Catalyst Decomposition During Olefin Metathesis Yields Isomerization-Active Ruthenium Nanoparticles**

Carolyn S. Higman, Anabel E. Lanterna, M. Luisa Marin, Juan C. Scaiano* and Deryn E. Fogg*

Abstract: The second-generation Grubbs catalyst, RuCl3[H2(IMes)(PCy3)=CHPh] (GII), is shown to decompose during olefin metathesis to generate Ru nanoparticles. These RuNPs appear to contribute significantly to competing isomerization during metathesis. Larger, partially oxidized RuNPs are also observed in commercial GII, which exhibit modest isomerization activity. Removal of RuNPs from the precatalyst does not prevent isomerization, because new, more reactive NPs are generated by catalyst decomposition during metathesis.

Ruthenium-catalyzed olefin metathesis is a core tool in organic synthesis, and an emerging protagonist in the pharmaceutical industry. Notwithstanding the importance of these advances, a number of reports cite challenges arising from competing olefin isomerization, the dominant non-metathetical side reaction encountered. Isomerization is particularly pronounced for the second-generation Grubbs catalyst GII, relative to its predecessor GI (Figure 1).

![Figure 1. Grubbs catalysts GI and GII.](image)

Tandem metathesis–isomerization or isomerization–metathesis protocols, employed as a deliberate synthetic strategy, can enable access to targets that are otherwise challenging or inaccessible. More commonly, however, isomerization is an unintended, often capricious side-reaction that results in variable control over product selectivity and yields, in processes ranging from ring-closing metathesis (RCM) to cross-metathesis (CM) and metathesis polymerization. Ruthenium hydride complexes generated by catalyst decomposition are widely viewed as responsible. Until now, only molecular complexes have been considered as potential culprits, despite the low isomerization activity documented for leading candidates. Here we show that ruthenium nanoparticles (RuNPs) are formed by decomposition of GII during metathesis, and that these are important, hitherto unrecognized contributors to competing olefin isomerization. It should be noted that while NP formation is common for low-coordinate Pd catalysts that cycle between Pd(II) and Pd(0), reports of such behavior for well-defined ruthenium complexes operating in organic media are rare, outside hydrogenation reactions mediated by n^6-arene complexes of ruthenium. This is the first report of metal NP formation by decomposition of a molecular metathesis catalyst.

Olefin isomerization by RuNPs has not, to our knowledge, previously been reported. Given the activity of such species in other catalytic contexts, however, we speculated that they might function as viable isomerization catalysts. This proved to be the case. RuNPs were prepared by a range of methods (see SI), and tested for their activity toward isomerization of estragole 1. Estragole is an important renewable allylbenzene used in metathesis reactions, which, as with its congeners, is readily isomerized. Figure 2 shows the isomerization activity recorded for four different Ru-containing nanostuctures. All are clearly capable of inducing 1→2 isomerization. By far most active, however, were the Chaudret-Philipott NPs (Type D), prepared under rigorously anaerobic conditions, and stabilized by N-heterocyclic carbene (NHC) ligands. The dramatically higher isomerization activity of these NHC-stabilized NPs reflects the absence of oxidized surface species.

![Figure 2. Isomerization promoted by RuNPs prepared by methods shown in the SI: A: RuNPs on mesoporous silica MCM-41 (Ru@MCM), B: RuNPs on crystall nanodiamonds (Ru@CND). C: RuNPs stabilized with ethylene glycol, D: RuNPs stabilized with the NHC 1,3-bis(2,6-diisopropylphenyl)imidazole-2-ylidene (IPi).](image)

Given this evidence that RuNPs promote olefin isomerization, and prior reports that such side-reactions decline when commercial GII was chromatographed prior to use, we questioned whether RuNP contaminants might be present in GII, which trigger competing isomerization during metathesis. We found that commercial GII catalysts do indeed contain RuNPs, present as aggregates that agglomerate on isolation to an average size of >500 nm (see SI). However, the isolated particles induce olefin isomerization with low efficiency, requiring 24 h to...
reach 45% to under the conditions of Figure 2. This is unsurprising given their large size and partial oxidation, both of which limit the number of active surface sites.

To determine whether isomerization could be inhibited by removing the RuNPs present in the precatalyst, we generated NP-free GII by ultracentrifugation under N₂. As illustrated in Figure 3, the purified GII effected both metathesis and isomerization of estragole 1. Thus, yields of the metathesis product 3 increased over the first hour of reaction, but then declined as 3 underwent isomerization (Figure 3a). Strikingly, the extent of isomerization was only ca. 15% less than non-purified GII (Figure 3b). Freshly-decomposed Ru species thus appear to be important contributors to isomerization, with a level of activity much higher than the RuNP impurities present in the precatalyst.

![Figure 3. Performance of NP-depleted vs. NP-rich GII (solid or dashed lines, respectively), in metathesis of estragole 1. a) Formation and consumption of the self-metathesis product 3. b) Net isomerization (sum of reagent and product isomerization). See SI, S5.2.](image)

Notable in Figure 3b is the ca. 30-min induction period that precedes the onset of isomerization. Formation of NPs over this timescale was confirmed by in situ nephelometry experiments, in which the intensity of scattered light was detected by synchronous wavelength scanning. As with conventional dynamic light scattering, increases in scattering intensity indicate NP formation. Intensity changes were monitored in the 600–700 nm region, to eliminate perturbation arising from absorption by the sample. The intensity of scattering increased over the first 30 min (see SI), a change that maps onto the induction period in isomerization. In the absence of substrate, scattering was significantly reduced.

