface morphology, particle size and the structure of the catalysts can be investigated using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The chemical compositions are investigated using energy-dispersive X-ray spectroscopy (EDX). X-ray fluorescence (XRF) is commonly used for the quantitative detection of metal oxides and X-ray photoelectron spectroscopy (XPS) analyses are routinely performed for the quantitative measurement of the elements present in the catalyst, and also provide the chemical state information of the catalyst. The surface area, pore volume and pore diameter are usually measured by Brunauer–Emmett–Teller (BET) analysis, whereas the thermal stability of the catalysts is analyzed using thermogravimetric analysis (TGA). The acidity and basicity of the catalysts are usually investigated using NH3 and CO2 temperature-programmed desorption (TPD) analyses. In addition, the basicity and acidity of the catalyst can be visualized by Hammett indicators tests and acid–base titration methods. Valuable information about the degree of carbonization and/or aromatization of carboneous material used as a catalyst can be obtained using solid-state magic-angle spin-nuclear magnetic resonance (MAS NMR). Likewise, the successful conversion of biodiesel feedstocks to FAME is confirmed using different analytical techniques. Usually, NMR analysis is used as a confirmation tool to identify the formation of FAME. Despite not being common, FT-IR analysis can also be used to identify the FAME formation. The chemical components of FAME, along with their respective percentages, are usually identified using gas chromatography-mass spectroscopy (GC-MS) technique. In addition, 1H NMR spectra can be used to give concrete information about the purity of FAME and the percentage conversion of vegetable oil to FAME using the Knothe and Kenar eqn (1).

\[ \text{% Conversion} = 100 \times \frac{2A_{\text{Me}}}{3A_{\text{CH}_2}} \]  

(1)

Here, \( A_{\text{Me}} \) and \( A_{\text{CH}_2} \) are the integration values of the methoxy protons and methylene protons of FAME, respectively.

6. Homogeneous catalyst

The homogeneous catalysts utilized for the transesterification reaction are classified into two groups, such as: (i) base catalysts (for example, NaOH and KOH), and (ii) acid catalysts, such as sulphuric, sulphonic, hydrofluoric, and hydrochloric acids.

6.1 Base catalyst

Homogeneous base catalysts are most widely investigated in the transesterification of vegetable oil to FAME, as they are cheap and easily accessible. To date, several homogeneous base catalysts have been utilized for the synthesis of FAME, e.g., KOH, NaOH, and NaOCH3, as shown in Table 3. The uses of NaOH and KOH as catalysts showed excellent catalytic activities towards biodiesel production, such as the minimum reaction time and high biodiesel yield, and occurred at ambient temperature and pressure. However, this process has certain limitations, such as water being formed as a byproduct, which reduces the biodiesel yield. Other than KOH and NaOH, sodium methoxide and potassium methoxide give better biodiesel performance, as water is not formed in these processes. An alkaline catalyst is not suitable for the transesterification of vegetable oils with high FFA content (>2 wt%). However, it is fit for refined vegetable oils with low FFA content (ranging from less than 0.5 wt% to less than 2 wt%).

Dmytryshyn et al. examined the transesterification of various vegetable oils, such as canola oil, green seed canola oil from heat-harmed seeds, handled waste fryer oil, and natural waste fryer oil with methanol to afford FAME using the KOH catalyst, and reported a biodiesel yield of 51–87% under the optimum reaction conditions. In another study, KOH was exploited to convert crude rubber oil and palm oil mixture to biodiesel in 98% yield under the optimum reaction conditions. The vegetable oil was esterified using an acid catalyst prior to a base-catalyzed transesterification process, to obtain a low FFA content vegetable oil. Similarly, KOH was utilized as a catalyst for the transformation of soybean oil to FAME in 96% yield.

Roselle oil, rapeseed oil, frying oil, used olive oil, palm kernel and duck tallow were also successfully transesterified to FAME using the KOH catalyst. Karmee et al. reported the transesterification of Pongamia pinnata to FAME in 92% conversion using the base catalyst KOH. Interestingly, the utilization of tetrahydrofuran (THF) as a co-solvent increased the conversion to 93%.

Meng et al. described an exceptionally high activity of NaOH towards biodiesel production from WCO with high FFA in 89.8% conversion under the optimized reaction settings. The high FFA substance of WCO was reduced by a pre-esterification
Table 3  Distinctive homogeneous base catalysts utilized for biodiesel production

| No. | Catalyst | Feedstock | Conditions | Yield (%) | Ref. |
|-----|----------|-----------|------------|-----------|------|
| 1   | KOH      | Vegetable oil | 6:1,1,25,40 | 51-87     | 51   |
| 2   | KOH      | Crude rubber/palm oil | 6:1,1,5,300 | 98        | 52   |
| 3   | KOH      | Soybean oil | 6:1,1,60,60 | ~96       | 53   |
| 4   | KOH      | Roselle oil | 6:1,65,120 | 99.4      | 54   |
| 5   | KOH      | Rapeseed | 6:1,1,60,60 | 95-96     | 54   |
| 6   | KOH      | Frying oil | 12:1,1,60,120 | 72.5     | 55   |
| 7   | KOH      | Waste frying oil | 6:1,1,60,60 | 96.15     | 56   |
| 8   | KOH      | Used olive oil | 12:1,26,5,90 | 94        | 57   |
| 9   | KOH      | Palm kernel | 6:1,1,60,60 | 96        | 58   |
| 10  | KOH      | Duck tallow | 6:1,1,65,180 | 83.6     | 59   |
| 11  | KOH      | Pongamia pinnata | 10:1,1,60,90 | 92.6^a  | 60   |
| 12  | NaOH     | Waste cooking oil | 6:1,1,50,90 | 89.8^b  | 23   |
| 13  | NaOH     | Waste frying oil | 6:1,1,65,60 | 98        | 61   |
| 14  | NaOH     | Waste frying oil | 6:1,1,60,60 | 96        | 62   |
| 15  | NaOH     | Canola oil | 6:1,1,45,15 | 98        | 63   |
| 16  | NaOH     | Sunflower | 6:1,1,60,120 | 97.1     | 64   |
| 17  | NaOH     | Refined palm oil | 6:1,1,60,30 | 95        | 65   |
| 18  | NaOH     | Cotton seed oil | 6:1,1,60,60 | 97        | 66   |
| 19  | NaOCH₃   | Soybean oil | 6:1,1,60,60 | 97        | 66   |
| 20  | NaOCH₃   | Rice bran | 7.5:1,0.88,55,60 | 83.3      | 67   |
| 21  | NaOCH₃   | Waste cooking oil | 6:1,0.75,65,90 | 96.6      | 68   |

^a Methanol-to-oil (M/O) molar ratio, catalyst loading (wt%), temperature (°C), reaction time (min). ^b Conversion.

process with sulphuric acid. Similarly, waste cooking/frying oil,^61,62 canola oil,^61 sunflower oil,^61 palm oil^61 and cotton seed oil^61 were converted to biodiesel using NaOH as a homogeneous catalyst. Furthermore, NaOCH₃ (ref. 67 and 68) was evaluated as a catalyst for the transesterification of rice bran oil to FAME by Rashid et al.,^67 where 83.3% biodiesel yield was observed in 60 min under the optimum reaction conditions.

6.2 Acid catalyst

Base catalysts are usually preferred over acid catalysts, as they are more reactive and low cost. However, base catalysts may react with the FFA present in the feedstock during transesterification, bringing about soap formation by saponification, which may consume the catalyst and diminish its reactivity. Meanwhile, an acidic catalyst is neutral to the FFA, and thus shows better outcomes for the transesterification or esterification of vegetable oils or fats having a high amount of FFA (≥2 wt%). Generally, acid catalysts are utilized to bring down the FFA content in WCO and animal fats by means of esterification prior to transesterification using a base catalyst. Several acids, such as H₂SO₄, HCl, H₃PO₄ and sulfonated acids, were mostly utilized for the (trans)esterification of vegetable oils. However, acid-catalyzed biodiesel production has some major limitations, such as a slow reaction rate (4000 times slower than the base of catalyzed transesterification), and require a high alcohol-to-oil molar ratio. Moreover, it has environmental and corrosive related problems. Because of these demerits, acid-catalyzed biodiesel synthesis is not very popular and is studied less. Some of the reported literature of acid-catalyzed biodiesel production and their results are listed in Table 4.

Wang et al.,^78 examined the biodiesel synthesis from WCO and reported a 90% yield. Moreover, Miao et al.,^72 examined the conversion of soybean oil to biodiesel using trifluoroacetic acid catalyst, and reported 98.4% biodiesel yield at optimal reaction conditions. Similarly, various edible/non-edible oils (such as WCO,^73 soybean oil,^73 zanthoxylum bungeanum^74 and tobacco seed oil^75) were used for biodiesel production using sulfuric acid. Moreover, trifluoroacetic acid was utilized as a homogeneous acid catalyst for the esterification/transesterification of soybean oil to biodiesel. The catalyst brought about a high biodiesel yield of 98.4% under the optimum reaction conditions. From the above discussion, it was observed that acid-catalyzed esterification/transesterification reactions usually require drastic reaction conditions, such as a high M/O molar ratio, catalyst loading, temperature and long reaction time, as compared to base-catalyzed transesterification reactions.

7. Heterogeneous catalysts

Although the homogeneous catalyst has its own advantages, such as high reactivity and low cost, its utilization in the production of biodiesel is accompanied by several shortfalls. These shortfalls include the low quality of glycerol produced, the fact that the catalyst cannot be regenerated, and the lengthy process involved in the purification of biodiesel. Thus, the whole process is labor-intensive and uneconomical. Hence, in recent years, the heterogeneous catalyst has attracted immense attention for biodiesel production, as it can be tailored to match specific requirements, and be easily recovered and reused for several cycles of catalytic reaction, thereby potentially bringing down the labor involved and the cost of biodiesel.
Unlike homogeneous catalysts, heterogeneous catalysts mostly appear in a solid form; thus, the reaction mixture and the catalyst are in a different phase. In the heterogeneous catalyzed reactions, the catalyst surface is the main site for the reaction to occur. The following advantages of utilizing a solid catalyst in transesterification make the process green: (i) the catalyst can be reused, (ii) there is a very minimal amount of wastewater generated during the process, (iii) glycerol separation from the final mixture (glycerol, biodiesel and catalyst) is much easier, and (iv) high purity glycerol is obtained.

Heterogeneous catalysts have several advantages over a homogeneous catalyst, such as simple separation, recyclability and reusability. Moreover, solid catalysts are eco-friendly, less toxic, and have minimum corrosion and reduced energy intake. Thus, solid catalysts provide an efficient and economical pathway for biodiesel production. Heterogeneous or solid catalysts can be grouped into two categories: (i) basic and (ii) acidic heterogeneous catalysts. Nowadays, researchers have developed several heterogeneous catalysts, which can promote esterification and transesterification reactions simultaneously in one reaction vessel (one-pot). These types of catalysts are mostly utilized for biodiesel synthesis from the vegetable oils or animal fats having a high amount of FFA without the requirement of an additional pretreatment step to reduce the FFA content.

### 7.1 Base Catalysts

In recent years, basic heterogeneous catalysts have been most widely investigated as it can overcome the constraints associated with homogeneous basic catalysts, and shows excellent catalytic activity under mild reaction conditions. However, these catalysts are suitable only for biodiesel feedstock with low FFA content; otherwise, the catalysts will react with the FFA to produce soap by means of the saponification reaction. This makes the separation of biodiesel from glycerol tedious, thereby diminishing the biodiesel yield. Several solid base catalysts reported in the literature, such as the alkaline earth metal oxides, transition metal oxides, mixed metal oxides, hydrotalcites, zeolites, and biomass-based catalysts, are discussed comprehensively in this section.

#### 7.1.1 Alkaline Earth Metal Oxides

Oxides of alkaline earth metals are one of the most widely studied catalysts for biodiesel synthesis due to their insolubility in methanol and low toxicities. The basicity of the alkaline earth metal oxides follows the order: MgO < CaO < SrO < BaO. MgO is almost inactive towards the transesterification reaction. Among all alkaline earth metal oxides, CaO is most widely utilized in FAME production, as it is highly basic, insoluble in alcohol, non-toxic, cheap and easily available. However, it is very sensitive to the FFA content and forms undesirable byproducts via saponification, and also loses its activity in the process. Despite its high activity, SrO is less studied in transesterification reactions as it is very sensitive to the atmospheric moisture, and reacts with CO₂ and water to form SrCO₃ and Sr(OH)₂. Table 5 shows the activity of various alkaline metal oxides towards biodiesel production.

Kouzu et al. examined the transesterification of soybean oil using the CaO catalyst, and reported a high biodiesel yield of 95% under the optimized reaction conditions. Granados et al. found that CaO calcined at 700 °C showed very high activity towards biodiesel production from sunflower oil, and attained 94% biodiesel yield. Furthermore, the transesterification of rapeseed oil was reported by Kawashima et al., where CaO was pretreated with methanol to form Ca(OCH₃)₂, which acted as an initiator for the transesterification reaction. A high biodiesel yield of 90% was observed using the optimized reaction conditions. In another work, the SrO-catalyzed transesterification of soybean oil has been reported by Liu et al. The catalyst showed excellent activity with a high yield of 95% at 70 °C and 30 min time. The catalyst is highly stable and can be reused for 10 successive cycles.

The ultrasonic-assisted biodiesel synthesis from palm oil was reported using diverse metal oxides, such as CaO, BaO and...
The activity of the catalyst in ultrasonic-assisted biodiesel synthesis was compared with the traditional magnetic stirring process, and it was found that the ultrasonic process showed 95.2% of yield using BaO within 60 min reaction time, which otherwise take 3–4 h in the conventional stirring process. Similarly, the ultrasonic-assisted transesterification using CaO and SrO resulted in an increase in the biodiesel yield from 5.5% to 77.3% and 48.2% to 95.2%, respectively. These findings show the advantages of using ultrasonication in the field of chemical synthesis, particularly in the field of biodiesel synthesis. The authors also investigated the influence of ultrasonic amplitude on the biodiesel synthesis from palm oil, and observed that 50% ultrasonic amplitude displayed the best result in terms of the biodiesel yield. The catalyst reusability test revealed that the catalytic activity of BaO decreased drastically, especially in the ultrasonic process during the reusability test, which was mainly due to catalyst leaching. The reaction set-up is depicted in Fig. 3.

7.1.2 Transition metal oxides. Despite the high reactivity of alkaline earth metal oxides, they have some serious drawbacks, such as low reusability and high sensitivity towards moisture, that reduced their catalytic efficacy. To overcome these inherent drawbacks, metal oxides of Zn, Ti, Zr and Zn are widely investigated in transesterification reactions, as they are easily available, highly stable and showed excellent catalytic activities. To date, numerous transition metal oxide-based catalysts have been reported in the field of biodiesel synthesis from vegetable oils, as depicted in Table 6. da Silva et al. reported on Cu(n) and Co(n) impregnated on chitosan catalysts for FAME synthesis from soybean oil. The adsorption process for Cu(n) on chitosan is better than Co(n). However, Co(n)@chitosan showed a higher biodiesel yield (94.01%), as compared to Cu(n)@chitosan (88.82%) using the optimal reaction conditions. In another work, Jitputti et al. investigated ZrO2, ZnO, SO42-/SnO2, SO42-/ZrO2, KNO3/KL zeolite and KNO3/ZrO2 for the FAME synthesis from the crude palm kernel oil and crude coconut oil, and found that the SO42-/ZrO2 catalyst displays the highest reactivity for both oils with a biodiesel yield of 90.30% and 86.30%, respectively. The decreasing order of the catalyst activity towards biodiesel synthesis from crude kernel oil is SO42-/ZrO2 > SO42-/SnO2 > ZnO > KNO3/ZrO2 > KNO3/KL zeolite > ZrO2. For the crude coconut oil, it is SO42-/ZrO2 > SO42-/SnO2 > ZnO > KNO3/ZrO2 > KNO3/KL zeolite > ZrO2.

Meanwhile, Baskar et al. used the Mn-doped ZnO nanomaterial for the conversion of Mahua oil to biodiesel, and observed that the catalyst calcined at 600 °C showed the highest biodiesel yield of 97% under the optimum reaction conditions. The kinetic investigation of the reaction revealed that 181.91 kJ mol\(^{-1}\) activation energy is necessary for biodiesel synthesis from Mahua oil utilizing the Mn-doped ZnO catalyst. The prepared Mn-doped ZnO catalyst was seen as a cluster, and is spherical in shape as depicted in Fig. 4A. FT-IR analysis was performed to confirm the formation of the biodiesel. Absorption bands at 1744 and 1703 cm\(^{-1}\) demonstrated the CO stretching of the methyl esters in Mahua oil and biodiesel, respectively. The main spectral region that allows for the chemical discrimination between Mahua oil and the produced biodiesel is in the range of 1500–900 cm\(^{-1}\), and is also called known as the fingerprint region. Fig. 4B reveals the symmetric and asymmetric stretching of the alkyl regions at 1376, 1463, 2852, 2922 cm\(^{-1}\), and the CO group of the lactones and esters at 1735 cm\(^{-1}\). Moreover, the stretching band of the CO group of the typical esters around 1703 cm\(^{-1}\) was observed in Fig. 4C. In light of these FT-IR bands, the product obtained after transesterification of Mahua oil using the Mn-doped ZnO catalyst was confirmed as biodiesel.

Na2MoO4 has been synthesized and investigated as a catalyst in the transesterification of soybean oil by Nakagaki et al. The catalyst displayed high activity towards the transesterification reaction, and afforded a biodiesel yield of 95.6%. The high reactivity of the catalyst is due to the acid sites of Mo(vi), which can easily polarize the O–H bond. Correspondingly, Serio et al. also reported the high reactivity of the vanadyl phosphate-based catalyst towards the transesterification reaction. Reproduced from ref. 86.

![Fig. 3. Schematic portrayal of experimental set-up for the ultrasonic-assisted transesterification reaction.](Image)

Table 6 Various transition metal oxide-catalyzed biodiesel production yields under different reaction conditions

| No. | Catalyst         | Feedstocks         | Conditions\(^{a}\) | Yield (%) | Ref. |
|-----|------------------|---------------------|--------------------|-----------|------|
| 1   | Cu(n)@chitosan   | Soybean oil         | 1 : 5\(^{b}\), 2, 70, 180 | 88.82     | 90   |
| 2   | Co(n)@chitosan   | Soybean oil         | 1 : 5\(^{b}\), 2, 70, 180 | 94.01     | 90   |
| 3   | SO4\(^{2-}\)/ZrO2 | Crude palm kernel oil | 6 : 1, 3, 200, 60   | 90.30     | 87   |
| 4   | SO4\(^{2-}\)/ZrO2 | Crude coconut oil   | 6 : 1, 3, 200, 60   | 86.30     | 87   |
| 5   | Mn doped ZnO     | Mahua oil           | 7 : 1, 8, 50, 50    | 97        | 91   |
| 6   | Na2MoO4         | Soybean oil         | 54 : 1, 3, 120, 180 | 95.6      | 92   |
| 7   | Vanadyl phosphate| Soybean oil         | 0.88 : 2, 0.5, 180, 60 | ≥88      | 93   |

catalyst in the biodiesel synthesis from soybean oil. Regardless of the low surface area, the high reactivity of the catalyst is attributed to the structural/surface morphologies. A biodiesel yield of $\approx 88\%$ was recorded using the optimal reaction conditions. The dehydrated product of the catalyst VOPO$_4 \cdot 2$H$_2$O can be converted to VOPO$_4$ simply by calcination at 400–500 °C.

