(Dated: February 2, 2008)

Spin propagation in systems of one-dimensional interacting fermions at finite temperature is intrinsically diffusive. The spreading rate of a spin packet is controlled by a transport coefficient termed “spin drag” relaxation time $\tau_{sd}$. In this paper we present both numerical and analytical calculations of $\tau_{sd}$ for a two-component spin-polarized cold Fermi gas trapped inside a tight atomic waveguide. At low temperatures we find an activation law for $\tau_{sd}$, in agreement with earlier calculations of Coulomb drag between slightly asymmetric quantum wires, but with a different and much stronger temperature dependence of the prefactor. Our results provide a fundamental input for microscopic time-dependent spin-density functional theory calculations of spin transport in 1D inhomogeneous systems of interacting fermions.

I. INTRODUCTION

Quantum many-body systems of one-dimensional (1D) interacting particles have attracted an enormous interest for more than fifty years and are nowadays available in a large number of different laboratory systems ranging from single-wall carbon nanotubes to semicon-ductor nanowires, conducting molecules, chiral Luttinger liquids at fractional quantum Hall edges, and trapped atomic gases.

Regardless of statistics, the effective low-energy description of these systems is based on a harmonic theory of long-wavelength fluctuations, i.e. on the “Luttinger liquid” model. The distinctive feature of the Luttinger liquid is that its low-energy excitations are independent collective oscillations of the charge density or the spin density, as opposed to individual quasiparticles that carry both charge and spin. This leads immediately to the phenomenon of spin-charge separation, i.e. the fact that the low-energy spin and charge excitations of 1D interacting fermions are completely decoupled and propagate with different velocities. This behavior has been recently demonstrated by Kollath et al in a numerical time-dependent density-matrix renormalization-group study of the 1D Hubbard model for fermions, by Kleine et al in a similar study of the two-component Bose-Hubbard model, and, analytically, by Kecke et al for interacting fermions in a 1D harmonic trap. The possibility of studying these phenomena experimentally in 1D two-component cold Fermi gases, where “spin” and “charge” refer, respectively, to two internal (hyperfine) atomic states and to the atomic mass density, was first highlighted by Recati et al.

In a recent paper two of us have pointed out a new aspect of spin-charge separation: namely, spin excitations are intrinsically damped at finite temperature, while charge excitations are not. The physical reason for this difference is easy to grasp. In a pure spin pulse the up-spin and down-spin components of the current are always equal and oppositely directed, so that the density remains constant. The relative motion of the two components gives rise to a form of friction known, in electronic systems, as “spin Coulomb drag”. This is responsible for a hydrodynamic behavior due to a randomization of “spin momentum” deriving from excitations in both the $q \to 0$ and $q \to 2k_F$ regions. In the course of time this leads to diffusive spreading of the packet. No such effect is present in the propagation of pure density pulses, which are therefore essentially free of diffusion in the long wavelength limit (by contrast, a density pulse in a normal Fermi liquid is always expected to decay into particle-hole pairs – a process known as Landau damping).

The analysis of Ref. was limited to spin-compensated (unpolarized) systems. In particular, the calculation of the spin-drag relaxation time $\tau_{sd}$ was done only for unpolarized systems. It is of great interest to extend the calculation to spin-polarized systems. First, a finite degree of spin-polarization is the most general situation in experiments. Second, and most important, any attempt to study the dynamics of spin packets beyond the linear approximation will have to take into account the spin-polarization of the liquid within the packet. This is particularly crucial in the time-dependent spin-current-density functional approach, which treats spin-current relaxation through a local spin-drag relaxation rate. Calculations done by this method will therefore require knowledge of $\tau_{sd}$ as a function of the local spin polarization and temperature. Finally, our study is relevant to the closely related problem of the regular Coulomb drag (no spin involved) between two semiconductor wires with different carrier densities. Here the two wires play formally the role of the two spin orientations, and the difference in density corresponds to the spin polarization. Our careful analysis of the low temperature regime yields a new formula for the temperature and polarization dependence of $\tau_{sd}$, which is completely different from the one that was obtained previously by a qualitative method.

The contents of the paper are briefly described as fol-
lows. In Sect. III we introduce the model Hamiltonian and we present our numerical calculations of the spin-drag relaxation rate of 1D spin-polarized Fermi gases. In Sect. IV we report and discuss our main analytical results. Finally, in Sect. V we summarize our main conclusions.