This evidence implies that RuNPs are formed by decomposition of ruthenium species generated during metathesis. We attribute the formation of nanoparticles, as opposed to molecular Ru products, to the loss of multiple ligands in the process of catalyst decomposition. Relevant in this context is the established pathway by which free PCy₃, liberated from the resting-state complex GIlm (Scheme 1), attacks the methylidene ligand of the active species Ru-1. Elimination of the α-alkyl ligand thus formed occurs via abstraction of a proton (most plausibly from the H₂IMes ligand) and bound chloride. This process culminates in extrusion of [MePCy₃]Cl A, a net loss of three ligands per Ru center. While isolation of the putative α-alkyl intermediate Ru-2 was precluded by its short lifetime, we recently succeeded in trapping out such a complex in the first-generation Grubbs system. The details of NP formation are now being probed by in situ X-ray absorption studies, but the low-coordinate Ru species resulting from such "ligand stripping" represent a plausible starting point.

![Scheme 1. Ejection of [MePCy₃]Cl A from the metathesis-active species Ru-1.](image)

Further experimental evidence for RuNP formation during metathesis comes from electron microscopy. In these experiments, styrene 4 was chosen as substrate, because the low solubility of its self-metathesis product 5 facilitates removal of organic species that otherwise occlude the micrographs. Scanning electron microscopy (SEM; Figure 4a) revealed NP-free solutions. Likewise, transmission electron microscopy (TEM) showed no NPs in analysis of multiple samples, down to the 0.2 nm detection level of the instrument. In contrast, abundant RuNP formation was evident following metathesis of 4, as shown in Figure 4b.

![Figure 4. Decomposition of NP-depleted GII into RuNPs during styrene metathesis.](image)

To examine whether isomerization is promoted by RuNPs generated by catalyst decomposition during metathesis, or by molecular species formed at an earlier stage, we carried out mercury poisoning experiments. Poisoning of metal(0) sites by elemental mercury is a common test for the involvement of surface-active species in catalysis. As shown in Figure 5, isomerization of 1 dropped by ca. 50% in the presence of Hg. Control experiments indicated that Hg had negligible impact on
the isomerization activity of common Ru hydride complexes (see SI). Indeed, the Hg test may under-report the contribution of RuNPs in Figure 5, given the reported instability of the Ru–Hg amalgam or adsorbate.[26]

Figure 5. Impact of added Hg on isomerization of 1 by initially NP-depleted GII. Conditions as in Figure 3.

Sub-stoichiometric poisoning experiments (Figure 6) were carried out to further probe the involvement of RuNPs in isomerization. Such experiments are predicated on the requirement for ≥1 equiv of a poisoning ligand to inhibit catalysis by molecular Ru species, in contrast with the smaller number of ligands required to inhibit NP catalysis (in which much of the initial metal charge is inaccessible in the NP core). Accordingly, we assessed the impact of PMe3, P(OMe)3 and PPh3Me (0.1 equiv vs. GII) on the rate of isomerization during self-metathesis of estragole 1. These experiments were carried out at 24 °C, to maximize the poisoning effect.[30] To compensate for the negative impact of the lower temperature on catalysis, we used a batch of estragole that showed much higher rates of isomerization,[31] as isomerization ceased immediately on adding the phosphine / phosphite poison (Figure 6).

Figure 6. Sub-stoichiometric poisoning experiments: impact of adding 10 mol% PR3 on the rate of isomerization during metathesis of 1. Conditions as in Figure 3, using NP-depleted GII, at 24 °C; poisons added at 1 h.

The foregoing demonstrates that RuNPs can show high activity for olefin isomerization, that RuNPs are formed by catalyst decomposition during GII-catalyzed metathesis, that Hg poisoning reduces isomerization, and that addition of a small proportion of a phosphine or phosphite poison, relative to the total Ru loading, is sufficient to completely shut down isomerization. On the basis of this cumulative picture, we propose that RuNPs formed by catalyst decomposition are important contributors to unwanted isomerization during olefin metathesis.

The context above focuses on unintended isomerization as a problem encountered during olefin metathesis. Insight into its origin, however, points toward new opportunities. The reaction conditions explored above were designed for metathesis, rather than NP formation or isomerization. Optimizing the synthesis of RuNPs, as well as the isomerization conditions, is expected to open new doors for the design of novel isomerization catalysts.

This hypothesis was inspired by Ananikov’s discovery that PdNPs are present in commercial sources of Pd$_2$(dba)$_3$. See: S. S. Zaleskiy, V. P. Ananikov, Organometallics 2012, 31, 2302–2309.

Also notable in Fig. 6 is the absence of an induction period. These differences suggest that catalyst decomposition is accelerated by unknown impurities that are not removed by Al$_2$O$_3$ pretreatment, and which vary in proportion from batch to batch (see Introduction).