7.1.3 Zeolites. Zeolites are crystalline aluminosilicates that possess a microporous structure. It can exist in different structural morphologies depending on the synthesis process and reaction conditions, such as the Si/Al molar ratio, pore sizes and proton exchange levels. The wide opportunity for the structural modification of zeolites makes them an excellent catalyst for various acid–base reactions. Recently, zeolites are intensively investigated in the field of biodiesel production due to their shape selectivity and acid character. Normally, zeolites are moderately active for the esterification reaction. However, by increasing the pore size and varying the Si/Al ratio, the catalytic properties can be improved. Moreover, zeolites can incorporate various metal ions (such as Na⁺, K⁺, Mg²⁺), which are mainly responsible for its basic nature.

In 2007, a NaX zeolite loaded with various concentrations of KOH was synthesized and reported as a catalyst in FAME production from soybean oil. A catalyst loaded with 10% KOH followed by heating at 393 K for 3 h gave the best result with 85.6% yield under the optimized reaction conditions. Shu et al. prepared the La/zeolite beta using La(NO₃)₃ as a precursor via ion exchange technique, and the developed catalyst was employed in the biodiesel synthesis. They reported that the La/zeolite beta has higher stability and catalytic activity towards FAME production compared to the zeolite beta catalyst. A yield of 48.9% was obtained using the La/zeolite beta under the optimized reaction conditions, such as the 14.5 : 1 M/O molar ratio, 0.011 wt% catalyst loading, 60 °C and 4 h time. In the year 2008, Ramos et al. studied three zeolites, such as mordenite, beta and X, for the conversion of sunflower oil biodiesel. They examined the effect of different loaded/stacked metals on such zeolites. Zeolite X showed the best catalytic activity, as it has a higher number of super basic sites, which is absent in other zeolites. The effect of the binder, sodium bentonite, on the catalytic reactivity of such zeolites was tested, where the X zeolite was agglomerated and thus, the catalytic activity was slightly reduced. A high yield of 93.5% and 95.1% of FAME was obtained at 60 °C with and without binder, respectively. In another report, Wu et al. synthesized a series of CaO supported on zeolites, such as NaY, KL and NaZSM-5 via microwave irradiation, and they were utilized in biodiesel synthesis from soybean oil. They reported that the supported CaO showed a better result compared to the naked CaO, as the supported catalyst has a high surface area, porosity and basic strength. Accordingly, the best result was exhibited by the NaY-supported CaO (30% CaO loaded on NaY) under the optimized reaction conditions.

The strontium nanocatalyst supported on ZSM-5 by the incipient wetness impregnation method was prepared and applied in biodiesel synthesis from sunflower oil. The authors reported the effect of the calcination temperature and Sr/ZSM-5, Ba–Sr/ZSM-5 mass ratios. Ba–Sr/ZSM-5 (Ba 4 wt% to the Sr weight and Sr 6 wt% to the ZSM-5 weight) exhibited the best performance with 87.7% yield under optimal conditions. In the meantime, Narkhede et al. synthesized a series of 12-tungstosilicic acid, SiW₁₂ (10–40 wt%) impregnated on zeolite Hβ, and applied it in biodiesel synthesis from soybean oil. Interestingly, the SEM image of the 30% SiW₁₂/Hβ (Fig. 5b) is similar to the pure zeolite Hβ (Fig. 5a), and revealed that the framework structure of Hβ was retained even after the impregnation of SiW₁₂. This suggested that SiW₁₂ was homogeneously distributed in the framework structure of the Hβ zeolite. They reported a 95% yield of FAME under the optimized reaction conditions.

In 2012, Babajide et al. synthesized a zeolite derived from fly ash and then ion-exchanged with K to form the FA/K/X zeolite, which was then applied in biodiesel synthesis from sunflower oil. They reported a high yield of 83.53% under the optimized reaction conditions. Similarly, Manique et al. prepared zeolite (sodalite) derived from coal fly ash via the hydrothermal process, and utilized in biodiesel synthesis from soybean oil. The developed sodalite has a definite surface area of 10 m² g⁻¹. They also reported a maximum conversion of 95.5% soybean oil using the optimized reaction conditions. Recently, Al-Jammal et al. prepared zeolite derived from zeolite tuft, followed by the impregnation of a series of KOH solutions (1–6 M), and heated at 80 °C for 4 h to form the KOH/zeolite catalyst. Finally, it was utilized in biodiesel synthesis from waste sunflower oil. The catalyst (1–4 M) KOH/zeolite exhibited a biodiesel yield of 96.7% under the reaction conditions: 11.5 : 1 M/O molar ratio, catalyst amount of 6 wt% w.r.t. oil, 50 °C temperature and reaction time of 2 h.

| No. | Catalyst          | Feedstocks     | Conditions⁴ | Yield (%) | Ref. |
|-----|-------------------|----------------|-------------|-----------|------|
| 1   | KOH@NaX zeolite   | Soybean oil    | 10 : 1, 3, 65, 480 | 85.6      | 96   |
| 2   | La/zeolite beta   | Soybean oil    | 14.5 : 1, 0.011, 60, 240 | 48.9      | 97   |
| 3   | Zeolite X         | Sunflower oil  | 6 : 1, 10, 60, 420 | 95.1      | 98   |
| 4   | CaO@NaY zeolite   | Soybean oil    | 9 : 1, 3, 65, 180 | 95        | 99   |
| 5   | Ba–Sr/ZSM-5       | Sunflower oil  | 9 : 1, 3, 60, 180 | 87.7      | 100  |
| 6   | H₄[Wi₄SiO₄₆]@zeolite Hβ | Soybean oil | 4 : 1, 0.2, 65, 480 | 95        | 101  |
| 7   | FA/K-X zeolite    | Sunflower oil  | 6 : 1, 3, 60, 480 | 83.53     | 102  |
| 8   | Sodalite          | Soybean oil    | 12 : 1, 4, 65, 120 | 95.5      | 103  |
| 9   | KOH/zeolite       | Waste sunflower oil | 11.5 : 1, 6, 50, 120 | 96.7      | 104  |
| 10  | La₂O₃/NaY zeolite | Castor oil     | 15 : 1, 10, 70, 50 | 84.6      | 105  |

⁴ Methanol-to-oil molar ratio, catalyst loading (wt%), temperature (°C), reaction time (min).
In the same vein, Du et al.\textsuperscript{105} developed La$_2$O$_3$ impregnated on the NaY zeolite catalyst having a spherical shape of 3–5 mm size, and utilized it in biodiesel synthesis from castor oil. In addition, they explored the impact of the calcination temperature in the range of 600–1000 °C on the biodiesel yield, and observed that the catalyst calcined at 800 °C showed the best result. They also revealed that the incorporation of the surfactant improved the dispersion of La$_2$O$_3$ and the pore size of the zeolite. The XRD patterns of the pure zeolite NaY and the catalyst La$_2$O$_3$/NaY zeolite calcined in the temperature range of 600–1000 °C are displayed in Fig. 6. The XRD patterns of the pure zeolite (Fig. 6a) and the catalyst calcined at 600 °C (Fig. 6b) and 800 °C (Fig. 6c) are almost the same, and revealed that the crystallinity of the zeolite NaY does not change upon the incorporation of La$_2$O$_3$. However, on increasing the temperature to 1000 °C, the XRD pattern (Fig. 6e) showed no characteristic peaks of zeolite, suggesting that at high calcination temperature, the crystallinity of the zeolite is lost.

### 7.1.4 Supported catalyst

To increase the stability and reusability of the alkaline earth metal oxides, the catalyst support plays an important role as it can reduce the mass transfer limitation and provide a high surface area with high porosity, where the metals are anchored.\textsuperscript{106} Until now, several catalyst supports (such as alumina, silica, ZnO and ZrO$_2$) had been proposed for the production of FAME. Alumina is extensively employed as the catalyst supports for various basic or acidic compounds exploited as a solid catalyst in esterification/transesterification reactions.\textsuperscript{107} Several alumina-supported catalysts were employed in the transesterification reaction for biodiesel synthesis, as shown in Table 8. In 2006, Xie et al.\textsuperscript{108} investigated the potential of KI loaded on an Al$_2$O$_3$ support catalyst for biodiesel synthesis from soybean oil. They prepared a series of KI@Al$_2$O$_3$ catalysts by changing the KI amount, and investigated their catalytic activities. They observed that the catalyst loaded with 35% KI and calcined at 773 K showed the highest FAME conversion of 96% against all other catalysts under the optimal reaction conditions. In another study, potassium oxide loaded on alumina derived from various potassium salts (such as KNO$_3$, KOH, KF, KI and K$_2$CO$_3$) were compared. It was found that KF@Al$_2$O$_3$ showed the best result compared to other catalysts because of the generation of the new phase K$_2$O on the surface of alumina, and as a result of the increasing basicity of the catalyst.\textsuperscript{109} In addition, Ma et al.\textsuperscript{110} reported the synthesis of FAME via transesterification of rapeseed oil using the K@KOH@Al$_2$O$_3$ catalyst. The formation of the Al–O–K composite enhanced the basicity of the catalyst and thus, the catalytic efficiency. They investigated the catalytic activity by varying the amount of K and KOH, and found that 7.5 and 20 wt% (w.r.t. alumina) of K and KOH, respectively, displayed the highest activity with 84.52% biodiesel yield. Moreover, Chen et al.\textsuperscript{111} reported on the biodiesel production from soybean oil using the K@Y-Al$_2$O$_3$ catalyst in a rotating packed bed (RPB) reactor. The schematic representation of the RPB model is displayed in Fig. 7. The main advantage of the RPB reactor is that it provides efficient mixing of three immiscible reactants, such as oil, methanol and the catalyst. A high yield of 96.4% was reported using the optimal reaction conditions.

Zhang et al.\textsuperscript{112} synthesized a KOH-impregnated modified alumina catalyst for biodiesel synthesis from microalgae oil. First, the alumina was modified with lanthanum and barium to increase its surface area, ensure that it possessed the desired pore volume and pore distribution, and finally impregnate KOH on the modified alumina to form the desired catalyst. They
reported that the condition of 25% KOH (w.r.t. modified alumina) impregnated on modified alumina and calcined at 550 °C for 4 h showed the best activity towards the transesterification reaction with 97.7% biodiesel yield under the ideal reaction conditions. Umdu et al.\textsuperscript{113} synthesized CaO@Al\textsubscript{2}O\textsubscript{3} via the sol-gel method and conducted a transesterification reaction of microalgae (Nannochloropsis oculata) oil to produce biodiesel. The catalyst has higher reactivity than the bare CaO, which was almost inactive towards transesterification of the desired microalgae. The alumina was loaded with 80 wt% (w.r.t. Al\textsubscript{2}O\textsubscript{3}) Ca(NO\textsubscript{3})\textsubscript{2}cdot 4H\textsubscript{2}O and calcined at 500 °C for 6 h to form 80 wt% CaO@Al\textsubscript{2}O\textsubscript{3} that possessed the highest catalytic activity with 97.5% biodiesel yield. In addition, Zabeti et al.\textsuperscript{114} synthesized a CaO@Al\textsubscript{2}O\textsubscript{3} catalyst using calcium acetate via calcination at 718 °C for biodiesel synthesis from palm oil. They have used the Response Surface Methodology (RSM) in association with the Central Composite Design (CCD) to determine the optimum reaction conditions, such as the M/O molar ratio, catalyst amount, reaction temperature and reaction time. A biodiesel yield of 98.64% was obtained under the optimum reaction conditions.

Apart from alumina, there are several materials that are used as a catalyst support, such as SiO\textsubscript{2}, ZrO\textsubscript{2} and activated carbon (AC) (Table 9). In 2010, Samart et al.\textsuperscript{115} conducted the transesterification reaction using CaO impregnated on a mesoporous SiO\textsubscript{2} catalyst for FAME production. They also investigated the influence of the CaO amount, and reported that 15 wt% CaO (w.r.t. SiO\textsubscript{2}) loading showed the maximum yield of 95.2%. In addition, the synthesis of FAME from palm oil using a CaO impregnated on a bimodal meso-macroporous SiO\textsubscript{2} support catalyst was reported by Witoon et al.\textsuperscript{116} They investigated the influence of CaO loading and pellet size on the biodiesel conversion, and also compared with the unimodal SiO\textsubscript{2}-supported CaO catalyst. CaO in 40 wt% CaO@SiO\textsubscript{2} was highly aggregated on the surface of the mesoporous SiO\textsubscript{2}, and hence increases the surface basicity. In contrast, CaO in 30 wt% CaO@SiO\textsubscript{2} was highly dispersed inside the mesopore of the silica support. Accordingly, 40 wt% CaO@SiO\textsubscript{2} showed higher FAME yield compared to 30 wt% CaO@SiO\textsubscript{2}. They also reported that the catalyst with a pellet size of 335 μm showed a maximum yield of 92.45%. Moreover, Wu et al.\textsuperscript{117} reported on catalysts consisting of three different potassium compounds (K\textsubscript{2}CO\textsubscript{3} and K\textsubscript{2}SiO\textsubscript{3}) impregnated on mesoporous SiO\textsubscript{2}, such as AlSBA-15 and SBA-15, for the production of FAME from JCO. Three potassium salts with different concentrations were impregnated on AlSBA-15 and SBA-15, and it was found that the basicity lies in the order of 35 wt% K\textsubscript{2}SiO\textsubscript{3}@AlSBA-15 > 35 wt% K\textsubscript{2}CO\textsubscript{3}@AlSBA-15 > 35 wt% K\textsubscript{2}CO\textsubscript{3}@SBA-15. Thus, 30 wt% K\textsubscript{2}SiO\textsubscript{3} showed the highest yield of 95.7% under the optimized reaction conditions.

The concept of the AC-based catalyst is an attempt towards the development of a novel alternative to homogeneous alkaline in the form of a heterogeneous catalyst. These kinds of catalysts have pulled in a lot of consideration from the scientific community because the uses of carbon as catalysts not only makes them reusable in the production process, but also greatly reduces the formation of the soap and increases the glycerol purity.\textsuperscript{118} To date, different kinds of activated carbon-based catalysts have been developed and successfully exploited in biodiesel production, and some of them are briefly discussed here (Table 18). Narowska et al.\textsuperscript{119} proposed the development of a novel carbon-based catalyst to replace the alkaline homogeneous catalyst as a solid catalyst, which has the potential to be reused multiple times, eliminating various limitations associated with other traditional catalysts. In this context, the authors demonstrated the preparation of FAME from corn oil via transesterification utilizing KOH supported on an activated carbon catalyst. The result showed that the highest yield

![Fig. 7 RPB experimental apparatus utilized for the heterogeneously catalyzed transesterification reaction. (92 wt%) of FAME was recorded using optimal reaction conditions. These findings indicated that activated carbon-supported catalysts can be promisingly employed in the transesterification of the waste corn oil using methanol.

Previously, Buasri et al.\textsuperscript{119} reported on calcium oxide impregnated on the AC catalyst in the synthesis of highly pure FAME from waste cooking palm oil through the continuous transesterification of FFA. After the optimization of various reactions, a maximum FAME yield (94%) was accomplished. In another study, Konwar et al.\textsuperscript{120} also synthesized AC-supported calcium oxide from the \textit{Turbonilla striatula} shell. Furthermore, their applicability as a catalyst has been investigated in biodiesel synthesis from vegetable oil. It was reported that the catalyst displayed more than 90% oil conversion under the optimized reaction conditions. Moreover, this approach is economically viable due to the easy recoverability of the catalyst. The catalyst was utilized for five progressive reaction cycles with minimum activity loss.

Hameed et al.\textsuperscript{121} examined a solid catalyst KF supported on AC for biodiesel synthesis from WCO. They designed a composite rotatable reactor to optimize the reaction parameters, and obtained 83% methyl ester yield. In 2010, Baroutian et al.\textsuperscript{122} studied FAME synthesis in a packed bed membrane reactor (PBMR) from palm oil using a solid catalyst of KOH supported on AC generated from palm shell (Fig. 8). They also investigated the impact of the reaction parameters using RSM. The highest biodiesel yield of 98.03% was reported using the catalyst with optimized reaction conditions. In addition, Li et al.\textsuperscript{123} reported the \textit{in situ} synthesis of K$_2$CO$_3$@KFA via mixing of K$_2$CO$_3$ and kraft lignin (KF), followed by calcination at 800 °C, and utilized the catalyst in biodiesel synthesis from rapeseed oil. They also investigated the influence of the reaction parameters on the FAME production, and reported a maximum yield of 99.6% under the optimized reaction conditions.

Furthermore, Buasri et al.\textsuperscript{124} conducted a synthesis process, where a solution of KOH was mixed with activated carbon (AC) originated from coconut shell to form KOH@AC, and used this catalyst in biodiesel synthesis from WCO. The authors claimed that the synthesized catalyst has extraordinary catalytic activity, and showed 86% biodiesel yield under the optimized reaction conditions. Similarly, Wan et al.\textsuperscript{125} examined a solid base catalyst CaO@AC for FAME synthesis from palm oil. RSM was utilized to investigate the impact of the reaction parameters on biodiesel synthesis. A maximum yield of 80.98% was reported under the optimal reaction conditions, and also claimed that the catalyst can retain its activity even after two cycles. Recently, Fadhil et al.\textsuperscript{126} conducted a transesterification reaction of bitter almond oil to produce biodiesel using KAc impregnated on activated carbon originated from the waste of polyethylene terephthalate. A maximum yield of 93.21% with high purity was reported. The authors claimed that the catalyst

### Table 9 Different solid supported catalysts for biodiesel synthesis

| No. | Catalyst | Feedstocks | Conditions\(^a\) | Yield (%) | Ref. |
|-----|----------|------------|-----------------|-----------|-----|
| 1   | CaO/SiO$_2$ | Soybean oil | 16 : 1, 5, 60, 480 | 95.2 | 115 |
| 2   | CaO/SiO$_2$ (bimodal) | Palm oil | 12 : 1, 5, 60, 240 | 94.15 | 116 |
| 3   | K$_3$SiO$_3$@AlSBA-3 | Jatropha oil | 9 : 1, 15, 30, 60, 180 | 95.7 | 117 |
| 4   | KOH/AC | Corn oil | 3 : 1, 0.75, 62.5, 60 | 92 | 118 |
| 5   | CaO/AC | WCO | 25 : 1, NR, 60, 480 | 94 | 119 |
| 6   | CaO/AC | Vegetable oil | 40 : 111, 120, 420 | >90 | 120 |
| 7   | KF/AC | WCO | 8.85 : 1, 3, 175, 60 | 83 | 121 |
| 8   | KOH/AC | Palm oil | 24 : 1, 30.3, 64.1, 60 | 98.03 | 122 |
| 9   | K$_2$CO$_3$@KFA | Rapeseed oil | 15 : 1, 3, 65, 120 | 99.6 | 123 |
| 10  | KOH@AC | WCO | 25 : 1, NR, 60, 120 | 86.3 | 124 |
| 11  | CaO@AC | Palm oil | 15 : 1, 5.3, 190, 81 | 80.98 | 125 |
| 12  | KAc/AC | Bitter almond oil | 9 : 1, 2.50, 65, 150 | 93.21 | 126 |
| 13  | KF/CaO/AC | Soybean oil | 12 : 1, 2.1, 63, 20 | 99.9 | 127 |
| 14  | Ag@ZnO | Palm oil | 10 : 1, 10, 60, 60 | 96 | 128 |
| 15  | KOH/AC | WCO | 12 : 1, 3, 60, 120 | 96.65 | 129 |

\(^a\) Methanol-to-oil molar ratio, catalyst loading (wt%), temperature (°C), reaction time (min).
showed excellent reactivity towards biodiesel synthesis compared to other reported solid base catalysts, as the catalyst showed a very high yield in very suboptimal reaction conditions. Moreover, according to the authors, the catalyst has great stability as it can be reused for 6 cycles.