II. SPIN-DRAg RELAXATION TIME FOR SPIN-POLARIZED SYSTEMS

We consider a two-component Fermi gas with N atoms confined inside a tight atomic waveguide of length L (an “atomic quantum wire”) along the x direction, realized e.g. using two overlapping standing waves along the y and the z axis as in Ref. 1. The atomic waveguide provides a tight harmonic confinement in the y−z plane, characterized by a large trapping frequency \( \omega_\perp \approx 2\pi \times 10 \text{ kHz} \). The two species of fermionic atoms are assumed to have the same mass \( m \) and different spin \( \sigma \), \( \sigma = \uparrow \) or \( \downarrow \). The number of fermions with spin \( \uparrow \) (\( N_\uparrow \)) is taken to be larger than the number of fermions with spin \( \downarrow \) (\( N_\downarrow \)), \( N_\uparrow > N_\downarrow \). The fermions have quadratic dispersion, \( \varepsilon_k = \hbar^2 k^2 / (2m) \), and interact via a zero-range s-wave potential \( v(x) = g_{\text{sd}} \delta(x) \). The Fourier transform of such a real-space potential is a simple constant, \( v_g = g_{\text{sd}} \). The system is thereby governed by the Yang Hamiltonian

\[
\mathcal{H} = -\frac{\hbar^2}{2m} \sum_{i=1}^{N_\uparrow} \partial_x^2 + g_{\text{sd}} \sum_{i=1}^{N_\uparrow} \sum_{j=1}^{N_\downarrow} \delta(x_i - x_j). \tag{1}
\]

The effective 1D coupling constant \( g_{\text{sd}} \) can be tuned by using a magnetic field-induced Feshbach resonance to change the 3D scattering length \( a_{3D} \). In the limit \( a_{3D} \ll a_{\perp} \), where \( a_{\perp} = \sqrt{\hbar^2 / (m \omega_\perp)} \), one finds \( g_{\text{sd}} = 2\hbar^2 a_{3D} / (m a_s^2) \). In the thermodynamic limit \( (N_\sigma, L \to \infty, N_\sigma/L = n_\sigma) \) the properties of the system described by \( \mathcal{H} \) are determined by the linear density \( n = n_\uparrow + n_\downarrow \), by the degree of spin polarization \( \zeta = (N_\uparrow - N_\downarrow) / N \), and by the effective coupling \( g_{\text{sd}} \). For future purposes it will be useful to introduce the dimensionless Yang interaction parameter \( \gamma = m g_{\text{sd}} / (\hbar^2 n) \). We also introduce the Fermi wave number \( k_F = \pi n / 2 \) of the unpolarized system, the Fermi velocity \( v_F = \hbar k_F / m \), and the Fermi energy \( \varepsilon_F \).

Within second-order perturbation theory the spin-drag relaxation rate (at zero frequency) is given by the formula

\[
\frac{1}{\tau_{\text{sd}}} = \frac{\hbar^2 n}{n_\uparrow n_\downarrow m k_F T} \int_0^{+\infty} \frac{dq}{2\pi} \frac{q^2 v_g^2}{\pi} \times \int_0^{+\infty} \frac{d\omega}{\pi} \frac{\Im \chi_\sigma(0)(q, \omega) \Im \chi_\sigma(0)(q, \omega)}{\sinh^2[\hbar \omega / (2k_B T)]}, \tag{2}
\]

where \( \Im \chi_\sigma(0)(q, \omega) \) is the spin-resolved finite-temperature expression for the imaginary part of the 1D Lindhard function \( \chi \).

Here \( k_F \sigma = k_F [1 + \text{sgn}(\sigma) \zeta] \) [by definition \( \text{sgn}(\sigma) = +1 \) for \( \sigma = \uparrow \) and to −1 for \( \sigma = \downarrow \)], \( N_\sigma(0) = m / (\pi \hbar^2 k_F \sigma) \) is the spin-resolved density of states at the Fermi level, \( \varepsilon_F \sigma = \varepsilon_F [1 + \text{sgn}(\sigma) \zeta]^2 \), and

\[
\nu_{\pm,\sigma} = \frac{m \omega}{q \hbar k_F \sigma} \pm \frac{q}{2 \hbar k_F \sigma}. \tag{4}
\]

In Eq. 5 \( \mu_\sigma(T) \) is the spin-resolved chemical potential, which is determined by the normalization condition

\[
n_\sigma = \int_0^{+\infty} \frac{dk}{2\pi} \frac{1}{\exp[(\varepsilon_k - \mu_\sigma(T)) / (k_B T)] + 1} \tag{5}
\]

In Fig. 1 we report some illustrative numerical results for the spin-drag relaxation rate \( \tau_{\text{sd}}^{-1} \) of a 1D spin-polarized Fermi gas as calculated from Eqs. (2)-(5). Note from the inset in Fig. 1 that a finite value of \( \zeta \) has a dramatic effect on the low-temperature behavior of the spin-drag relaxation rate, changing it from linear \( 12 \) to exponentially activated. At high temperatures \( \tau_{\text{sd}}^{-1} \) is seen to be insensitive to the degree of spin polarization, becoming asymptotically equal to the unpolarized \( \zeta = 0 \) result. Both observations will be demonstrated in the next Section with analytical calculations.