Liu et al.\textsuperscript{127} examined a solid base catalyst KF/CaO/AC calcined at 500 °C for 5 h for the conversion of soybean oil to biodiesel. The authors claimed that the main catalytic role was played by K\textsubscript{2}O and KCa\textsubscript{3}, which are present in the catalyst. The catalyst demonstrated a high yield of 99.9% in only 20 min. Nonetheless, they reported that the catalyst is highly sensitive towards the water contents in methanol and oleic acid. Therefore, it is necessary to use anhydrous oil and methanol to overcome this problem. In conclusion, from all of these above-mentioned studies, a collective inference can be drawn that the activated carbon-based catalysts will be the next-generation novel alternative to traditionally available catalysts for the efficient transesterification of different oils.

In the meantime, the application of zinc oxide-supported silver nanoparticles (ZnO@Ag NPs) as a solid catalyst for the conversion of palm oil to FAME was reported by Laskar et al.\textsuperscript{128} The transformation of palm oil to FAME was confirmed using NMR analysis and 10 components of FAME were identified using GC-MS technique, with methyl octadecanoate (C18:0) being the major component. A mixture with different ratios of Ag on ZnO were prepared, where 10 wt% ZnO@Ag was found to be the most active catalyst producing 96% FAME under the optimum reaction conditions. In the recent past, Taslim et al.\textsuperscript{129} also demonstrated the efficacy of low-cost AC-based catalysts developed from candlenut shells (an agricultural waste) through the impregnation of KOH for biodiesel production from WCO. The results obtained have shown a yield of biodiesel up to 96.65% using the optimized reaction conditions.

7.1.5 Hydrotalcite. Recently, hydrotalcites have attracted interest as a solid catalyst in the transesterification reactions due to their tunable properties and excellent performance. They belong to the layered double hydroxide (LDH) family. The general formula of hydrotalcite is [M\textsubscript{x}\textsuperscript{2+}M\textsubscript{m}\textsuperscript{3+}(OH)\textsubscript{2}x(n-m)\textsuperscript{y}\textsuperscript{z}][A\textsuperscript{z-}]\textsubscript{m}x\textsubscript{y}\textsubscript{z}H\textsubscript{2}O, where M\textsuperscript{2+} is a divalent metal, e.g., Ca\textsuperscript{2+}, Zn\textsuperscript{2+}, and Mg\textsuperscript{2+}; M\textsuperscript{3+} is a trivalent metal, most frequently Al\textsuperscript{3+}; whereas A\textsuperscript{z-} is an anion with x in the range of 0.1–0.5.\textsuperscript{130,131} Table 10 shows various reported hydrotalcite catalysts employed in the biodiesel synthesis from different feedstocks. Navajas et al.\textsuperscript{132} prepared Mg/Al hydrogel with composition within the range of 1.5–5 by co-precipitation method, and applied it in the conversion of sunflower oil to biodiesel. The basicity of the catalyst increased with the increase in the Mg/Al molar ratio and degree of rehydration. They reported a 96% conversion of oil to FAME (92% yield), utilizing the rehydrated hydrotalcite under the optimal reaction conditions.

Zeng et al.\textsuperscript{133} reported on Mg–Al hydrotalcite with various Mg/Al molar ratios, and used them as a heterogeneous catalyst for the transesterification of soybean oil. The hydrotalcite calcined at 773 K and 3 : 1 Mg-to-Al molar ratio exhibited the highest catalytic activity with 90.5% conversion of oil. Recently, Ma et al.\textsuperscript{134} investigated a heterogeneous catalyst Mg–Al hydrotalcite in the production of biodiesel from WCO. They mentioned that the catalyst with a Mg/Al molar ratio of 3 : 1 and calcined at 500 °C has a high surface area, excellent crystallinity and mesoporous structure, and subsequently showed excellent activity. They also reported 95.2% FAME yield under the optimized reaction condition. In the same manner, Zeng et al.\textsuperscript{135} prepared Mg/Al–CO\textsubscript{3} with a Mg/Al molar ratio of 4 : 1 via urea method, and compared their structures and catalytic activities with those prepared by co-precipitation for the biodiesel synthesis from microalgae oil. They studied the crystal size and surface basicity of all of the prepared hydrotalcites, and reported that the crystal size of the hydrotalcites prepared using the urea method is greater than the as-synthesized ones. They also reported that the mixed oxide of the hydrotalcite prepared via urea method showed the highest catalytic reactivity with the maximum conversion of 90.30%.

Furthermore, the Mg–Al hydrotalcite loaded with 1.5% K was prepared and used as a catalyst for the synthesis of biodiesel from palm oil.\textsuperscript{136} A maximum 86.6% yield was reported using the optimized reaction conditions. They also studied the effect of the synthesized biodiesel on six types of elastomers, such as NBR, HNBR, NBR/PVC, acrylic rubber, co-polymer FKM, and terpolymer FKM, which are commonly found in the fuel system. For testing, the elastomers were immersed in B10 (10% biodiesel in diesel) and found that only terpolymer FKM and co-

\textsuperscript{a} Methanol-to-oil molar ratio, catalyst loading (wt%), temperature (°C), reaction time (min). \textsuperscript{b} NR = not reported.
polymers. Polymer FKM showed a slight change in the properties. Thus, it was concluded that B10 is compatible with the diesel engines without any modification. In another work, Liu et al.137 prepared Zn–Al hydrotalcite within the temperature range of 413–773 K to form dehydrated Zn–Al hydrotalcite and Zn–Al mixed oxides, and used both catalysts in the transesterification reaction in a fixed-bed reactor. The OH groups in the dehydrated Zn–Al are responsible for the high basicity of the catalyst. However, the Mn–O2− pairs and isolated O2− anions are the main basic sites in the Zn–Al metal oxides. Furthermore, they compared the catalytic activity of both dehydrated Zn–Al HT and Zn–Al oxides, and found that the dehydrated HT calcined at 473 K showed the highest catalytic activity and stability towards biodiesel synthesis with a maximum yield of 76% at 140 °C for 1 h. Similarly, a heterogeneous base catalyst, KF/Ca–Al was developed for the biodiesel production from palm oil.138 The catalyst was prepared from layered double hydroxides of Ca–Al, where the introduction of KF enhanced the catalytic activity. It was observed that 100 wt% loading of KF decreased the particle size of the catalyst, as shown by the SEM image of KF/Ca–Al (Fig. 9). The authors also reported a biodiesel yield of 97.14% under the optimized reaction conditions. Besides, biodiesel production from poultry fats was reported by using a solid base catalyst, Mg–Al hydrotalcite.139 The influence of the calcination temperature for the preparation of the catalyst was investigated, and it was disclosed that the catalyst calcined at 550 °C showed the maximum catalytic activity. Moreover, the authors detailed that the rehydration of the catalyst before the transesterification reaction and preferential adsorption of TAGs on the surface of the catalyst reduced the catalytic activity.

Helwani et al.140 synthesized a Mg–Al hydrotalcite via combustion method using saccharose for biodiesel synthesis from JCO. The SEM image of the catalyst calcined at 850 °C displays a lamellar microstructure with closely packed flakes (Fig. 10). The catalyst calcined at 850 °C and recrystallized with 20% saccharose fuel showed the best reactivity with 75.2% biodiesel conversion under the optimized reaction conditions. A layered double hydroxide of zinc hydroxide nitrate was also reported for FAME synthesis from palm oil.141 The catalyst showed excellent reactivity towards the transesterification reaction with 96.5% biodiesel yield.

7.1.6 Mixed metal oxides. Mixed metal oxides provide exceptionally fascinating properties, especially when each component differs from one another. The basic idea of synthesizing the mixed metal-oxide catalysts is to increase the basic or acid strength, surface area, and stability of these catalysts when compared with the single metal oxides. Henceforth, a series of highly efficient, reusable, and stable solid catalysts were prepared. For example, a combination of two metal oxides can show acid–base properties or some unique properties irrespective of their individual properties.142 The basicity of the metals increases as it becomes less electronegative down the group. In the meantime, the highly basic metal oxides formed with alkaline and alkaline earth metals are usually carbonated in air, and are thus inert. Hence, the strong basicity can be achieved only after a high temperature treatment to obtain a carbonate-free metal oxide surface, making the process highly energy-demanding.143 Interestingly, mixed metal oxides with high reactivity can be obtained at a much lower temperature, making it highly demanded in catalysis. To date, several mixed metal oxides have been reported in transesterification reactions, and are listed in Table 11.

Kawashima et al.144 investigated various calcium-containing catalysts (CaTiO3, CaMnO3, Ca2Fe2O5, CaZrO3, and CaO–CeO2) in the biodiesel production from rapeseed oil. Among these, CaO–CeO2 showed excellent results (approximately 90% yield) with high stability compared to the other calcium-containing heterogeneous catalysts under the optimized reaction conditions. The catalyst can be reused for 7 times with a high yield of >80% each time. Sun et al.145 also prepared a La2O3-loaded ZrO2 catalyst by varying the La2O3 amount from 7 to 28 wt%, and investigated for the synthesis of biodiesel. The conditions of 21 wt% La2O3 loading on ZrO2 and calcination at 600 °C demonstrated the highest catalytic activity towards biodiesel production from sunflower oil. The authors proposed a model for the preparation of the catalyst, where La(NO3)3 was impregnated on the surface of ZrO2, followed by drying to form...
Similarly, SrO/SiO₂ and SrO/CaO have been utilizing the catalyst MT-1-923 and the optimal reaction conditions. A biodiesel yield of 92.3% was observed when the molar ratio, and calcined at 923 K is the most active one in the catalyst. It was revealed that the catalyst with a 1 : 1 Ti to Mg ratio, and enhanced both the activity and stability of the prepared catalyst. They recorded 82% yield in just 15 min, the biodiesel yield shrank to 68.9% when the reaction was performed for 3 h. They reported that the reason for the unusual decrease in biodiesel yield was due to a reverse reaction between FAME and glycerol, which showed that the catalyst not only catalyzed the forward reaction, but also catalyzed the reverse reaction. In contrast, modiﬁcation of SrO with SiO₂ and CaO provided excellent activity, as well as high stability. They observed that around 95% conversion was obtained at 65 °C using SrO/SiO₂ and SrO/CaO in 10 and 20 min, respectively. However, they reported that on decreasing the reaction temperature to 45 °C, SrO/CaO showed only 20.20% conversion as compared to SrO/SiO₂, which showed 76.9% conversion. Thus, SrO/SiO₂ displayed better reactivity towards the transesterification of olive oil than SrO/CaO, and possessed high tolerance to the water content and FFA of the biodiesel feedstocks.

In the recent past, Madhuvilakk et al.¹⁴⁸ developed a TiO₂–ZnO nanocatalyst and utilized it in the FAME synthesis from palm oil. The arrangement of deformities on the catalyst surface as a result of the substitution of Ti on the Zn grid improved the reactivity and stability of the prepared catalyst. They recorded that 92% biodiesel yield was achieved under the optimized reaction conditions. Similarly, a series of ZnO–La₂O₃ catalysts have been examined in the biodiesel synthesis from waste oil by Yan et al.¹⁴⁹ Incorporation of La promoted the dispersion of ZnO and improved the acidic-basic sites, thereby increasing the catalytic activity towards both transesterification and esteriﬁcation reactions. The molar ratio of 3 : 1 Zn to La showed the highest activity towards biodiesel production. A high yield of 96% was reported under the optimal reaction conditions. The authors also reported that the catalyst could endure FFA and water contents, and thus allowed for the direct conversion of waste oil to FAME. In another work, the transesteriﬁcation of palm kernel oil to produce biodiesel was also reported using a mixed metal oxide solid base catalyst CaO–ZnO.¹⁵⁰ Upon incorporation of Zn to the CaO phase, the particle size of the catalyst decreased and reduced the calcination temperature required for the decomposition of carbonates to their oxides. The lowering of the calcination temperature for the decomposition of CaCO₃ upon the incorporation of Zn can be explained by the particle size reduction coupled with a loss of H₂O and CO₂ from the zinc carbonate. The schematic representation for the decomposition of CaCO₃ and formation of CaO–ZnO mixed metal oxides is displayed in Scheme 3. It is well known that decarbonisation is a reversible process, which mostly depends on atmospheric CO₂, particle size and composition. The dissociation of CO₂ normally occurs in the outer surface (Scheme 3A). Moreover, upon calcination, the evolved CO₂ may

![Fig. 11. Proposed model for the solid-state reaction on the catalyst surface. Reproduced from ref. 145.](Image)
form a layer on the surface of the material during the continuous disjunction of CaO to CaCO₃ (Scheme 3B). However, incorporation of ZnCO₃ resulted in the formation of voids due to its decomposition to zinc oxide. The resulting voids facilitated heat transfer to the interior particles and evaporation of the gaseous compounds. Moreover, due to the small particle size of CaO–ZnO, the diffusion distance of CO₂ decreased, and thus the calcination temperature also decreased.

Among solid base catalysts, solid ZrO₂ catalysts became popular because of their environmentally benign nature and economic viability for biodiesel production. To date, different types of ZrO₂ catalysts have been developed for use in biodiesel production. In this line, Su et al. synthesized microporous solid base MgO–ZrO₂ composites and utilized them as effective heterogeneous catalysts in biodiesel synthesis. They claimed that such microporous catalysts are of great significance as the presence of porous materials in the preparation of these catalysts provided the ability to interact with atoms, ions, and molecules.

Recently, Ibrahim et al. examined the influence of different support materials like Al₂O₃, Fe₂O₃, TiO₂ and SiO₂ on the physicochemical properties and efficacy of the ZrO₂ solid catalysts commonly used in biodiesel synthesis. From the results obtained, it was revealed that ZrO₂ supported on SiO₂ showed the highest conversion rate due to a comparatively high surface area and a high number of Lewis acid sites. In another study, Faria et al. developed a nanosized catalyst mixed metal oxides SiO₂/ZrO₂ catalyst prepared via sol–gel strategy, and examined its reactivity in the synthesis of biodiesel from soybean oil. It was observed that this catalyst displayed promising reactivity and gave 96.2 ± 1.4% biodiesel yield after 3 h of reaction time. In addition, the catalyst can be reused for 6 progressive cycles with little drop in activity. In 2008, Albuquerqu et al. synthesized MgO–CaO mixed metal oxides with different Mg/M (M = Al or Ca) molar ratios, and used it as a highly active catalyst for the transformation of sunflower oil to biodiesel in 92% yield under the optimized reaction conditions. The highest activity towards the transesterification reaction was found for a bulk Mg : Ca molar ratio of 3.8, whereas bare CaO was found to afford a lower yield of biodiesel under the same reaction conditions. The authors attributed this interesting activity to the higher BET surface area of the MgO–CaO mixed metal oxide (12.8 m² g⁻¹), in comparison to CaO (1.2 m² g⁻¹).

7.1.7 Biomass-based catalyst. In recent years, the bio-waste derived heterogeneous catalyst has gained significant attention both in the realm of catalysis and biofuel research, and has been reviewed recently by several authors. The advantages of using waste materials as a catalyst are largely due to them being cheap, abundant, non-toxic, ecofriendly, economic, renewable, sustainable and easily available. Many researchers utilized waste biomass as a catalyst for low FFA oil (edible oil), as well as high FFA oil (edible and non-edible oils). The biomass includes plant ashes, waste shells, bones, and industrial wastes. Profitably, catalysts derived from waste biomass potentially make biodiesel production highly cost-effective and environmentally benign.

7.1.7.1 Waste shells. Although several of the chemically synthesized heterogeneous catalysts mentioned earlier show promising and comparatively high biodiesel yield, their synthesis routes are sometimes complicated, expensive, chemically wasteful, time consuming and non-economical.

Scheme 3 Proposed models for CaCO₃ decomposition to CaO (A) and mixed precipitate of Ca–Zn (B). Reproduced from ref. 150.

<sup>a</sup> Methanol-to-oil molar ratio, catalyst loading (wt%), temperature (°C), reaction time (min). <sup>b</sup> Conversion. <sup>c</sup> NR = not reported, WCPO = waste cooking palm oil.
Therefore, with the growing high demand for renewable energy, there is a need to search for an ideal heterogeneous catalyst that is easy to synthesize, non-toxic, low cost, widely available, biodegradable and eco-friendly in nature, yet exhibits high catalytic activity in biodiesel production. In light of this, the utilization of CaO (derived from the high-temperature calcination of waste shells containing CaCO3) has been a front-runner in recent times. The use of waste shells as a source of CaO not only make the whole production of biodiesel sustainable, but also solved the problem associated with the waste disposal of huge quantities of waste shell generated due to human consumption.

7.1.7.1.1 Eggshell. Various eggshell-derived heterogeneous catalysts are available for the transformation of edible/non-edible oils to FAME, as listed in Table 12. For the first time, CaO originated from chicken eggshell calcined at 1000 °C was utilized for biodiesel synthesis by Wei et al.163 Biodiesel yield greater than 95% was obtained. They calcined the eggshell at different temperatures from 200 °C to 1000 °C, and then tested their efficacy for the transformation of soybean oil to FAME. They observed that those calcined above 800 °C were the most active catalysts, where the XRD spectra display a crystalline CaO (Fig. 12). Samples calcined at 700 °C for 2 h contain CaCO3 as the principal constituent and CaO as a minor one; hence, a medium yield (90%) was obtained. Calcinations below 600 °C did not result in the formation of CaO; hence, low catalytic activity was observed (<30% biodiesel yield). Hence, CaO in the catalyst is the principal basic constituent, which led to the high reactivity of the catalyst. From this experiment, it is suggested that waste shells have to be calcined at a temperature of at least 800 °C for 2 h to fully convert CaCO3 to CaO, a highly basic catalyst.

In recent years, CaO derived from eggshell has been widely investigated in the transformation of various edible/non-edible oils, such as soybean oil,162-164 karanja oil,165 WCO,166-175 palm oil,176-179 rapeseed oil,180,181 sunflower oil,182-185 JCO,186 micro-algae oil,187-189 chicken fat,190 catfish oil,191 Helianthus annuus L oil,192 cotton oil193 and sativa oil194 for FAME production. In 2014, Niju et al.172 examined a highly active modified chicken eggshell derived CaO catalyst for the synthesis of FAME from WFO. The authors reported that highly reactive CaO can be obtained from eggshells via calcination–hydration–dehydration treatment. While the FAME conversion was only 67.57% for the commercial CaO catalyst, CaO obtained from the eggshell calcined at 900 °C followed by hydration and dehydration at 600 °C (eggshell-CaO-900-600) gave 94.52% conversion under the optimized reaction conditions. Calcination followed by hydration and dehydration greatly increased the surface area of the eggshell-derived CaO as compared to those obtained with the only calcination. The high activity of the modified CaO

![Fig. 12 XRD patterns of natural eggshell and the materials obtained by calcining natural eggshell in the range of 200–1000 °C. Reproduced from ref. 161.](image1)

![Fig. 13 SEM image of (a) eggshell-CaO-900 and (b) eggshell-CaO-900-600. Reproduced from ref. 172.](image2)
(eggshell-CaO-900-600) is attributed to the high surface area (8.6401 m² g⁻¹) compared to both commercial CaO (3.0022 m² g⁻¹) and eggshell derived-CaO calcined at 900 °C (eggshell-CaO-900) (3.7262 m² g⁻¹). The basicity of the modified catalyst lies in the region 12.2 < H_b < 15.0. Fig. 13b depicts the SEM image of CaO generated from the calcination–hydration–dehydration treatment of eggshells (i.e., egg shell-CaO-900-600), which shows a honeycomb-like porous surface. However, in the case of eggshell-CaO-900, a rod-like structure with microporous particles (size ranging from 1.29 to 2.0 μm) was observed (Fig. 13a).