Note finally that \( \tau_{\text{sd}}^{-1} \) is largest for the unpolarized case, simply because the “overlap” between \( \Im \chi_\sigma(0)(q, \omega) \) and \( \Im \chi_\sigma(0)(q, \omega) \) is maximum at \( \zeta = 0 \).

III. ANALYTICAL RESULTS

Low- and high-temperature analytical expressions for \( \tau_{\text{sd}}^{-1} \) have been derived in the unpolarized case in Ref. 12. Here we proceed to derive some analytical results for \( \tau_{\text{sd}}^{-1} \) for \( \zeta \neq 0 \). Similar calculations have been performed earlier by Pestunih et al. \( 36 \) with the aim of studying the Coulomb drag between slightly asymmetric quantum wires. We will comment at length below on the
the authors focus only on the low-
q to what happens in the unpolarized case

ary spin population.
}

FIG. 1: (Color online) Spin-drag relaxation rate \( \tau_{sd}^{-1} \) (in units of \( \varepsilon_F / \hbar \) and divided by \( \gamma^2 \)) as a function of the reduced temperature \( k_B T/(2\varepsilon_F) \) for three different values of the spin polarization \( \zeta \). In the inset we show a zoom of the low-temperature region \( 0 \leq k_B T/(2\varepsilon_F) \leq 0.5 \).

connection between our calculations and the calculations reported in Ref. 20.

It is crucial to realize20 that a finite degree of spin polarization implies the existence of a new temperature scale (i.e. in addition to the Fermi temperature \( T_F \)), that we define as \( T_\zeta \equiv T_{F\uparrow} - T_{F\downarrow} = 4\zeta T_F \), where \( T_{F\uparrow} = \varepsilon_{F\uparrow}/k_B \). In what follows we will derive analytical results for \( T \ll \min(T_\zeta, T_{F\downarrow}) \). Note that this inequality guarantees also that the minority \( \downarrow \)-spin component is always in the regime of quantum degeneracy, thus allowing us to use Eq. 12 also for the imaginary part of the spin-resolved density-density response function for the minority spin population.

Before proceeding to illustrate our analytical procedure [outlined from Eq. (5) down below], it is instructive to summarize the main steps followed by Pustilnik et al. to derive Eq. (16) in Ref. 20. As it will be clear below, there are two contributions to the inverse spin-drag relaxation time, one coming from the low-\( q \) region and the other one coming from the \( q \approx 2k_F \) region, similarly to what happens in the unpolarized case22. In Ref. 20 the authors focus only on the low-\( q \) contribution and use the \( T = 0 \) rectangular form for the imaginary part of the Lindhard response function, i.e. \( \Im m\chi_0^{(0)}(q, \omega) |_{T=0} = [m/(2\hbar^2 q^2)](\Theta(hq^2/(2m) - |\omega - v_{F\sigma} q|), \) where \( \Theta(x) \) is the Heaviside step function. This immediately implies that the product \( \Im m\chi_0^{(0)}(q, \omega)\Im m\chi_0^{(1)}(q, \omega) \) in Eq. (20) is itself a rectangle of width \( \delta \omega = \hbar q^2/m - 2\zeta hv_{F\sigma} q/m \) centred at \( \omega = \nu F \). For this reason Pustilnik et al.20 substitute the thermal factor \( 1/\sinh^2(\omega/(2k_B T)) \) with \( 1/\sinh^2(\hbar qv_F/(2k_B T)) \), bringing it outside the \( \omega \) integration in Eq. (2). Then, using the fact that

\[
\alpha(q, \zeta) = \int_0^{+\infty} d\omega \Im m\chi_0^{(0)}(q, \omega)\Im m\chi_0^{(1)}(q, \omega) |_{T=0} = \frac{m}{4\hbar^2 q} (q - 2\zeta k_F) \Theta(q - 2\zeta k_F),
\]

they arrive at the result

\[
\frac{1}{\tau_{sd}} |_{\text{PMGA}} = \int_{2k_F}^{+\infty} dq v_F^2 \frac{q(q - 2\zeta k_F)}{\sinh[\hbar qv_F/(2k_B T)]} \propto \zeta T \exp\left(-T_\zeta/T\right),
\]

for \( \zeta \ll 1 \).