In another work, waste chicken fat obtained from a slaughterhouse was converted to FAME using calcined chicken eggshell catalyst under microwave irradiation (Fig. 14).

Esterification was carried out to lessen the FFA content of the chicken oil below 1 mg KOH per g of oil, followed by transesterification to yield FAME. A flow diagram of the biodiesel production using chicken eggshell as a catalyst is presented in Fig. 15. Optimization of the transesterification process parameters by response surface methodology was performed.

Similarly, Helianthus annuus L oil was converted to FAME using eggshell-derived CaO. The preparation route of CaO

starting from the shell is presented in Fig. 16. Under the optimized reaction conditions, 99.2% of the FAME yield was achieved. The catalyst is stable up to the fourth cycle, where 87.8% yield was observed.

Earlier, Ansori et al.\textsuperscript{195} reported a chicken shell-derived CaO catalyzed synthesis of FAME from \textit{C. inophyllum} L oil under a microwave (MW) irradiation. Initially, the oil FFA content was pre-esterified utilizing H\textsubscript{2}SO\textsubscript{4}, which was then transesterified by utilizing the CaO catalyst (originated from chicken shell), and they reported 98.90% FAME yield in 12.47 min. In another work, Mansir et al.\textsuperscript{196} examined the application of the W/Mo/CaO catalyst, where tungsten and molybdenum were impregnated on CaO derived from waste eggshell, for the transformation of WCO via a concerted esterification/transesterification to produce FAME in a one-pot process. Moreover, the authors investigated the influence of W and Mo loading on CaO in its catalytic activity, and found that catalytic activity increased when the wt\% of W was higher than the wt\% of Mo over the range of 0.3–0.7%. A maximum yield of 96.2% was reported under the optimum reaction conditions using 0.6 W/0.4 Mo/ CaO. In addition, several studies in the literature are available for the transesterification of WCO having FFA content in the range of 4–7.1% to produce the methyl ester using various eggshell-derived CaO catalysts impregnated with acidic and basic compounds. Examples of such catalysts are CaO/anthill,\textsuperscript{197} CaO/Zn,\textsuperscript{198} CaO/KF/Fe\textsubscript{2}O\textsubscript{4},\textsuperscript{199} CaO/SiO\textsubscript{2} based on palm empty fruit bunch (PEFB),\textsuperscript{200} and Mo–Zr/CaO.\textsuperscript{201}

In 2015, Joshi et al.\textsuperscript{184} synthesized various metal oxides, for example, ZnO, MnO\textsubscript{2}, Fe\textsubscript{2}O\textsubscript{3}, and Al\textsubscript{2}O\textsubscript{3}, impregnated on CaO derived from eggshell via calcination at 900 °C, and explored these catalysts in the conversion of non-edible JCO to FAME. Among all of the mixed metal oxides, the surface area and pore volume of ZnO–CaO were highest and thus showed an excellent 95.2% JCO conversion. The authors also reported that the catalyst is very stable towards the transesterification of JCO, and can be reused for 4 cycles. Similarly, Teo et al.\textsuperscript{202} synthesized CaO NPs derived from \textit{Gullus domesticus} eggshell via precipitation method, and utilized it for the conversion of JCO to give FAME with 97% yield under the optimal reaction conditions.

The TEM images and particle size distribution of the waste eggshell of \textit{Gullus domesticus} derived nano-CaO catalyst is displayed in Fig. 17(a–c), which revealed that the particles were regular spheroidal shape and the average particle diameter is 16–27 nm. Fig. 17d displays the basicity measurement of the catalyst and commercial CaO using CO\textsubscript{2}-TPD technique. All CaO catalysts showed a broad desorption peak owing to the existence of the strong basic strength. The desorption peaks of both catalysts observed over the temperature ranging from 550 to 700 °C are attributed to the super-basic characteristics of the nanoparticles.

In 2011, Olutoye et al.\textsuperscript{203} reported a mixed metal solid catalyst, where Mg(NO\textsubscript{3})\textsubscript{2} and KNO\textsubscript{3} were impregnated on CaO originated from eggshell, and exploited it in the transformation of palm oil to FAME. The authors made three sets of a catalyst by changing the loading amount of Mg(NO\textsubscript{3})\textsubscript{2} and KNO\textsubscript{3} on CaO with wt% ratios of 6 : 1 : 1, 2 : 1 : 1 and 1 : 1.5 : 1.5, and investigated their influence on the transesterification reaction. They reported that the catalyst with wt% ratio of 6 : 1 : 1 showed the maximum yield of 85.8%. In addition, several works are reported in the literature regarding the transesterification of palm oil using chicken shell-derived CaO modified solid catalysts, such as CaO/SiO\textsubscript{2} (ref. 204 and 205) and CaO/rice husk.\textsuperscript{206} Recently, Sulaiman et al.\textsuperscript{207} successfully synthesized a mixture of calcined coconut waste and egg waste for the transformation of palm oil to biodiesel. The authors employed RSM based on CCD to study the ideal reaction conditions: coconut waste/eggshell waste ratio, M/O molar ratio, catalyst amount, reaction temperature and reaction time. After a successful investigation, they reported that 5 : 1 wt% ratio of coconut waste/eggshell waste showed the maximum yield of 81% under the optimal reaction conditions.

In another work, A Li-doped CaO catalyst derived from eggshell was examined for the transformation of nahor oil to produce FAME by Boro et al.\textsuperscript{208} They measured the FFA content in the nahor oil and found 15 mg KOH per g. Due to this high FFA contents, a two-step process was investigated. First, an esterification was performed using sulfuric acid to bring down the FFA amount to <1, followed by transesterification reaction using the Li/CaO catalyst. They also examined the impact of Li doping on the conversion of oil to FAME, and reported a maximum 94% conversion when the Li doping was 2 wt%. Recently, Rahman et al.\textsuperscript{209} modified CaO derived from chicken eggshell with transition metals, such as Zn and Cu, and applied the catalyst in the transformation of eucalyptus oil to FAME. The authors reported that the surface area and basicity of Zn/CaO are higher than the Cu/CaO, therefore Zn/CaO showed better results with 93.2% FAME yield. Moreover, the impregnation of Zn on CaO improved the stability of the catalyst and can be used for 7 consecutive cycles. In another report, a magnetically recoverable KF-modified CaO derived from eggshell was prepared and employed in the transformation of neem oil to FAME.\textsuperscript{199} The author reported that the primary advantage of the catalyst is that the catalyst circumvented the saponification reaction. Therefore, the transesterification of neem oil (FFA content 4.2%) can proceed through the one-step process, and 94.5% FAME can be achieved.
In 2010, a novel eggshell originated CaO impregnated with fly ash was reported for the transesterification of soybean oil to form FAME. The influence of CaO loading was studied by the authors, and it was found that 30 wt% CaO loading showed a maximum yield of 96.97%. Moreover, CaO supported on fly ash enhanced the catalyst reusability and reactivity compared to commercial CaO based catalysts.

Fig. 17 TEM images and particle size distributions of the surfactant assistant CaO nanocatalysts: after 40 min (a), after 80 min (b), and after 120 min (c). the neat eggshell originated CaO. In addition, a KF modified CaO originated from eggshell was examined for the transformation of soybean oil to FAME. The modified catalyst has higher basicity than the neat CaO due to the addition of KOH in the process. Recently, Chowdhury et al. synthesized a Na-doped CaO derived from chicken eggshell, and exploited it in the transesterification of Madhuca indica oil. A two-step process was employed as the oil has 45% of FFA content. They first esterified the oil using 5 wt% sulfuric acid to lessen the FFA content of the oil, followed by transesterification using Na-doped CaO catalyst. To study the influence of the reaction parameters on the transformation of oil to biodiesel, the Taguchi approach was used, where they observed that the M/O molar ratio and the reaction temperature have the highest impact, and the reaction time has minimal impact on the transformation of oil to FAME. In 2014, Chen et al. demonstrated the synthesis of FAME from palm oil using CaO catalyst derived from ostrich egg-shell via ultrasonication. They compared the production of biodiesel using both mechanical stirring and ultrasonication process, and reported that the latter case showed higher yield (92.7%). Moreover, the catalyst can be used for 8 consecutive cycles. A transesterification process for soybean oil deodorizer distillate (SODD) to produce FAME was reported using CaO derived from the duck eggshell. They measured the FFA content of SODD and found 53.2%. Therefore, to overcome the saponification problem, the oil was pre-

### Table 13 Various mollusk and seashell-derived solid catalyst yields for biodiesel production

| No. | Catalyst source | Feedstock | Conditions | Yield (%) | Ref. |
|-----|-----------------|-----------|------------|-----------|-----|
| 1   | Oyster shell    | CaO/KI    | Soybean    | 10 : 1, 1 mmol g⁻¹, 50, 240 | 79.5 | 220 |
| 2   | Oyster shell    | CaO       | Soybean oil| 6 : 1, 25, 65, 300           | 73.8 | 221 |
| 3   | Oyster and Pyramidella shells | CaO | Jatropha oil | 15 : 1, 4, MW, 6 | 93 | 222 |
| 4   | River snail shell | CaO | WCO | 9 : 1, 3, 65, 60 | 92.5 | 223 |
| 5   | River snail shell | CaO | Palm oil | 12 : 1, 5, 65, 90 | 98.5 | 224 |
| 6   | River snail shell | CaO | Soybean oil | 9 : 1, 3, 65, 180 | 98 | 225 |
| 7   | River snail shell | CaO | WCO | 6.03 : 1, 2, 60, 420 | 87.28 | 226 |
| 8   | Snail shell     | CaO/KBr/kaolin | Soybean oil | 6 : 1, 2, 65, 120 | 98.5 | 227 |
| 9   | Snail shell     | CaO       | Soybean oil| 6 : 1, 3, RT, 420           | 98 | 228 |
| 10  | Snail shell     | CaO       | WCO | 6 : 1, 3, 60, 60           | 96 | 229 |
| 11  | Snail shell     | CaO       | WCO | 9 : 1, 9, 60, 180          | 84.14 | 230 |
| 12  | Snail shell (S. canarium) | CaO | WCO | 12 : 1, 3, 65, 240 | 83.5 | 231 |
| 13  | Snail shell     | Nano-CaO  | H. wightiana oil | 12.4 : 1, 0.892, 61.6, 145.154 | 98.93 | 232 |
| 14  | Snail shell     | CaO       | A. africana seed oil | 6 : 1, 1.5, 55, 65 | 85 | 233 |
| 15  | Mussel/cockle/scallop shell | CaO | Palm oil | 9 : 1, 10, 65, 180 | 95 | 234 |
| 16  | Mussel shell (Perna varidis) | C/CaO/NaOH | Palm oil | 0.5 : 1, 7.5, 65, 180 | 95.12 | 235 |
| 17  | Mussel shell    | CaO/KOH   | Castor oil | 6 : 1, 2, 60, 180 | 91.17 | 236 |
| 18  | Mussel shell    | CaO       | Soybean oil | 24 : 1, 12, 60, 480 | 94.1 | 237 |
| 19  | Mussel shell    | CaO       | Soybean oil | 9 : 1, 4, 65, 180 | >98 | 238 |
| 20  | Fresh water mussel shell | CaO | Chinese tallow oil | 12 : 1, 5, 70, 90 | 97.5 | 239 |
| 21  | Mussel/clamp/oyster | CaO | C. sativa oil | 12 : 1, 1, 65, 120 | 95/93/91 | 240 |
| 22  | Angel wing shell | CaO | N. oculata (microalgae) oil | 150 : 1, 9, 65, 60 | 84.11 | 241 |
| 23  | Angel wing shell | CaO-SO₄ | PFAD | 15 : 1, 5, 80, 180 | 98b | 242 |
| 24  | Clams shell     | CaO       | Palm oil | 9 : 1, 1, 65, 120 | 98 | 243 |
| 25  | Short necked clam (O. orbiculata) shell | CaO | JCO | 20 : 1, 4, 65, 360 | 93 | 244 |
| 26  | Clams shell (M. mereterix) | CaO | WFO | 6.03 : 1, 3, 60, 180 | >89 | 245 |
| 27  | White bivalve clams shell | CaO | WFO | 18 : 1, 8, 65, 180 | 95.84 | 246 |
| 28  | Venus clam (Tapes belcheri S.) | CaO | Palm oil | 15 : 1, 5, 360 | 97 | 247 |
| 29  | Abalon shell    | CaO       | Palm oil | 9 : 1, 7, 65, 150 | 96.2 | 248 |
| 30  | T. jordani shell | CaO | Palm oil | 3 : 1, 10, 80, 420 | 99.33b | 249 |
| 31  | A. cristatum shell | CaO | Palm oil | 8 : 1, 3, 60, 360 | 93 | 250 |
| 32  | Cockleshell     | CaO       | Palm oil | 0.54 : 1, 4.9, reflux, 180 | 99.4 | 251 |
| 33  | Obtuse horn shell | CaO | Palm oil | 12 : 1, 5, reflux, 360 | 86.75 | 252 |
| 34  | Biont (turtle) shell | CaO/KF | Rape seed oil | 9 : 1, 3, 70, 180 | 97.5 | 253 |
| 35  | Turbonilla striatula shell | CaO | Mustard oil | 9 : 1, 3, 65 ± 5, 360 | 93.3 | 254 |
| 36  | Turbonilla striatula shell | CaO/Ba | WCO | 6 : 1, 1, 65, 120 | >98 | 255 |
| 37  | Chicoreus brunnus shell | CaO | Rice bran oil | 30 : 1, 0.4, 65, 120 | 93 | 256 |
| 38  | Shrimp shell    | CaO/KF    | Rape seed oil | 9 : 1, 2.5, 65, 180 | 89.1 | 257 |
| 39  | P. erosa seashells | Nano-CaO | Jatropha oil | 5.15 : 1, 0.02, RT, 133.1 | 95.8 | 258 |
| 40  | Crab shell (S. tranquebarica) | CaO | Sunflower oil | 12 : 1, 8, 95, 75 | 94.2 | 259 |
| 41  | Crab shell      | CaO/Na-ZSM-5 | Neem oil | 12 : 1, 15, 75, 360 | 95 | 260 |
| 42  | Crab shell (S. serrata) | CaO | Palm oil | 0.5 : 1, 5, 65, 150 | 98.8 | 261 |
| 43  | Crab shell      | CaO       | Karanja oil | 8 : 1, 2.5, 65, 120 | 94 | 262 |

esterified with sulfuric acid and then the transesterification was performed for the pre-esterified SODD using the CaO catalyst to produce FAME with an overall yield of 94.6%. In addition, CaO derived from quail eggshell was utilized for the transformation of palm oil and JCO to biodiesel in high yield.

7.1.7.1.2. Mollusk shell and other seashells. Mollusk shell and other seashell-derived solid catalysts have been widely investigated in the transformation of edible/non-edible oils to produce biodiesel, and are listed in Table 13. Examples include a basic solid catalyst developed by the impregnation of KI on the calcined oyster shell, which was utilized in the transformation of soybean oil to FAME. The authors reported that the impregnation and calcination increased the surface area to an extent of 32-fold, and therefore increased the catalytic activity. The main disadvantages of the catalyst are the reusability factor and higher loading of KI. In addition, there are various studies in the literature, where neat CaO derived from oyster shell was utilized for the transformation of soybean oil to FAME and microwave-assisted (800 W) biodiesel synthesis from jatropha oil. Recently, a basic heterogeneous catalyst was developed from the river snail shell by calcination at 800 °C for 4 h. The catalyst was employed for the transesterification of WCO for biodiesel production. They performed KOH titration and found that the FFA content in the WCO is 0.3%. Therefore, direct transesterification was carried out and 98.19% yield was achieved under the optimal reaction conditions. Elsewhere, reports are also available where CaO derived from calcined river snails were used for the transesterification of various edible/non-edible oils, for example, palm oil, soybean oil, and WFO.

In 2016, Liu et al. developed a solid catalyst, where KBr was loaded on calcined snail shell and kaolinite mixture, followed by activation of the catalyst via calcination at 500 °C for 4 h, and applied the catalyst in the transformation of soybean oil to FAME. They also investigated the effect of the loading of KBr and the wt% ratio of the snail shell/kaolinite mixture on biodiesel yield. It was found that the catalyst showed a maximum yield of 98.5% when the KBr loading and wt% ratio of the snail shell/kaolinite were 40 wt% and 4 : 1, respectively. The mixing of the snail shell and kaolinite together provides the catalyst with extra stability compared to their pure form. In addition, Laskar et al. developed a solid basic catalyst CaO derived from a calcined snail shell for the conversion of soybean oil to biodiesel. Under the ideal reaction states, 98% biodiesel yield was achieved. It is reported that at 400–600 °C calcination temperature, CaCO3 of the snail shell was transformed to calcite. When the calcination temperature was further increased to 700 and 800 °C, a minor and major component of CaO was achieved, which was later completely transformed into CaO at 900 °C calcination temperature. Fig. 18 reveals that 100% transformation of CaCO3 into CaO can be achieved above 800 °C calcination temperature.

In another work, El-Gendy et al. reported on a CaO catalyst originated from snail shell calcined at 800 °C, and utilized it in the transesterification reaction. RSM was utilized to investigate the influence of the reaction parameters on biodiesel production, and it was reported that 96.76% yield was observed under the optimized reaction conditions. Similarly, there are various studies in the literature available for the transesterification of WCO to FAME using CaO derived from snail shell collected from different sources. Very recently, Krishnamurthy et al. developed a solid catalyst, CaO nanoparticles derived from snail shell via the hydrothermal method, and investigated its application in the transesterification of H. wightiana oil to produce FAME. However, a high FFA content (7.57%) in the oil led the authors to follow a two-step process: (1) pre-esterification and (2) transesterification for the production of FAME. RSM was utilized to examine the impact of reaction parameters on FAME synthesis, which resulted in 96.92% yield under the optimal reaction conditions. In a similar vein, CaO derived from snail shell was also investigated for the transformation of A. africana seed oil and showed 85% FAME yield.

A calcined mussel/cockle/scallop shell-derived CaO was developed for the transformation of palm oil for FAME production. The authors reported on the high catalyst reactivity and catalytic activity with great stability towards the transesterification of palm oil with 95% conversion. In the meantime, Hadiyanto et al. developed a solid catalyst, modified CaO (derived from green mussel shell) with activated carbon (C), followed by impregnation of NaOH, and utilized the catalyst in the transesterification of palm oil. The wt% C/CaO ratio of 2 : 3 showed the maximum yield of 95.12% under the optimal reaction conditions. Similarly, KOH impregnated mussel shell derived CaO was examined for castor oil transformation to biodiesel. The authors made a comparison between the non-impregnated and KOH impregnated catalysts, and revealed

Fig. 18 XRD spectra of normal and calcined (400–1000 °C) snail shells. Reproduced from ref. 228.
that the KOH impregnated catalyst displayed higher reactivity, as well as basicity, and they reported 91.7% FAME yield using the KOH impregnated catalyst.\textsuperscript{236} Moreover, the calcined mussel shell-derived catalysts were widely examined for the transformation of vegetable oils, for example, soybean oil,\textsuperscript{237,238} Chinese tallow oil,\textsuperscript{239} and Camelina sativa oil\textsuperscript{240} for biodiesel production.

Syazwani et al.\textsuperscript{241} examined CaO, which originated from angel wing shell (AWS) and was calcined at 900 °C for 2 h, for the conversion of N. oculata micro-algae oil to FAME. The catalyst possessed high reactivity with great stability, and could be reused for 3 consecutive cycles. Furthermore, a bifunctional catalyst was developed for the conversion of palm fatty acid distillate (PFAD) to FAME. The angel wing shell was calcined to form CaO, followed by sulfonation to afford the catalyst. The authors reported that the catalyst surface area increased by two-fold after the modification. As a result, the catalyst showed excellent activity towards the esterification of PFAD. Unfortunately, the catalyst was reusable only for two cycles as blocking of active sites occurred in each reaction cycle. Therefore to enhance the reusability of the catalyst, pretreatment of the catalyst such as washing and re-calcination are necessary before each reaction cycles.\textsuperscript{242} In 2015, Askin-Mijan et al.\textsuperscript{243} developed a waste clam shell-derived CaO using hydration–dehydration treatment, and investigated its catalytic application in the conversion of palm oil to FAME. They also examined the effect of the hydration–dehydration time on biodiesel conversion. The authors found that the catalytic activity increased with increasing hydration time. This was because the extended hydration enhanced the formation of Ca(OH)$_2$, increased the basicity, reduced the crystallinity, and enhanced the surface area. They reported that the rehydration for 12 h showed the maximum 98% FAME yield under optimized reaction conditions. Similarly, an investigation of the naked CaO catalyst, derived from a calcined short-necked clamshell, recorded 93% biodiesel yield under the optimal reaction conditions.\textsuperscript{244} In addition, CaO derived from various calcined clamshell was utilized for the transformation of diverse edible/non-edible oils, for example, palm oil\textsuperscript{245,246} and WFO\textsuperscript{247} to produce biodiesel.

A solid ethanol-treated catalyst CaO, derived from calcined abalone shell, was examined for the production of FAME from palm oil. The authors investigated the impact of ethanol treatment at different temperatures (RT, 100 °C and 160 °C). They found that the catalyst treated with ethanol at 100 °C showed the maximum yield of 96.2%, as the ethanol treatment provides high basicity, high surface area and lowered the catalyst crystallinity. Moreover, a comparison of the modified CaO with naked CaO showed that the modified CaO has higher reusability and provided higher biodiesel yield.\textsuperscript{248} In addition, there are several reports available in the literature regarding the transesterification of palm oil to FAME utilizing the CaO-based solid catalyst originating from various waste shells, such as T. jourdani shell,\textsuperscript{249} A. cristatum shell,\textsuperscript{250} cockle shell\textsuperscript{251} and obtuse horn shell.\textsuperscript{252}

In 2009, Xie et al.\textsuperscript{253} synthesized a solid catalyst via three-step process: (i) incomplete carbonization of a bont shell at 500 °C, (ii) KF impregnation and (iii) catalyst activation at 300 °C. The developed catalyst was utilized for the conversion of rapeseed oil to FAME. They reported that the catalyst displayed excellent reactivity due to the formation of a higher amount of active sites during the reaction between the incomplete carbonized shell and KF. The effect of KF loading was also examined, and it was found that 25% KF loading is optimal and showed 97% FAME yield under the optimized reaction conditions. Correspondingly, Boro et al.\textsuperscript{254} demonstrated the synthesis of the CaO catalyst by calcination of Turbonilla striata shell, and utilized it for the transformation of mustard oil to FAME. The effect of the calcination temperature was examined, and it was observed that the catalyst calcined at 900 °C displayed the maximum 93.3% FAME yield. In addition, CaO derived from calcined Turbonilla striata was modified with Ba in the range of 0.5–1.5 wt%. It was utilized for the transformation of WCO to biodiesel. Due to the high acid value of 22 mg KOH per g, the oil was pretreated with sulfuric acid to reduce the acid value to <1. Then, the pretreated oil was transesterified with Ba/CaO catalyst. The authors also examined the effect of Ba loading and found that 1% of Ba doping showed >98% biodiesel yield.\textsuperscript{255} In addition, Chicoreus brunneus shell was calcined above 800 °C to convert CaCO$_3$ to CaO, followed by hydration/dehydration to form a solid base catalyst. It was then examined for the transformation of rice bran oil. Calcination and hydration provided the catalyst with high porosity, enhancing the basicity, catalytic activity and reusability.\textsuperscript{256} In addition, shrimp shell originated catalysts have been utilized for the transformation of various edible/non-edible oils to FAME. Yang et al.\textsuperscript{257} synthesized a catalyst via a three-step process: (i) inadequate carbonization of shrimp shell, (ii) reaction with KF, and (iii) activation of the catalyst under the heating condition for the rapeseed oil transformation. The authors examined the impact of the carbonization temperature, KF amount and activation temperature. They found that 89.1% biodiesel was achieved under the reaction states: carbonization temperature of 450 °C, KF amount of 25 wt%, and an activation temperature of 250 °C. The excellent catalyst reactivity is attributable to the formation of active sites during the reaction between the incomplete carbonized shrimp shell and KF. Moreover, a solid catalyst, CaO nanoparticles with a diameter of 66 nm derived from Polymedosa erosa shell via calcination–hydration–dehydration process was developed for the transformation of JCO to FAME in a two-step procedure: (1) pre-esterification and (2) transesterification. The influence of the reaction parameters on the oil conversion was examined by RSM technique, and displayed 98.54% FAME yield.\textsuperscript{258}

In the recent past, Sivakumar et al.\textsuperscript{259} developed a solid catalyst derived from Scylla tranquebarica crab shell calcined at 750 °C for sunflower oil transformation to FAME. The developed catalyst displayed similar reactivity to that of commercial CaO, and reported a very high conversion of 94.2% under the optimal reaction conditions. Similarly, Shankar et al.\textsuperscript{260} prepared a solid catalyst, where CaO (derived from crab shell calcined at 900 °C) was impregnated on Na-ZSM-5 followed by activation at 550 °C for 10 h. It was utilized for the production of FAME from neem oil. The impact of CaO loading was examined, and it was found that 15 wt% CaO impregnation showed a maximum 95% biodiesel...
formation. Moreover, various reports are available for the transesterification of edible/non-edible oils, such as palm oil and karanja oil, utilizing CaO originated from calcined crab shells.

### Table 14 Different plant ash catalyst yields in biodiesel production

| No. | Catalyst source | Feedstock | Conditions | Yield (%) | Ref.  |
|-----|-----------------|-----------|------------|-----------|-------|
| 1   | L. perpusilla Torreya | JCO       | 9 : 1, 5, 65 ± 5, 300 | 89.43     | 263   |
| 2   | Oil palm ash     | WCO       | 18 : 0, 5.35, 60, 30 | 71.74     | 264   |
| 3   | Oil palm ash/boiler ash (BA) | Palm olein | 15 : 1, 3, 60, 30 | 90       | 265   |
| 4   | Musa paradisiaca L. (plantain) peels | Thevetia peruviana oil | 3.3 : 1, 3, 60, 60 | 95.2      | 266   |
| 5   | Ripe plantain fruit peel | Azadirachta indica oil | 1 : 0.73, 0.65, 65, 57 | 99.2     | 267   |
| 6   | Coconut husk     | JCO       | 12 : 1, 7, 45, 30 min | 99.86      | 268   |
| 7   | Cocoa pod husks  | Soybean oil | 6 : 1, 1, 60, 60/120 | 98.7/91.4 | 269   |
| 8   | Musa balbisiana Colla peel | Thevetia peruviana seed oil | 20 : 1', 20, RT, 180 | 96b      | 270   |
| 9   | Musa balbisiana Colla underground stem | JCO | 9 : 1, 5, 275, 60 | 98       | 271   |
| 10  | Musa ‘Gross Michел’ peel | Napoleon’s plume seed oil | 7.6 : 1, 2.75, 65, 69.02 | 98.5     | 272   |
| 11  | Rubber seed shell | Rubber seed oil | 0.20 : 1², 2.2, 60, 60 | 83.06     | 273   |
| 12  | Musa balbisiana Colla peel | WCO       | 6 : 1, 2, 60, 180 | 100b      | 274   |
| 13  | M. acuminate peel | Soybean     | 6 : 1, 7, RT, 240 | 98.95     | 275   |
| 14  | Wood (Acacia nilotica) stem | JCO | 12 : 1, 5, 65, 180 | 98.7b     | 276   |
| 15  | Birch bark/fly ash | Palm oil    | 12 : 1, 3, 60, 180 | 88.06 ± 0.72/99.92 ± 0.01 | 277   |
| 16  | Musa spp “Pisang Awak” peduncle | Ceylan pantana oil | 9.20 : 1, 1, 1978, 65, 60 | 98.69 ± 0.18 | 278   |
| 17  | Musa acuminate peduncle | Ceylan pantana oil | 11.46 : 1, 2.68, 65, 106 | 98.73 ± 0.50b | 279   |
| 18  | Theobroma grandiflorum seeds | Soybean     | 10 : 1, 10, 80, 480 | 98.36b     | 280   |
| 19  | Brassica nigra plant | Soybean     | 12 : 1, 7, 65, 25 | 98.79      | 281   |
| 20  | Kola nut pod husk | Kariya seed oil (KSO) | 6 : 1, 3, 65, 75 | 98.67 ± 0.01 | 282   |
| 21  | Orange peel      | Soybean     | 6 : 1, 7, RT, 420 | 98b        | 283   |
| 22  | Sesamum indicum plant | Sunflower oil | 12 : 1, 7, 65, 40 | 98.9       | 284   |
| 23  | Tucumá peels     | Soybean     | 15 : 1, 1, 80, 240 | 97.3b       | 285   |
| 24  | Tectona grandis leaves | WCO | 6 : 1, 2.5, RT, 180 | 100b       | 286   |
| 25  | Cocoa pod husk   | Azadirachta indica oil | 0.73 : 1², 0.65, 65, 57 | 99.3      | 287   |
| 26  | Walnut shell     | Soybean     | 12 : 1, 5, 60, 10 | 98         | 288   |
| 27  | Sugar beet waste | Sunflower oil | 4.5 : 1, 1, 75, 60 | 93b        | 289   |
| 28  | M. acuminate trunk | Soybean     | 6 : 1, 1, 80, 360 | 98.39b      | 290   |
| 29  | Banana peel/cocoa pod husk | Palm kernel oil | 0.80 : 1², 4, 65, 65 | 99.5/99.3 | 291   |
| 30  | Carica papaya stem | Scenedesmus obliquus | 9 : 1, 2, 60, 180 | 93.33b     | 292   |
| 31  | Musa balbisiana underground stem | Messisa ferrnea oil | 9 : 1, 5, 60, 275 | 95        | 293   |

7.1.7.2 **Ashes of biomass.** In recent years, the application of waste plant ashes as a highly active heterogeneous catalyst has drawn increasing attention in the realm of biodiesel production. A huge amount of alkali or alkaline earth elements, mostly K, Ca and Mg present in the ashes of waste plant biomass, acted as a highly basic catalyst in the transesterification reaction to produce biodiesel from vegetable oil with low FFA. In the case of vegetable oil with high FFA, a reduction of FFA to <1% (by acid-catalyzed esterification) before the transesterification reaction is mandatory to elude catalyst consumption in soap formation, which otherwise leads to low biodiesel yield. Usually, the biomass is collected, washed and dried either in oven or sunlight, burnt in the open air or burnt in the air. This is followed by calcination to produce a highly basic ash catalyst, as shown in Fig. 19. Different basic ash catalysts were utilized, and their efficacy in the synthesis of biodiesel is presented in Table 14. In a pioneering work, Chouhan et al.⁵ reported the use of amphibian plant *L. perpusilla* Torreya ash as a solid catalyst in biodiesel synthesis from JCO. The plant biomass was subjected to calcination at 550 ± 5 °C for 2 h to obtain the ash catalyst. The crystallinity of the catalyst was affirmed by XRD patterns. The impact of catalyst loading revealed that 5 wt% (w.r.t. oil) is enough to obtain a high 89.43% biodiesel yield under the optimal reaction conditions. Nevertheless, the reusability study

---

**Fig. 19** Flowchart for the synthesis of ash catalyst derived from plant biomass.
demonstrated that the catalyst lost its reactivity in each progressive reaction cycle, owing to leaching of the reactive elements in the catalyst. Thereby, the catalyst was recycled up to 3 cycles only.

In another work, oil palm ash was seen as an active catalyst for biodiesel synthesis from WCO by Chin et al. Fig. 20 depicts the SEM micrograph of the palm ash, which displayed the porous nature of the ash catalyst, while Table 15 lists the elements existing in the palm ash determined from the EDX analysis. It was observed that the palm ash consisted of a large amount of potassium, while a relatively low quantity of aluminum, zinc, and magnesium was also found. Besides, it was seen that K2O was the primary driver for the high basicity of the ash catalyst, while Table 15 lists the permeable nature of the ash catalyst, while Table 15 listed the atomic wt% for compositions of palm ash by Ref. 264.

| Elements        | Atomic wt% |
|-----------------|------------|
| Potassium (K)   | 40.59      |
| Magnesium (Mg)  | 0.76       |
| Silicone (Si)   | 2.63       |
| Aluminum (Al)   | 0.50       |
| Zinc (Zn)       | 0.33       |
| Oxygen (O)      | 29.36      |
| Carbon (C)      | 14.56      |
| Chlorine (Cl)   | 7.07       |

The authors examined the reactivity of MgO impregnated CPH (MgO@CPH) and bare CPH in biodiesel synthesis under the optimal reaction states, and achieved 98.7% and 91.4% biodiesel yields, respectively. Moreover, the synthesized fuel satisfies the European biodiesel quality norm (EN 14112). In another study, the production of biodiesel from yellow oleander (Thevetia peruviana) seed oil using banana (Musa balbisiana Colla) peel ash was reported. The K, Na, CO3, and Cl present in the ash are responsible for the high basicity, and thus the reactivity of the catalyst. Oil transformation of 96% was demonstrated in just 3 h under room temperature. The produced biodiesel conforms to standards set for ASTM D6751, EN 14214 and others. The BET surface area measurement of the catalyst revealed that the surface area is 1.487 m² g⁻¹. The biodiesel was free from sulfur, and has displayed a high cetane number. Meanwhile, Musa balbisiana Colla underground stem (MBCUS) ash was examined as a solid base catalyst for biodiesel synthesis from high FFA containing JCO by Sarma et al. Characterization of the ash catalyst revealed that it is composed of oxides and carbonates of various alkali and alkaline earth metals, which leads to the high basicity of the catalyst, and the surface area is 39 m² g⁻¹. It was reported that the catalyst is very effective during the biodiesel synthesis process at 275 °C and internal pressure (4.2 MPa), and resulted in 98.0% biodiesel yield.

Betiku et al. led an investigation on the application of banana (Musa ‘Gross Michel’) peel waste as a catalyst for biodiesel synthesis from Bauhinia monandra (Napoleon’s plume) seed oil (BMSO), with a motive to develop a low-cost fuel. The burnt ash of the banana peel was further calcined at 700 °C for 4 h to produce a highly active catalyst. They utilized the RSM model to determine the optimal reaction conditions for biodiesel synthesis using the ash catalyst. The RSM plot of the M/O molar ratio and catalyst loading on Bauhinia monandra (Napoleon’s plume) methyl ester (BMME) yield is shown in Fig. 22a. It was identified that the catalyst produced at 350 °C calcination temperature was found to be the most reactive one for biodiesel synthesis, giving 99.86% yield within 30 min at the moderate reaction temperature. XRD patterns of the catalysts are presented in Fig. 21, which revealed the presence of several components of ash, such as KCl, K2SiO3, K2SO4, K2S3, KAlO2, K2CaSiO3, and FeCa2Al2Si4O15OH.

Cocoa pod husks (CPHs) were used as a solid catalyst for biodiesel synthesis from soybean oil by Ofori-Boateng et al. The authors examined the reactivity of MgO impregnated CPH (MgO@CPH) and bare CPH in biodiesel synthesis under the optimal reaction states, and achieved 98.7% and 91.4% biodiesel yields, respectively. Moreover, the synthesized fuel satisfies the European biodiesel quality norm (EN 14112). In another study, the production of biodiesel from yellow oleander (Thevetia peruviana) seed oil using banana (Musa balbisiana Colla) peel ash was reported. The K, Na, CO3, and Cl present in the ash are responsible for the high basicity, and thus the reactivity of the catalyst. Oil transformation of 96% was demonstrated in just 3 h under room temperature. The produced biodiesel conforms to standards set for ASTM D6751, EN 14214 and others. The BET surface area measurement of the catalyst revealed that the surface area is 1.487 m² g⁻¹. The biodiesel was free from sulfur, and has displayed a high cetane number. Meanwhile, Musa balbisiana Colla underground stem (MBCUS) ash was examined as a solid base catalyst for biodiesel synthesis from high FFA containing JCO by Sarma et al. Characterization of the ash catalyst revealed that it is composed of oxides and carbonates of various alkali and alkaline earth metals, which leads to the high basicity of the catalyst, and the surface area is 39 m² g⁻¹. It was reported that the catalyst is very effective during the biodiesel synthesis process at 275 °C and internal pressure (4.2 MPa), and resulted in 98.0% biodiesel yield.
was observed that the BMME yield improved from 0 to >90 wt% as the M/O molar ratio expanded from 7 : 1 to 14 : 1, and the catalyst loading increased from 1.5 to 3.5 wt%. This might be ascribed to the increase in the active site number as a result of the increased catalyst loading. Besides, the BMME yield diminished marginally when the catalyst loading was above 3.5 wt% (Fig. 22a). In addition, the plot revealed a direct connection between the M/O molar ratio and catalyst loading on the biodiesel yield. As the two parameters increased, the biodiesel yield also increased (Fig. 22a). The transformation of the pre-esterified oil to biodiesel was done inside the time span of 33.79–76.21 min. The extended reaction time, somewhere in the range of 33.79 and 55 min, favoured biodiesel yield. After 55 min, the yield diminished. Fig. 22b displays the impact of the reaction time and catalyst loading on the biodiesel yield. It was observed from the surface plot that the rise in catalyst loading and reaction time led to an increase in the biodiesel yield. Moreover, the plot displayed that 90 wt% biodiesel yield was reached using 4.5 wt% catalyst loading within 80 min reaction time. In addition, Fig. 22c illustrates the surface plot to examine the impact of the M/O molar ratio and reaction time on the biodiesel yield. It was observed from the plot that the increases in two parameters, such as the M/O molar ratio and reaction time, led to a rise in the biodiesel yield. It can be seen from the figure that the increases in M/O molar ratio from 7 : 1 to 14 : 1 improved the biodiesel yield from 33% to 100%. Therefore, the highest biodiesel yield was recorded at 14 : 1 M/O molar ratio and 80 min reaction time.

Meanwhile, Onoji et al. built up a novel technique to utilize rubber seed shell (RSS) ash calcined at 800 °C as a solid base catalyst for the transformation of rubber seed oil to biodiesel. The high FFA content of the RSS (9.01 ± 0.07%) was pre-esterified using H₂SO₄ to >1% FFA. The reusability study of the catalyst revealed that >80% biodiesel yield was noticed after 4 successive reaction cycles. The surface area and pore size of the calcined RSS was found to be 2.29 nm and 352.51 m² g⁻¹, respectively. Similarly, Gohain et al. studied the application of the Musa balbisiana Colla peel ash catalyst to produce biodiesel from WCO. It was observed that the calcination procedure improved the mesoporous and microporous morphology of the catalyst, and upgraded its surface area, bringing about the higher catalytic activity. The external morphology of the catalyst examined by SEM analysis revealed aggregation of the particles, and porosity in the range of micro and meso. Moreover, 100%
conversion of WCO to biodiesel was confirmed by $^1$H NMR spectra (Fig. 23b), utilizing the Knothe and Kenar eqn (1). The $^1$H NMR spectrum of WCO (Fig. 23a) displays two peaks at 4.1 and 5.3 ppm because of the glyceridic protons (Fig. 23a). The presence of a peak of the methoxy protons at ~3.6 ppm and the vanishing of the signs of the glyceridic peak close to 4–4.2 ppm (Fig. 23b) confirmed the formation of biodiesel.