Using the zero-temperature expression for the product \( \Im m\chi_0^{(0)}(q, \omega)\Im m\chi_0^{(1)}(q, \omega) \) results, however, in the wrong pre-exponential factor: the thermal tails of \( \Im m\chi_0^{(0)}(q, \omega) \) are exponentially small but they have a finite overlap for the two spin populations precisely in the low-frequency region where the factor \( 1/\sinh^2(\omega/(2k_B T)) \) is large and thus can originate contributions that are much larger, in the low-temperature limit, than the contributions retained in Eq. (7). The two regions where the thermal tails of \( \Im m\chi_0^{(0)}(q, \omega) \) and \( \Im m\chi_0^{(0)}(q, \omega) \) overlap are depicted as dark grey regions in Fig. 2 and will be discussed at length below. In what follows we will show that the functional dependence on \( \zeta \) and \( T \) of the pre-exponential factor in Eq. (7) is incorrect. In particular the prefactor \( T \) should be replaced by the much larger \( T^{-1} \). To show this, we proceed as follows.

Inserting Eq. (9) in Eq. (2) we find, after some straightforward algebraic manipulations, the following expression for \( \tau_{sd}^{-1} \)

\[
\frac{1}{\tau_{sd}} = \frac{mn\beta}{8\pi^2 \hbar^2 n_{\uparrow} n_{\downarrow}} \int_{0}^{+\infty} dq v_F^2 \int_{0}^{+\infty} d\omega \frac{I(q, \omega)}{\sinh[\beta\hbar q^2/(2k_B T)]}
\]

Here \( \beta = (k_B T)^{-1} \) and \( I(q, \omega) \) can be written as

\[
I(q, \omega) = \frac{\sinh[\beta\hbar q^2/2]}{\cosh(\beta q^2/2) + \cosh(\beta q^2/2) + \cosh[\beta(\hbar q^2/2) + 2\cosh(\beta q^2/2) \cosh(\beta q^2/2) \cosh(\beta q^2/2)]}
\]

with

\[
\begin{align*}
\theta_1 &= 4\zeta \varepsilon_F \\
\theta_2 &= \frac{m\omega^2}{q^2} + \frac{\hbar^2 q^2}{4m} - 2\varepsilon_F (1 + \zeta^2)
\end{align*}
\]

We would like to stress at this point that Eq. (8) has
been obtained from Eq. (2) without any approximation. Two facts are remarkable. To begin with, we note that, quite surprisingly, an exact cancellation occurs between the factor \(\sinh^2(\beta \omega) / 2\) in the numerator of Eq. (9) and the same factor in the denominator of the \(\omega\)-integral in Eq. (8). Secondly, a new temperature scale, \(T_\zeta = 4 \zeta \varepsilon_F / k_B\), has set in. A color plot of the function \(I(q, \omega) / \sinh^2(\beta \omega) / 2\), i.e. the integrand in Eq. (8), is reported in Fig. 3 for two values of \(\zeta\) at \(T = 0.1 T_F\). We can thus distinguish clearly two regions in the \((q, \omega)\) plane where this function is non-zero: one region, “close” to \(q = 0\), which has the shape of an olive leaf and another region, “close” to \(2 k_F\), which has the shape of a shark fin. These two regions will be defined accurately in what follows. Note also that on decreasing \(\zeta\) the area of each of these regions decreases (see also Fig. 4): in the limit \(\zeta \to 0\) the two regions become two points located at \((0, 0)\) and \((2 k_F, 0)\) in the \((q, \omega)\) plane, as expected from the calculations performed in Ref. (12).

Thanks to the aforementioned cancellation, to make some analytical progress in the calculation of \(\tau_d\) for \(T \to 0\) we just need to understand what happens for \(T \to 0\) to the four cosh terms in the denominator of Eq. (2). To begin with, note that the first term \(\cosh(\beta \theta_1) / 2\) is independent of \(q\) and \(\omega\). In the limit \(T \to 0\) we can substitute all hyperbolic cosine functions with simple exponentials.