In recent years, Pathak et al. utilized the Musa acuminata peel ash (MAPA) catalyst for biodiesel synthesis from soybean oil at room temperature. The catalyst characterization reported the existence of various alkali and alkaline earth metals that enhance the catalyst basicity and reactivity of the ash catalyst. K (14.27%), C (47.51%) and O (30.27%) are the primary/main elements that exist in MAPA, as revealed by the XPS data (Fig. 24). The authors reported 98.95% biodiesel yield under the optimized reaction conditions.

Sharma et al. investigated the reactivity of wood ash catalyst calcined at different temperatures for biodiesel synthesis from JCO. Ester conversion in the range of 97–99% could be achieved with wood ash catalysts. Wood ash calcined at 800 °C afforded 98.7% oil conversion under the ideal reaction conditions. Uprety et al. studied the application of wood ash derived from birch bark and fly ash blazed at 800 °C for 4 h synthesis of biodiesel from palm oil. Birch bark ash gave a FAME yield of 88.06 ± 0.72, whereas fly ash from wood pellet afforded 99.92 ± 0.01% yield. Recently, the application of banana peduncle ash as an efficient solid base catalyst for the synthesis of biodiesel from Ceiba pentandra oil (CPO) was investigated. Based on the response surface methodology (RSM) study, the ideal reaction conditions for the transformation of CPO into FAME was found to be 1.978 wt% catalyst loading, 60 min response time, 9.20 : 1 M/O molar ratio with a maximum predicted FAME yield of 99.36%, which was assessed experimentally as 98.69 ± 0.18%. The same research team also investigated the utilization of Musa acuminata peduncle for biodiesel preparation from CPO. The authors calculated the surface area and pore diameter of the calcined ash catalyst from BET analysis data, and reported 45.99 m$^2$ g$^{-1}$.

Fig. 23 $^1$H NMR spectrum of (a) WCO and (b) Biodiesel. Reproduced from ref. 274.
and 9.77 nm, respectively. Moreover, the catalyst consists of diverse minerals (along with potassium) as primary components, which leads to the higher reactivity of the catalyst (Fig. 25). A high conversion of 98.73 ± 0.50% FAME was observed under the optimum reaction conditions.

In 2019, Mendonça et al. reported the utilization of calcined (800 °C for 4 h) waste cupuaçu seeds as a solid base catalyst in the synthesis of biodiesel from soybean oil and ethanol. Similarly, Nath et al. utilized a solid base catalyst derived from waste Brassica nigra plant for the efficient preparation of biodiesel. The SEM-EDX analysis of the catalyst revealed the existence of potassium (56.13%) and calcium (26.04%) in a huge amount, which may be considered as key ingredients for the high basicity of the catalyst. The authors also measured the surface area pore volume of the catalyst via BET analysis, and came about 7.308 m² g⁻¹ and 0.011 cm³ g⁻¹, respectively. The catalyst possessed excellent reactivity in transforming the soybean oil to FAME and displayed 98.79% FAME yield in a short time frame of 25 min under the optimum reaction conditions.

Betiku et al. prepared an ash catalyst from kola nut pod husk and used it to convert Kariya seed oil (KSO) to biodiesel, namely Kariya oil methyl esters (KOME), via transesterification process. A maximum of 98.67 ± 0.01 wt% of FAME yield was observed. Moreover, the reusability examination of the catalyst suggests that it can be reused for 4 progressive cycles. Recently, Changmai et al. converted soybean oil to biodiesel using orange peel ash in 98% yield. XRF analysis showed the presence of potassium oxide (51.64%) and calcium. The Hammet indicator strategy was employed to examine the catalyst basicity, and it was seen as 9.8 < H < 12.2. The authors measured the catalyst pore volume and surface area from BET analysis, and found 0.428 cm³ g⁻¹ and 605.60 m² g⁻¹, respectively. Moreover, GC-MS analysis (Fig. 26) revealed the existence of six components in the synthesized FAME; methyl palmitate (11.63%), methyl oleate (25.32%) and methyl linoleate (54.34%) were found to be the major components.

**Fig. 24** XPS survey (a), C 1s (b), O 1s (c), and K 2p (d) spectra of MAPA. Reproduced from ref. 275.
The waste *Sesamum indicum* plant ash catalyst was also successfully utilized for the transformation of sunflower oil to biodiesel. The measured surface area of the catalyst was 3.66 m\(^2\) g\(^{-1}\), as obtained from the BET analysis data. A high 98.9% biodiesel yield was accomplished. They reused the catalyst up to the 3\(^{rd}\) cycle, which yielded 94.2% biodiesel. In addition, Mendonça et al. utilized waste tucumã peels ash catalysts for biodiesel synthesis from soybean oil. The catalyst characterization by XRF showed that it was mostly composed of potassium oxides, calcium and magnesium. Because of its heterogeneous and non-leachable nature, the catalyst derived from tucumã peels could be reused at least 5 times. In another study, an ash catalyst from *Tectona grandis* leaves was developed and utilized for the transformation of WCO to FAME by Gohain et al. The measured surface area and pore size of the catalyst were 116.833 m\(^2\) g\(^{-1}\) and 112.210 Å, respectively, as calculated from BET data. 100% oil transformation to FAME was accomplished at room temperature using the optimized reaction conditions. Furthermore, cocoa pod husk-derived solid base catalyst was employed in the transformation of neem seed oil to FAME. A two-step process was employed for the conversion of neem seed oil to FAME: (i) pretreatment of the oil was performed using the Fe\(_2\)(SO\(_4\))\(_3\) catalyst to reduce the FFA content from 28.76% to 0.39%, and (ii) the transesterification of the pretreated oil using the calcined bio waste-derived catalyst. The authors also studied the effect of the reaction parameters using the Box–Behnken design (BBD), and the CCD of RSM was utilized to determine the optimized reaction conditions. Similarly, a walnut shell derived catalyst was developed for the transformation of sunflower oil to biodiesel.
prepared from walnut shells via air combustion, thereby bringing down the cost involved in the calcination process to afford ash. The authors reported a 98% FAME yield within a brief time frame of 10 min. Recently, the transformation of sunflower oil to synthesize FAME using calcined sugar beet generated from agro-industry waste was reported. The catalyst has a high amount of highly basic CaO, and showed very high reactivity towards the transesterification process to afford

Fig. 27  Contour and surface plots for PKOME synthesis. Reproduced from ref. 290.
about 93% FAME yield. 98.39% soybean oil transformation to FAME under room temperature was recently reported using *M. acuminata* trunk ash catalyst.299

Most biomass ash catalysts are usually applied for the transesterification reactions of different biodiesel feedstocks and different reaction conditions. These make a comparison of the effectiveness of such catalysts under the same reaction condition impossible. Hence, to have a better insight into the activities of the catalysts under the same reaction conditions and feedstock, Odude et al.299 examined the transformation of the pre-esterified palm kernel oil (PKO) to FAME utilizing two diverse catalysts, viz., calcined banana peel ash (CBPA) and calcined cocoa pod husk ash (CCPHA) under the same reaction conditions. The RSM technique was utilized for the optimization of both CBPA and CCPHA catalyzed transformation processes of PKO to FAME. CUD was utilized to acquire the best possible combination of the M/O ratio, catalyst loading and reaction time for the highest conversion of oil to FAME, as portrayed in Fig. 27. The observed FAME yields under the optimized conditions utilizing the catalysts CBPA and CCPPA were 99.5 and 99.3 wt%, respectively. The created models, when exposed to statistical assessment, demonstrated that the CBPA-catalyzed transformation model was better than the CCPHA-catalyzed transformation model. In the meantime, the *Carica papaya* stem296 and *Musa balbisiana* underground stem297 were also reported as a solid catalyst to convert *Scenedesmus obliquus* and *Mesua ferrea* oil, respectively, to FAME.

### 7.2 Acid catalysts

Acids can catalyze both transesterification and esterification reactions without soap formation.291 Hence, unlike base catalysts, an acid catalyst has the potential to afford biodiesel from poor quality oil with high FFA and high water content. In the transesterification reaction, alkaline catalysts are superior in promoting methoxide anion formation from methanol. In contrast, acidic catalysts are less active in methoxide anion formation, but could activate the carbonyl bonds via H+ addition (Brønsted acidic sites) or via coordination of the carbonyl oxygen with the coordinatively unsaturated metal ion sites (Lewis acidic sites), and thereby promote transesterification. Hence, an increase in the number of either Bronsted or Lewis acidic sites promotes faster FAME formation via transesterification. Delightfully, heterogeneous acid catalysts are endorsed as a potential alternative to homogeneous acid catalysts as they possess certain advantages. These include their ease of separation and reuse, lower corrosiveness and lower toxicity.294 In recent years, several research groups have studied the feasibility of solid acid catalysts for esterification/ transesterification processes, and proposed economical and environment-friendly approaches for biodiesel production.295–297

#### 7.2.1 Ion exchange resin

It is a well-known fact that several catalysts have been employed for FAME production from various feedstocks. However, due to the certain disadvantages of conventional catalysts, researchers are always in search of an ideal catalyst that should overcome all associated limitations. These specifications include the ability of the catalyst to be active at lower temperatures, exhibit high catalytic efficacy in terms of conversion of FAME, and have easy availability, low cost, easy downstream processing and reusability. Such an ideal catalyst can be considered as potential and economically viable candidates for biodiesel production.298 In this context, one of them is ion exchange resin, which meets most of the specifications of an ideal catalyst. Thus, many research groups have studied the role of ion exchange resins as solid catalysts in FAME production.299,300 Resin is the insoluble solid material that can retain and discharge ions simultaneously.301 Resins are broadly categorized into cationic and anionic resin based on their functional groups and degree of cross-linkages. It possesses specific functional groups responsible for the permutation of ions.301 Having one of the important properties, the resin-based catalyst undergoes easy recovery from liquid mixtures by simple methods and are active at low temperature.

Since the last few years, the cationic resins have gained considerable attention due to their advantages, such as functioning at soft reaction conditions, non-corrosive nature, more numbers of active sites and lower residual water production.302,303 The cationic resin catalysts possess numerous active acid sites that play a crucial role in FAME production via esterification/transesterification reactions.304,305 Various ion exchange resin catalysts utilized for FAME production, together with ideal reaction conditions, are listed in Table 16. In 2007, Shibasaki-Kitakawa et al.302 reported in a comparative study that cation exchange resins showed less efficacy than anion exchange resins towards the conversion of triacylglycerols to biodiesel. Moreover, while evaluating the conversion rates of various commercial resins, such as Diaion PA308, PA306, PA306S and Diaion HPA25, it was observed that highly porous resin-like Diaion HPA25 showed a lower conversion rate. It is believed that this might be due to resistance of the resin towards water. According to Ren et al.,303 transformation of soybean oil to FAME was reduced from 95.2% to 87.7% in the presence of D261 anion-exchange resin when the water content was enhanced from 0.0% to 1.0% by the mass of oil. Similarly, in another study, Deboni et al.304 also reported a lowering of the reaction rate due to the presence of water inside the resin.

Generally, ion exchange resins are utilized for the purification and softening of water at room temperature. Recently, Kanseso et al.305 compared the catalytic efficiencies of different ion exchange resins like Amberlyst 15, Dowex DR-2030 and DR-G8 for the transformation of FFA into FAME via esterification of the sea mango oil (hydrolyzed) at RT. The results revealed that Amberlyst 15 showed maximum efficacy with the highest FAME production compared to Dowex DR-2030 and Dowex DR-G8. However, Jaya et al.306 utilized ion exchange resin catalysts at a moderately lower temperature (50 °C to 80 °C) for biodiesel production, which is analogous to those of the homogeneous catalytic process. Furthermore, Umer and co-worker investigated the transformation of *Lagenaria vulgaris* seed oil to biodiesel, exploiting the Amberlyst 15 resin and calcium oxide (egg cell) catalyst. The authors reported 93.2% yield of biodiesel when the Amberlyst 15 ion exchange resin was used as a catalyst with the loading of 5% w/w and M/O ratio of 40% w/w for 40 min.
reaction time at 60 °C. Similarly, Kangseo and Lee investigated the esterification of hydrolyzed sea mango oil utilizing different cationic ion exchange resins, and over 80% yield of FAME was recorded using the Amberlyst 15 catalyst at a comparatively lower temperature within 1 h of reaction time and with catalyst loading of less than 5% w/w.

Recently, Deboni et al. reported 99% yield of methyl and ethyl esters from soybean oil with methanol and ethanol, respectively, using optimal reaction conditions. Conversely, Ilegen et al. recorded 63% yield of FAME from canola oil utilizing Amberlyst-26 under the optimized reaction conditions. Moreover, in another study, a yield of about 67% was observed for canola oil and methanol with almost similar reaction conditions. The conversion of tallow fat with methanol showed the yield of methyl and ethyl esters around 95% using Amberlyst-A26 OH with reaction conditions, like a tallow fat-to-methanol molar ratio of 6 : 1, and a resin loading of 2 mol L⁻¹ at 65 °C temperature for about 8.5 hours.

Hartono et al. investigated the catalytic efficacy of a heterogeneous catalyst obtained from a different source, like Lewatit macroporous resin, Amberlite gel resin and natural zeolite from Bayah, to transform WCO to biodiesel. Authors reported the 85.94% yield of biodiesel production by Lewatit macroporous anion exchanger with 6 M NaOH. Whereas, Amberlite gel with 6 M HCl displayed 65.22% biodiesel generation. Previously, Shibasaki-Kitakawa et al. reported the usefulness of the anion-exchange resin from their catalytic and adsorption abilities for the transformation of WCO to FAME. In their other study, Shibasaki-Kitakawa et al. also developed an ion-exchange resin catalyst-based continuous process for the production of biodiesel. The FFA conversion rate was estimated for different catalysts with reactions conditions, like the mole ratio of M/O (6 : 1), temperature (63.83 °C), reaction time (2 h) and catalyst load (20 wt%). The maximum FFA conversions of 79.7% were recorded for NKC-9. For 001 × 7 and D61 catalysts, it was found to be only 32.2% and 10.3%, respectively. Jalilnejad-Falizi et al. achieved the highest FFA conversions by ion exchange resins (PD206-Na⁺ and PD206-H⁺) under the optimal reaction conditions. All of the above-mentioned reports are enough to summarize that ion exchange resins can be employed as one the potential heterogeneous catalysts in biodiesel production.

### 7.2.2 Sulfated catalyst

Among the solid acid catalysts, the sulfated catalysts have attracted considerable attention for transesterification due to their super-acid property. Sulfated inorganic metal oxides are reported to be chemically stable, and have super acidity comparable to 100% sulfuric acid, remarkable acid-base and redox properties. Different kinds of sulfated catalysts, such as sulfated zirconia, tin oxide, and zirconia-alumina, have been successfully exploited in the production of biodiesel. However, among these, sulfated zirconia is the most widely studied catalyst (Table 17). Various reports are available on the transformation of oil to FAME utilizing the sulfated zirconia catalyst, but there are some studies that presented certain drawbacks of these catalysts, which include low catalytic activities, drastic reaction conditions, and reusability issues. Moreover, the lack of uniform pore size and low surface area are the other factors that restrict their wide uses in catalyzing bulky molecules of biodiesel feedstocks. In this context, several attempts have been made to modify the sulfated zirconia catalysts with an intention to increase their catalytic efficacy.

Xia et al. demonstrated the synthesis of mesoporous materials, which has the potential to improve the activity of the sulfated zirconia catalyst owing to their promising and outstanding properties, like high surface area, uniform and controllable pore size. According to Alexander et al., the modification of the sulfated zirconia catalyst enhanced the total acidity, which basically increased the catalyst active sites. In another study, Guoliang et al. proposed that a change in the phase structure of sulfated zirconia can also increase its catalytic activity. Therefore, they developed tetragonal sulfated zirconia, which showed enhanced catalytic activity in the FAME synthesis procedure. Moreover, some of the studies proposed the modification of sulfated zirconia on a MCM-41 (Mobil Composition of Matter No. 41) support for the generation of methyl tert-butyl ether to improve its catalytic performance. The results obtained revealed that the catalytic performance of the

**Table 16 Different ion exchange resin catalysts used for the production of biodiesel**
prepared supported sulfated zirconia catalyst was 2.5–3.0 times greater than neat sulfated zirconia.137,138 Similarly, Muthu et al.131 reported the preparation of FAME from neem (Azadirachta indica) oil using sulfated zirconia catalyst. It was revealed that the catalyst is highly stable to oils with high FFA concentration. The strong acid sites of this catalyst showed a considerable impact on its reactivity in the transformation of neem oil.

Recently, Lam et al.122 developed a SO42-/SnO2 catalyst by impregnation method, and exploited it for the conversion of WCO to biodiesel. Furthermore, the authors studied the bimetallic impact of the catalyst, in which SnO2 was blended in with SiO2 and Al2O3 at various weight ratios to increase the activity of SnO2. The finding confirmed that the SO42-/SnO2-SiO2 weight ratio of 3 showed exceptionally high reactivity with 92.3% biodiesel yield using optimal reaction conditions. Similarly, Pereira et al.133 demonstrated the application of the SnSO4 catalyst for the esterification of oleic acid (as model feedstock) and acid soybean oil having high contents of FFA. It was found that the model feedstock containing 70 wt% of FFA showed 92% FAME yield using excess ethanol, 5 wt% SnSO4 at 100 °C for 3 h. Moreover, it was also reported that the catalyst is stable up to ten cycles without any significant decrease in the biodiesel yield. Moreover, one of the studies involved the application of sulfated tin oxide modified with the SnO2 (SO42-/SnO2-SiO2) catalyst to produce FAME from JCO.129 The sulfated titania-based solid superacid catalysts are another kind of sulfated catalysts. Li et al.123 prepared three different titania-based solid superacid catalysts, and these were exploited for the transformation of rapeseed oil to FAME at 353 K with a 12 : 1 molar ratio of M/O under atmospheric pressure. It was found that all three prepared catalysts showed a significant yield of biodiesel due to their stronger surface acidities. Moreover, Alaba et al.124 reviewed that apart from these, there are various other sulfated metal oxides, such as titania and silica, and a combination of both also showed remarkable performance. It was also proved thorough the investigation led by several researchers, who applied sulfated silica as catalysts for esterification and transesterification.131,132 In this context, Gardy and co-workers demonstrated a facile preparation of the sulfated doped TiO2 catalyst that was utilized efficiently in the petroleum refinery. The authors reported that the synthesized catalyst has better reactivity than other sulfated metal oxides, primarily because of the acidic properties of the TiO2 particles, which was subjected to sulfonation to enhance its acidity. The catalyst displayed great efficiency in the synthesis of FAME from WCO.128,129

### 7.2.3 Mixed metal oxides

A wide range of acidic mixed metal oxide catalysts has been utilized to overcome the problem associated with high FFA content in low-cost biodiesel feedstock employed in FAME production (Table 18). Suzuta et al.138 reported the utilization of the Fe2O3-SiO2 catalyst in the conversion of JCO to FAME. The catalyzed reaction displayed 95.6% FAME yield under the optimized reaction conditions. When the Fe loading was raised from 0.07 to 2.1 wt%, the acidity of the catalyst drastically increased. The Fe-oxygen species scattered over the SiO2 surface were recognized as the active sites. In the meantime, the ZnAl2O4/ZnFe2O4 catalyst was also examined for the transformation of oil, such as sunflower oil, WCO and JCO.139 During the reaction, the Zn 3d electrons of the ZnAl2O4 and ZnFe2O4 spinels were likely to take part in the electronic excitation; thereby, the Zn 3d electrons are probably going to undertake a vital job to enhance the catalyst reactivity. In 2012, Xie et al.132 synthesized the SnO2-SiO2 catalyst by loading 8 wt% Sn onto SiO2 followed by calcination (550 °C) and exploited it in the transformation of soybean to FAME, yielding 81.7% under the optimal reaction conditions.

Impregnation followed by calcination (600 °C) was used to synthesize the Fe-Mn–MoO3/ZrO2 catalyst, which could provide a high 95.6 ± 0.15% yield of FAME.132 It is interesting to observe that ZrO2 and MoO3/ZrO2 gave a lower FAME yield of 48.6 ± 1.14 and 73.0 ± 0.25%, respectively. The high activity of the Fe–Mn–MoO3/ZrO2 catalyst is attributed to the high surface area (49.5 m2 g-1) and availability of huge active sites (2411 μmol g-1) in the catalyst. Moreover, the catalyst reusability examination revealed that it is stable up to 6 progressive reaction cycles of transesterification of WCO without a loss in its efficiency. On the other hand, the enhanced catalytic activity was observed in a mixed metal oxide of WO3/SnO2 in the soybean oil transformation in comparison with the individual WO3 and SnO2 species.134 The bonding of WO3 with SnO2 was believed to upgrade the WO3/SnO2 acidity. The catalyst is highly stable and was reused up to 4 times without much depreciation in the biodiesel yield.

Further, Xie et al.135 studied 30 wt% WO3 loading on the AlPO4 catalyst and recorded a good 72.5% conversion to biodiesel under the optimized reaction condition. The high catalyst reactivity was attributed to the existence of WO3 that enhanced the surface acid sites. Similarly, Amani et al.136 reported a series of Mn1.5Zr0.5Al1.5O3 catalysts for the transformation of WCO to FAME. The Mn1.4Zr0.35Al1.64O4 catalyst demonstrates better catalyst reactivity, as far as the FAME yield (>93%), than the Mn1.4Zr0.35O2 catalyst (52.8%). The bonding between metals in the crystal structure efficiently influenced the catalyst reactivity. It was observed that the amphoteronic component of the Al developed the surface region of the catalyst and framed a complex structure with other metal oxides, although Mn alternated the morphology and catalyst basic site density. In the meantime, Zhang et al.137 reported the Zr–Mo mixed metal oxide functionalized with various carboxylic acids, for example, lauric

This article is licensed under a Creative Commons Attribution-NonCommercial 3.0 Unported Licence.
acid, stearic acid, palmitic acid and myristic acid for the biodiesel production from oleic acid. The modification of the Zr–Mo metal oxide using such monofunctional carboxylic acids enhances the catalyst acidity and surface area, and thus upgraded the rate of the reaction. They also reported that among all catalysts, the stearic acid-functionalized Zr–Mo metal oxide showed the best result with the maximum oleic acid conversion of 94.2%. The catalyst reusability test revealed that the catalyst is stable for up to 6 progressive cycles. Similarly, WCO was utilized for the FAME production using ferrimanganese doped tungstate molybdena nanoparticles (FMWMo).\(^{338}\) The Fe–Mn dopants enhance the surface area, density of acidic sites, and the stability towards the esterification of WCO. A maximum yield of 92.3 ± 1.12% methyl ester was achieved under the optimized reaction conditions.

### 7.2.4 Sulfonated carbon-based catalyst

In the last few decades, various carbon materials with different shapes, sizes, and structures have been developed by several research groups and utilized as low-cost catalysts for diverse industrial processes, including transesterification.\(^{339}\) Currently, sulfonated carbons, i.e., SO\(_4\)H-functionalized acidic carbon materials, are considered as a new group of the metal-free solid acid catalyst described by their original carbon structure and Bronsted acidity equivalent to concentrated H\(_2\)SO\(_4\). Sulfonated carbon acid catalysts can be easily prepared by processes, like the incomplete carbonization of aromatic compounds in concentrated H\(_2\)SO\(_4\) (ref. 340) or sulfonation of incompletely carbonized natural organic matter, such as sugar\(^{341,343}\) and cellulosic materials.\(^{344,345}\) Sulfonation can also be achieved by treating the carbon material with a sulfonating reagent, such as gaseous SO\(_3\), ClSO\(_3\)H, P-toluensulfonic acid, 4-benzenediazonium sulfate or SO\(_4\)H-containing aryl diazoniums.\(^{346–349}\)

These materials possess promising features, such as biogenic, environment-friendly, lower production costs, distinctive surface chemistry, high chemical and thermal stability.

The acid-catalyzed chemical reactions, such as saccharification, esterification, transesterification and acetylation, are vital operations commonly used for the valorization of biomass or their components to useful products in various food, fuel and chemical industries.\(^{350}\) The functionalized acidic carbons from inexpensive sources, including natural organic carbon matter (such as sugars, carbohydrates, cellulosic materials, and lignin), have been achieved by several researchers.\(^{344,351–355}\) Besides this, agro waste such as husk, straw, seed cover, cow manure, corn cob,\(^{342,343,354,355}\) carbonaceous waste from industries (char, oil pitch, coke, glycerol)\(^{346,348,356,357}\) and polymer resins\(^{349,358,359}\) were also used. Various carbon supports (e.g., zeolite-templated carbons, mesoporous carbons, active carbon)\(^{352,353,360,361}\) and more recently nanostructured carbons (such as graphene, graphene oxide, carbon nanotubes, and carbon dots)\(^{362–367}\) have been exploited for the same purpose.

Over the last few years, there is growing interest from researchers towards the application of sulfonated carbon-based catalysts due to their noteworthy efficacies mentioned earlier. Many reports are available, which demonstrated the efficient nature of the sulfonic acid-functionalized catalyst in biodiesel production using various feedstocks.\(^{350,362,367}\) One of the reports presented the synthesis of organosulfonic acid (i.e., propylsulfonic and arenesulfonic groups) functionalized mesoporous silicas through a simple one-step process. The synthesized novel catalysts that possessed propylsulfonic groups and arenesulfonic groups were further evaluated for their catalytic efficacy in the esterification of fatty acids with methanol to produce methyl esters, and the authors also compared the efficacy of these heterogeneous catalysts with a variety of commercially available catalysts (such as sulfuric acid, p-toluene sulfonic acid, Nafton NR50, and Amberlyst-15). The obtained results indicated that the organosulfonic acid-functionalized mesoporous silica catalysts showed the highest reactivity compared to all of the above-mentioned commercial solid acid catalysts in the fatty acid esterification process. Moreover, it was also recorded that the efficiency of these catalysts largely depended on important factors, such as the median pore diameter of the catalyst and the acidic strength of the organosulfonic acid group present over this catalyst. Considering these findings, it can be proposed that there is a huge potential to develop catalysts using organic–inorganic mesoporous materials.\(^{363}\)

| No. | Catalyst | Feedstocks | Conditions* | Yield (%) | Ref. |
|-----|----------|------------|-------------|-----------|-----|

FAME production are listed in Table 19. Numerous reported catalysts demonstrated promising outcomes in the (trans) esterification of biodiesel feedstocks with high FFA and afforded >85% FAME yield. In the meantime, several investigations had been conducted using model acids (e.g., palmitic acid, oleic acid, which are the major components of vegetable oil as a reactant) that mainly focused on the esterification reaction. In a pioneering work towards the preparation of the biomass-based sulfonated carbon catalyst, Toda et al. synthesized the sulfonated carbon catalyst by partial carbonization of sugar, followed by sulfonation in fuming H$_2$SO$_4$. The prepared catalyst consists of sheets of indistinctive carbon having a high amount of sulfonic groups, along with hydroxyl and carboxyl as a minor group (Fig. 28). The highly active biomass-based carbon catalyst was utilized for the transformation of oleic and stearic acid to FAME via esterification. Apart from the –SO$_3$H group, the presence of the –OH and –COOH groups in the catalyst greatly enhance the catalytic activity and make it highly water tolerant. The successful incorporation of the –SO$_3$H group and the formation of carbonized materials can be easily confirmed by using FT-IR and $^{13}$C MAS NMR analysis, respectively, as depicted in Fig. 33. The FT-IR spectra (Fig. 29a) displayed two bands at 1040 and 1377 cm$^{-1}$ (in SO$_3$H), ascribed to the SO$_3$ and O–S–O stretching vibrations, respectively, suggesting the existence of the –SO$_3$H groups. $^{13}$C MAS NMR (Fig. 29b) depicted three major peaks at 130, 155, and 180 ppm, ascribed to the polycyclic aromatic carbon atoms, phenolic OH, and COOH groups, respectively.

In another work, Hara et al. examined the sulfonated carbon catalyst in biodiesel synthesis. The findings showed that the amorphous carbon material-containing sulfonic acid groups enhances the catalytic performance, and thus displayed

extraordinary reactivity in the esterification/transesterification reactions in comparison with the ordinary solid acid catalyst.

Likewise, Nakajima et al. synthesized an amorphous cellulose-originated carbon solid acid (CCSA) catalyst and exploited it in the transformation of oleic acid to FAME, and observed a 99.9% yield under the optimized conditions. The carbon material displayed much higher catalytic activity in the esterification reaction in comparison with the ordinary solid acid catalysts examined, such as niobic acid, Amberlyst-15 and Nafion NR50. Interestingly, those CCSA catalysts prepared at a lower carbonization temperature before being subjected to sulfonation gave a much better biodiesel yield, as compared to those prepared at higher carbonization temperature. This is attributed to the huge amount of –OH and –COOH groups in the former, which enhanced its acidic nature, and thereby its catalytic activities (Fig. 30). The catalyst reactivity remains intact after 10 progressive cycles.

The simultaneous carbonization and sulfonation in a one-pot synthesis of solid acid catalyst directly from biomass have also been explored by various experts, as it is a straightforward, cost and time-efficient approach. Malins et al. synthesized C–SO3H via the simultaneous carbonization-sulfonation approach, and utilized it for FAME production. The C–SO3H catalysts with the highest density of SO3H groups (0.81 mmol H/5 per g) were prepared using optimal reaction conditions. It was noted that under these optimized reaction conditions, 96.5% of FAME was recorded. Interestingly, the catalyst has great stability, and can be easily recovered and reused for subsequent reaction cycles. Moreover, in the comparative study of the esterification reactions of rapeseed oil fatty acids, the prepared catalyst exhibited similar reactivity to Amberlyst-15.

Another recent report proposed a synthesis of the heterogeneous sulfonated catalyst using activated carbon to overcome several problems, like drastic reaction conditions (such as very high temperature, pressure, longer reaction time and expensive overall process cost). The above-mentioned activated carbon catalyst was prepared from corncobs as a precursor, and utilized in the microwave-assisted conversion of soybean oil with ethanol to FAME. In this study, about 88.7% yield of pure biodiesel was reported at 0–600 W of microwave power. Moreover, the catalyst was reused for up to 5 cycles. Fig. 31 represents the schematic illustration of the application of the activated carbon-based catalyst in the transesterification of various oils using methanol.

In 2009, Yuan et al. examined the application of a solid acid catalyst originated from sulfonated activated carbon (H2SO4/C) for catalyzing the transesterification of castor oil and methanol as feedstock. Melero et al. synthesized the sulfonic acid-modified mesostructured (SAM) catalysts and studied their efficacy in the transformation of crude vegetable oils to FAME. The results obtained noted that this catalyst has the ability to yield 95 wt% pure FAME and oil transformation close to 100%. Despite the presence of FFAs, this catalyst displayed significantly high activity toward the simultaneous esterification and transesterification reactions. Similarly, Zuo et al. developed various sulfonic acid-functionalized mesoporous SBA-15
catalysts, and tested their catalytic activity in the microwave-assisted conversion of soybean oil and 1-butanol to biodiesel. The authors observed that the catalytic efficacy of these catalysts mainly depends on the acid strength and not on the number of acid sites. Furthermore, propyl-SO$_3$H and arene-SO$_3$H functionalized SBA-15 catalysts were found to have comparatively better reactivity in the transesterification process. However, the perfluoro-SO$_3$H functionalized SBA-15 catalyst displayed leaching of the active sites in each progressive cycle, and thus, the reactivity decreased. Shah et al.$^{372}$ demonstrated esterification of FFAs in acid oil (which is a byproduct of oil refining) using a sulfonic acid-functionalized silica (SiO$_2$-Pr-SO$_3$H) catalyst to prepare the biodiesel. Furthermore, the authors optimized various reaction conditions, such as temperature, reaction time, catalyst concentration, and M/O molar ratio, which usually affect the conversion to FAME. A high conversion (i.e., 96.78% conversion after 8 h was reported at optimized conditions) can be achieved using these solid acid catalysts.

Moreover, in the recent past, Varyambath et al.$^{373}$ developed different sulfonic acid-functionalized organic knitted porous polyaromatic microspheres (OPPSO$_3$H) utilizing pyrene, anthracene, and naphthalene as monomers via Friedel–Crafts alkylation, followed by crosslinking reactions. Furthermore, these heterogeneous catalysts were utilized for the transformation of long-chain fatty acids and triglycerides to biodiesel. These solid acid catalysts were found to be very promising for biodiesel synthesis, as they showed excellent surface acidity. In addition, several other sulphonic acid-functionalized catalysts were successfully developed and exploited in the production of biodiesel. In this context, Shahgufa et al.$^{374}$ reviewed all such sulphonic acid-functionalized catalysts in esterification and transesterification reactions. This review can be consulted for more detailed information.

Yu et al.$^{375}$ studied biodiesel production by exploiting coal-based acid catalysts, and reported an oleic acid conversion of 97.6% under the optimal reaction conditions. Similarly, Tang and Niuf$^{376}$ investigated the synthesis of carbon-based solid acid catalysts from bamboo through the partial carbonization and sulfonation approach. The microstructure of the catalyst was activated by phosphoric acid impregnation. The catalyst

**Fig. 30** Schematic structures of the SO$_3$H-bearing CCSA materials carbonized at below 723 K (A) and above 823 K (B). Reproduced from ref. 365.

**Fig. 31** Schematic representation of transesterification of various oils using activated carbon-based catalysts.
afforded a biodiesel yield of 97.3% at optimum conditions, which decreased to 83.7% in the fourth reaction cycles. In addition, biodiesel production from oleic acid was reported using sulfonated activated carbon from bamboo. A sulfonated carbonaceous material synthesized via the single-step hydrothermal sulfonation of glucose has also been used as a catalyst for the esterification of waste cooking oil to produce biodiesel. FESEM images of the carbonaceous material (C) (Fig. 32a) and the sulfonated carbonaceous material (C-SO3H) (Fig. 32b) showed the carbonaceous microsphere and the sulfonated carbonaceous microsphere with an attached sulfonic group on the surface, respectively. The catalyst showed great stability with 93.4% FAME yield under the optimized reaction conditions.

Guan et al. synthesized the sulfonated multi-walled carbon nanotube (S-MWCNT) for the conversion of triglyceride to FAME in 97.8%. The high catalytic reactivity is because of the high surface area (198.9 m² g⁻¹), high porosity (10–15 nm) and high acid sites. Similarly, the sulfonated carbonaceous material from starch was utilized as a solid catalyst for the esterification of PFAD. A novel, efficient, inexpensive and environmentally friendly acid catalyst was synthesized from coconut meal residue (CMR). The CMR-D8-SO3H catalyst was prepared by a one-step direct in situ carbonization in concentrated H2SO4, and reported for the transformation of the waste palm oil (WPO) to biodiesel. The prepared sulfonated catalyst has an acid density of 3.8 mmol g⁻¹, surface area of 1.33 m² g⁻¹ and means pore volume of 0.31 cm³ g⁻¹. The results obtained recorded a high yield of 92.7% biodiesel from WPO. Moreover, Wang et al. investigated the application of the monodispersed hollow carbon/silica solid acid catalyst HS/C-SO3H, which was prepared by chemical activation approach, in the esterification of oleic acid with methanol to produce the biodiesel.

Besides this, another kind of sulfonated functionalized carbon material, i.e., sulfonated ordered mesoporous carbon (SOMC) catalyst, showed promising biodiesel production (73.59% yield). Recently, the sulfonated acid catalyst obtained from corn cob (SO₄²⁻/corn cob) has been reported as an excellent catalyst for the conversion of oleic acid to obtain methyl oleate in good yield (>80% after 8 h at 60 °C). Mahdavi and Darab prepared a sulfonated carbon catalyst by treatment of sucrose and concentrated H₂SO₄ at high temperature (sulfonation and carbonization approach). The synthesized C-SO₃H catalyst was further utilized for the conversion of oleic acid to FAME in 93.04% yield. Moreover, a solid acid catalyst generated from the sulfonation of microcrystalline cellulose powder was successfully applied for oleic acid esterification, showed 99.9% biodiesel yield under the optimized reaction conditions.

In another investigation, waste cooking oil was transformed to produce biodiesel, utilizing an environmentally benign sulfonated carbon microsphere catalyst. The catalyst with surface area 86 m² g⁻¹ and acidity 1.38 mmol g⁻¹ was developed by consecutive hydrothermal carbonization and sulfonation of xylose. Using this catalyst, a biodiesel yield of 89.6% was recorded at optimal reaction conditions. The catalyst reusability report revealed that in each cycle, the biodiesel yield was reduced by 9%. Furthermore, the sulfonated carbon-based solid acid catalyst was also utilized for the transformation of PFAD and Mesua ferrea Linn oil to biodiesel.

To bring down the cost of biodiesel production, several sulfonated raw biomasses have been prepared and investigated for their catalytic activities. In this line, a sulfonated solid-acid catalyst obtained from coconut shells (SO₄²⁻/coconut shell) reported 88.03% biodiesel yield. In the same vein, oil palm trunk/sugarcane bagasse, corn straw, bamboo, Jatropha curcas seed, bio-glycerol, glycerol, microalgae residue, oil cake waste, de-oiled waste cake, de-oiled canola meal, pine chip char and biochar are reported as a catalysts for FAME production.

### 7.3 Enzyme catalyst

In recent years, enzyme catalysts have been widely examined for the production of biodiesel, as they produce high-quality biodiesel, improve the product separation process, mild reaction conditions and most importantly, their ecological benignness. Besides, they do not form soap with FFA, contrary to the alkaline catalyst. Hence, they can be utilized in biodiesel production on the industrial scale.

In biocatalyst-mediated reactions, enzymes can usually be used in the free form or they can be immobilized on a matrix, i.e., immobilized lipase. The free enzymes are more sensitive.
towards the pH, temperature and impurities of the reactants, which may create an obstacle in the bioprocesses. However, these problems can be overcome by immobilizing the enzyme onto different types of support materials. The commonly adopted immobilization methods for biological processes include entrapment, adsorption and covalent bonding. Among these techniques, the entrapment method was found to be effective, offering greater advantages, such as ease of process scale-up, higher stability of the enzyme, and longer enzymatic activity retention. Mostly, the lipase enzymes obtained from microbial sources that have been used for biodiesel production proposed the entrapment method for the large scale production of bacterial or fungal lipases due to their extracellular nature. Moreover, lipases obtained from diverse plant sources are also considered as the potential substitute for catalysing the transesterification process. The advantages associated with the lipase catalyst over the other catalysts used in biodiesel production are its superior quality and higher yield of biodiesel, freedom from soap formation, lower reaction temperature and ability to work on a variety of feedstock.

Compared to homogeneous and heterogeneous catalysts, enzymatic catalysts are less studied; hence, there is scant literature that is available when compared with reports on the above-mentioned two catalysts. However, the high cost of the free lipase catalyst along with the limited long-term use has led to the exploitation of the immobilized lipase catalyst to reduce the cost of the catalyst and its reusability. Apart from that, the immobilized lipase catalyst showed greater tolerance to pH variation, high thermal stability and high substrate selectivity. To date, a large number of studies in the literature are available in the field of biodiesel production using both free and immobilized enzyme catalysts.

Recently, Jayaraman et al. demonstrated the lipase enzyme-mediated transesterification of waste cooking oil (WCO), and reported 88% of biodiesel yield. Marin-Suárez et al. demonstrated the lipase-catalyzed transesterification of low quality fish oil through the process optimization. Moreover, the reusability of the enzyme was also studied. Authors evaluated the efficacy of the commercially available immobilized enzymes, such as Liposome RM IM, Lipozyme TL IM and Novozym 435 (ref. 425) for biodiesel production from waste fish oil. The results obtained revealed that Novozym 435 showed the maximum catalytic activity, resulting in the highest yield of FAME, i.e., 82.91 wt% and the enzyme can be reused for about ten successive cycles. In another study, it was reported that the immobilized lipase (Epobond P. cepacia) employed in the transesterification of waste vegetable oil was reported to achieve an ester yield of 46.32%. Similarly, the Candida cylindracea lipase immobilised on the functionalised activated carbon was tested as a catalyst in the transesterification of Jatropha curcas oil. It was found that a free fatty acid yield of 78% was achieved at the optimized reaction conditions. Furthermore, the biocatalyst was found to be stable for up to four consecutive cycles of transesterification. Besides, the lipase obtained from the plant source (like the rice bran lipase) produced 83.4 wt% FAME yield from rice bran oil under optimized conditions.

Moreover, Muanruksa and Kaewkannetra examined the biodiesel production from sludge palm oil (SPO) via two steps of extraction and enzymatic esterification. The immobilised Rhizopus oryzae lipases on alginate-polyvinyl alcohol (PVA) beads were used for the conversion of FFAs from SPO to fatty acid methyl esters (biodiesel). It was found that at the optimum condition, the maximum biodiesel yield of 91.30% was achieved and the biocatalyst showed higher stability and catalytic efficiency for up to 15 cycles. It is reported that the enzymatic transesterification reaction for producing biodiesel is the slowest pathway among all of the known transformations. Taking this into account, the application of ultrasonication in the enzyme-catalysed transesterification improves the reaction rate and hence, reduces the reaction time. Thus, it can be a promising technique for the industrial-scale production of biodiesel in a very short time.

Table 20 Different enzyme catalyst yields reported for the production of biodiesel

| S. no. | Catalyst | Feedstock | Conditions* | Yield | Ref. |
|-------|----------|-----------|-------------|-------|-----|
| 1     | Lipase immobilized on biosupport beads | Hybrid non edible oils | 6 : 1’, 10, 50, 1440 | ~78 | 407 |

7.4 Bifunctional solid catalysts

Despite the high reactivity of the basic solid catalyst towards biodiesel production, they are not an effective catalyst for the transesterification of oils having a high amount of FFA, as such catalysts are highly sensitive to the FFA, which leads to soap generation and thus interferes in the separation process of glycerol from biodiesel. On the other hand, solid acid catalysts are insensitive to the FFA content and esterify waste oils or low-cost oils without any requirement of pretreatment. However, water formed during the course of the reaction may lead to the decomposition of triglycerides to diglycerides, resulting in the formation of more FFA and catalyst leaching.\(^{415}\) Taking these difficulties into account, developing a new type of solid catalyst that possesses dual characteristics, such as solid acidic character, to tackle the FFA and solid basic character for easy transesterification of triglycerides to FAME has been a recent interest in the realm of biodiesel research. To date, numerous bifunctional catalysts are reported for the FAME production (Table 21), which will be discussed in this section. Farooq et al.\(^{78}\) developed a bifunctional Mo–Mn/\(\gamma\)-Al\(_2\)O\(_3\)–MgO catalyst and utilized it for the simultaneous esterification/transesterification of WCO, having FFA content of 3.27 mg KOH per g. The authors investigated the effect of MgO loading (5–20 wt%) on its catalytic activity, and found that 15 wt% MgO loading showed the highest catalytic activity with 91.4% biodiesel yield under the ideal reaction conditions. Moreover, the catalyst showed excellent stability towards the biodiesel production from WCO, as it is stable for up to 8 progressive reaction cycles without any major loss of its activity. In another study, the Cu/Zn/\(\gamma\)-Al\(_2\)O\(_3\) catalyst was utilized for the simultaneous esterification/transesterification of WCO for the production of FAME via RSM.\(^{416}\) The effect of the Cu/Zn wt% ratio and calcination temperature on the catalytic reactivity was also examined, and it was found that the 10 : 90 Cu/Zn wt% ratio and 800 °C calcination temperature showed 88.82% FAME yield. The authors also studied the structure and particle size of the synthesized catalyst via TEM micrographs (Fig. 33). Fig. 33a showed that the average diameter of the particles lies in between 4–6 nm. The lattice fringes measured from Fig. 33b, c and d are 0.201, 0.282 and 0.242 nm, and matched with the \(hkl\) planes (400), (220) and (311) of alumina, respectively. The lattice fringe in Fig. 33e is 0.240 nm fitted with the \(hkl\) plane (200) of CuO, and the lattice fringe 0.281 nm (Fig. 33f) fitted with the ZnO plane (100). Similarly, the biodiesel production from WCO was reported using diverse bifunctional solid catalysts, such as Mg/MCM-41,\(^{417}\) \(\gamma\)-Al\(_2\)O\(_3\)–CeO\(_2\),\(^{418}\) KAcZX\(^{414}\) and Sr/ZrO\(_2\).\(^{419}\)

Nizah et al.\(^{420}\) synthesized a bifunctional catalyst Bi\(_2\)O\(_3\)–La\(_2\)O\(_3\) via wet impregnation procedure, and employed it for the one-pot esterification/transesterification of JCO, having a FFA content of 6.1 mg KOH per g. The authors investigated the influence of Bi\(_2\)O\(_3\) impregnation on La\(_2\)O\(_3\) support by varying the wt% of Bi\(_2\)O\(_3\) in the range of 1–7 wt%, and found that 5 wt% Bi\(_2\)O\(_3\) impregnated on La\(_2\)O\(_3\) showed the maximum biodiesel yield of 94%. The high catalyst reactivity is attributed to the good dispersion of Bi\(_2\)O\(_3\) on the La\(_2\)O\(_3\) support, which directly enhanced the surface area, and thus increases the selectivity and rate of the reaction. Similarly, the biodiesel production from JCO having a high amount of FFA was reported by using a bifunctional solid catalyst CaO–La\(_2\)O\(_3\).\(^{421}\) The esterification/transesterification was performed in a high-temperature reactor (Fig. 34). The effect of the Ca/La atomic ratio on the catalytic activity was examined, and it was observed that a Ca/La atomic ratio of 0.8 showed the maximum biodiesel yield of 98.76% under the optimized reaction conditions. The high catalytic reactivity is because of the good dispersion of CaO on the surface of La\(_2\)O\(_3\), which led to an increase in the catalytic surface area. Moreover, the synthesized catalyst is chemically stable and can be used for 4 consecutive cycles.

Another study revealed the synthesis of the mixed metal oxide Mn@MgO–ZrO\(_2\) via co-precipitation and impregnation method, and the utilization of the catalyst in the FAME production from kernel oil.\(^{422}\) The efficiency of the catalyst in the FAME production was tested by changing the Mg/Zr ratio from 0.2 to 0.5, and it was found that 0.4 Mg/Zr has the optimal active sites, followed by impregnation of 4 wt% Mn to the MgO–ZrO\(_2\) composite to enhance its reactivity and displayed 96.4% biodiesel yield. The high catalyst reactivity is due to a large number of active sites and

Table 21 Different bifunctional solid catalyst yields reported for biodiesel production

| No | Catalyst | Feedstocks | Conditions\(^a\) | Yield (%) | Ref. |
|----|----------|------------|-----------------|-----------|-----|
| 1  | Mo–Mn/\(\gamma\)-Al\(_2\)O\(_3\)–15% MgO | WCO | 27 : 1, 3, 100, 240 | 91.4 | 78 |

\(^a\) Methanol-to-oil molar ratio, catalyst loading (wt%), temperature (°C), reaction time (min). \(^b\) Conversion.
the mesoporous nature of the catalyst. Jeon et al. synthesized heteropolyacid (HPA) functionalized ZIF-8 (zeolite imidazole framework-8) to form a bifunctional catalyst for the production of biodiesel from rapeseed oil in a batch reactor. The catalyst possesses a core–shell nanostructure as displayed by the TEM micrograph (Fig. 35), where the rhombic dodecahedral ZIF-8 core was surrounded by thin-wrinkled HPA shell, and thus enhances the surface area and catalyst reactivity. Moreover, the effect of the concentration of HPA for the functionalization was also tested by varying the amount of HPA, such as 0.05, 0.1, 0.3 and 0.5. It was found that 0.1 g HPA functionalized ZIF-8 showed a maximum FAME conversion of 98.02% under the optimized reaction conditions. Similarly, another bifunctional catalyst organo-triphosphonic acid-functionalized ferric alginate (ATMP-FA) was developed for the oleic acid esterification to produce biodiesel. The reaction conditions were optimized by using the Box–Behnken model of RSM. Moreover, the catalyst is very stable towards the esterification reaction, and can be reused for 5 consecutive cycles.
Recently, a solid bifunctional catalyst originating from the bio-waste angel wing shell (AWS) via two-step processes: (i) calcination of angel wing shell, and (ii) sulfonation of the calcined angel wing shell to produce sulfonated angel wing shell (AWS/SO$_4^{2-}$/C0$_{1}$), was reported for the esterification of PFAD to produce biodiesel. The sulfonation procedure increases the surface area of bare AWS from 3.88 to 6.53 m$^2$/g, and thus enhanced the catalytic reactivity. The authors tested the influence of the sulfuric acid concentration by varying the sulfuric acid amount from 3 to 11 M, and found that the sulfonation with 7 M sulfuric acid showed 98% FAME yield. The authors also checked the reusability of the catalyst, and observed a blockage of the active sites of the catalyst after the 2$^{nd}$ consecutive cycles, which necessitated pretreatment of the spent catalyst to increase its reusability. In addition, a coordinated polymer of Zn, [Zn(4,4'-bipy)(OAc)$_2$], was tested for the soybean oil transformation to FAME. The catalyst showed excellent reactivity and showed 98% FAME yield under the optimized reaction conditions. The authors reported that the high reactivity of the catalyst is attributed to the bipyridine present in the catalyst. In another study, the conversion of canola oil to FAME was reported using potassium-impregnated titania (K/TiO$_2$). The addition of K on the surface of titania increases the surface energy from 86 to 102 m$^2$/g, and thus enhanced the catalytic activity. The authors investigated the effect of K loading on the catalytic activity, and found that 20 wt% K-loaded titania was optimal and showed 100% conversion of canola oil to biodiesel.

8. Biodiesel production process

Biodiesel can be produced by (trans)esterification, thermal cracking and pyrolysis. Among all these methods, transesterification is generally utilized for the synthesis of biodiesel. The generalized diagram for the biodiesel production process is presented in Fig. 36, which consists of the synthesis and purification steps. Alkali, acid and enzyme are routinely exploited as a catalyst for the transesterification reactions. These catalysts had their own merits and demerits, as compiled in Table 22. Until now, the homogeneous base catalysts (such as NaOH, KOH) are normally utilized for biodiesel synthesis in the industrial scale. In the meantime, owing to their capacity to catalyze both esterification/transesterification reactions, a homogeneous acid catalyst (such as H$_2$SO$_4$ and HCl) are generally picked for feedstock having high FFA, such as non-edible vegetable oil, WCO and animal fats. Recently, the heterogeneous catalyst has attracted interest to a great extent.
for biodiesel synthesis because of their easy recyclability and reusability for successive reaction cycles.

9. Catalyst comparison

It can be seen from the literature that the reactivity of both homogeneous base and acid catalysts are very high compared to heterogeneous catalysts.\textsuperscript{44,70} Despite the high reactivity, homogeneous catalysts have some serious shortfalls. These include the low quality of glycerol produced, the inability to regenerate the catalyst, and the lengthy process involved in the purification of biodiesel. Thus, the whole process becomes labour-intensive and uneconomical.\textsuperscript{76} To overcome these shortfalls, solid catalysts have been widely investigated. Alkaline earth, basic metal oxides and supported solid base catalysts show excellent activity towards biodiesel production. However,
their low stability and high sensitivity against the FFA limit its industrial application.\textsuperscript{445} In contrast, their acid counterparts are not efficient towards the transesterification reactions. Recently, mixed metal oxides are gaining immense attention in the field of biodiesel production due to their generally high surface area, excellent thermal and chemical stability, and tailored acid–base properties. Hence, they can be predominantly used for the (trans)esterification of vegetable oil having high FFA.\textsuperscript{445}

Prior studies from literature revealed that the enzyme-based catalysts have various advantages over other catalysts, such as being environmentally benign, operating at mild reaction conditions and displaying high specificity.\textsuperscript{422} Unfortunately, due to their sensitivity towards heat, poor operational stability and narrow pH range, the use of such catalysts for the industrial scale production of biodiesel is not a wise choice.\textsuperscript{433} However, the immobilized lipase has various advantages compared to free lipase, such as cost-effectiveness, high thermal stability and greater tolerance to pH changes.\textsuperscript{435} Thus, it has a scope for utilization in biodiesel production on the industrial scale. Besides, the present study suggests that the bio-waste derived catalyst can potentially be used in the industrial scale production of biodiesel as they are easily available, cost-effective and most importantly, environmentally benign.\textsuperscript{164} The main limitation is their reusability due to the leaching of the active sites.\textsuperscript{165} Apart from that, the metal-free carbon based solid acid catalyst is also a promising candidate for the industrial scale production of biodiesel as these materials possess promising features, such as being biogenic and environment-friendly, and having lower production costs, distinctive surface chemistry, high chemical and thermal stability.\textsuperscript{184} The bifunctional catalyst has been of recent interest in the realm of biodiesel research, as it possesses dual characteristics such as solid acidic character to tackle the FFA and solid basic character for the easy transesterification of triglycerides to FAME. Hence, it can be utilized for the (trans)esterification of diverse oil systems. Apart from that, the bifunctional catalysts are highly reusable, thermostable and insensitive to the moisture.\textsuperscript{418} Thus, the bifunctional solid catalyst can be utilized in the successful production of industrial scale biodiesel.

10. Conclusion and outlook

The exponential growth in the human population around the globe and industrial globalization tremendously increases the demand for petroleum fuels like diesel for various purposes. However, considering the limited resources of fossil fuels, searching for a novel, renewable and sustainable alternative fuel was required. In this context, researchers focused on the FAME production from different renewable sources as an effective way. A variety of methods have been proposed for biodiesel production. However, among all the existing methods, transesterification is considered as the foremost choice.

The transesterification reaction involves the use of a basic catalyst, such as homogeneous and heterogeneous catalysts. The use of homogeneous catalysts is found to be promising as far as the rate of biodiesel production is concerned. However, it is associated with certain limitations. The homogeneous catalyst-based transesterification reaction involves the consumption of high energy. Moreover, the treatment of wastewater generated is essential due to the presence of unreacted chemicals. These limitations created the need for the development of efficient catalysts, which was completed in terms of the heterogeneous catalysts. These catalysts attracted a great deal of attention from the scientific community all over the world because of its several advantages over homogeneous catalysts, such as the simple realization of continuous reactors, production of cleaner glycerol, and the absence of both the alkaline catalyst neutralization step and the necessity to replace the consumed catalyst. Due to these advantages, heterogeneous catalysts have opened up the chance for another powerful pathway for FAME production. However, the reactivity of the solid catalyst is dependent on several variables, which mainly involve the oil type, alcohol to oil molar ratio, temperature, and type of reactor. Therefore, the selection of these variables at an optimum level is a crucial step. The heterogeneous catalysts are considered comparatively promising because only the external-surface active species of the porous solid support is involved in the reaction, and these catalysts can be recovered in some cases. However, in the case of certain catalysts like CaO, leaching was reported, which adversely influences the reaction. Hence, researchers are looking at nanotechnology as a new hope.

Nanotechnology is the most emerging branch of science, having promising applications in catalysis. Moreover, it is reported to have the ability to fabricate the catalyst surface in order to meet the prerequisites of explicit applications, and beat the different issues related to both homogeneous and heterogeneous catalysts. Nanocatalysts can act as an interface between the homogeneous and heterogeneous catalysts having the possibility to develop promising solid-acid or solid-base catalysts, which can be easily recovered using conventional filtration and centrifugation techniques. The development and use of magnetic nanoparticle-supported catalysts is a path-breaking research because such catalysts can be easily recovered by using a simple magnetic field and reused for progressive reaction cycles, which helps to reduce the overall process cost involved in biodiesel production, which is the ultimate aim.

It is well proven that the application of a biological catalyst (enzyme) is more effective over all kinds of chemical catalysts, but the involvement of an expensive enzyme increases the overall cost of the FAME production process. In this context, immobilization of such enzymes on the surface of various magnetic nanoparticles was found to be a novel concept because of the easy recovery of the immobilized enzyme, along with magnetic nanoparticles and its reusability. Moreover, it also solves the problem of leaching the enzymes during the reaction due to immobilization. Although nanocatalysts were reported to have promising applications, the toxicological concerns associated with nanoparticles are a topic of debate because there are mixed opinions from the scientific community.

The present study revealed that the properties of the catalyst (such as basicity and acidity) play a pivotal role in the biodiesel production. Several literature studies suggest that the basicity of the catalyst is directly proportional to the transesterification
activity.\textsuperscript{171,\textsuperscript{195}} Similarly, the acidity of the catalyst decides the esterification activity of the catalyst.\textsuperscript{185,\textsuperscript{200}} The esterification activity increases with increasing acidity of the catalyst. Apart from the basicity and acidity, the catalytic activity of the solid catalyst depends on its surface area and porosity. Literature studies revealed that the high surface area of the catalyst enhances the rate of biodiesel production.\textsuperscript{184,\textsuperscript{225}}

It is believed that several newly introduced catalysts will take a central position in the near future, and help produce biodiesel through eco-friendly and economically viable processes. The development of a novel heterogeneous catalyst having both acid and basic sites on its surface will have a promising future in biodiesel production technologies because it will have the ability to overcome the issues usually caused because of the utilization of homogeneous catalysts. The application of bifunctional solids can be a novel way in heterogeneous catalyst-mediated biodiesel production because they showed the capability to accomplish the simultaneous esterification and transesterification reactions in a one-pot process. In addition, the development and application of the nanocatalysts will be a milestone in biodiesel production. These nanocatalysts will be the next-generation catalysts, which will help to develop the most effective, sensitive, sustainable and economically viable technology for the FAME production in the near future. Although recent advances in the developments of various homogeneous, heterogeneous and nanocatalysts showed a promising future for biodiesel industries or biorefineries, more efforts are required to develop even more effective and cheap catalysts, which will help overcome the present issues with all of the above-mentioned catalysts and increase the efficiency of sustainable biodiesel production.