\[
I'(q, \omega) \equiv \frac{I(q, \omega)}{\sinh^2(\beta \omega) / 2} \xrightarrow{T \to 0} \frac{4}{\exp(\beta \theta_1) + \exp(\beta |\theta_2|) + \exp(\beta \omega) + \exp[\beta(\theta_1 + |\theta_2| - \omega)] / 2} \xrightarrow{T \to 0} \frac{4 \exp(-\beta \theta_1)}{1 + \exp[\beta(\theta_2 - \theta_1)] + \exp[\beta(\omega - \theta_1)] + \exp[\beta(\theta_2 + \omega - \theta_1)] / 2},
\]

where we have taken into account the possibility that \(\theta_2\) becomes negative [contrary to the other arguments of the \(\cosh\) functions in Eq. (9) that are positive definite]. In the limit \(T \to 0\) the exponentials in the denominator of the second line of Eq. (11) are either zero (if their argument is negative) or infinity (if their argument is positive). This implies that \(\exp(\beta \theta_1) I'(q, \omega)\) differs from zero only when the arguments of all the exponentials in the denominator of Eq. (11) are negative. Thus \(I'(q, \omega)\) reduces to a very simple form,

\[
I'(q, \omega) \xrightarrow{T \to 0} \frac{4 \exp(-\beta \theta_1) \Theta(\theta_1 - |\theta_2| - \omega)}{\Theta(\theta_1 - |\theta_2| - \omega)}.
\]

More explicitly, \(I'(q, \omega) \xrightarrow{T \to 0} 4 \exp(-\beta \theta_1)\) if \(\theta_1 - |\theta_2| - \omega > 0\), i.e.

\[
\left| \frac{m \omega^2}{q^2} + \frac{\hbar^2 q^2}{4 m} - 2 \varepsilon_F (1 + \zeta^2) \right| + \omega < 4 \varepsilon_F,
\]

and zero elsewhere. Eq. (13) determines two disconnected regions in the \((q, \omega)\) plane where \(I'(q, \omega)\) is non-zero: (i) a region that we have called above “olive leaf” \((D_{OL})\) enclosed between the two parabolic arches

\[
\begin{align*}
\omega_{up}(q) & = -\varepsilon_q / h + h k_F (1 + \zeta) q / m, \\
\omega_{down}(q) & = \varepsilon_q / h + h k_F (1 - \zeta) q / m,
\end{align*}
\]

with \(0 \leq q \leq 2 \zeta k_F\): and (ii) a region that we have called above “shark fin” \((D_{SF})\) enclosed between the two parabolic arches

\[
\begin{align*}
\omega_{left}(q) & = \varepsilon_q / h + h k_F (1 - \zeta) q / m, \\
\omega_{right}(q) & = -\varepsilon_q / h + h k_F (1 + \zeta) q / m,
\end{align*}
\]

with \(2(1 - \zeta) k_F \leq q \leq 2(1 + \zeta) k_F\). These regions have been shown in Fig. 2 \(\text{vis-à-vis}\) the region implicitly considered in Ref. (20). Note that in these domains \(I'(q, \omega)\) is a constant = \(4 \exp(-\eta T_\zeta / T)\), independent of \(q\) and \(\omega\).

At this point we can easily calculate analytically the asymptotic \(T \to 0\) behavior of the spin-drag relaxation
FIG. 3: (Color online) A color density plot of $I'(q, \omega)$ as a function of $q/k_F$ and $\hbar\omega/\varepsilon_F$ for $T = 0.1 T_F$. Top panel: $\zeta = 0.4$. Bottom panel: $\zeta = 0.75$. The two regions, olive leaf and shark fin, are clearly distinguishable.

rate in Eq. (8): for $v_q = g_{1D}$ we find

$$
\frac{1}{\tau_{sd}} \xrightarrow{T \to 0} \frac{4m}{8\pi^2\hbar^2 n(1 - \zeta^2)k_B T} g_{1D}^2 \times 4 \exp(-T\zeta/T) 
\times \int \int_{D_{OL}\cup D_{SF}} dq d\omega
= \left[ \frac{32}{3\pi^3} \gamma^2 \frac{3\zeta^2 + \zeta^3}{1 - \zeta^2} \frac{2\varepsilon_F}{k_B T} \exp\left(-\frac{T\zeta}{T}\right) \right] \frac{\varepsilon_F}{\hbar},
$$

(16)

where we have used that $\int \int_{D_{OL}\cup D_{SF}} dq d\omega = (8\zeta^2 + 8\zeta^3/3)k_F\varepsilon_F/\hbar$ (sum of the two areas of the olive leaf and shark fin domains). In this equation the first contribution $\propto \zeta^2$ comes from the shark fin region (i.e. the region “close” to $q = 0$). The activation law $\exp(-T\zeta/T)$ in Eq. (16) is identical to the one reported above in Eq. (7) (see Ref. 20). The prefactor, however, has a completely different functional dependence on temperature (proportional to $T^{-1}$ rather than $T$) and polarization. Quite interestingly, the scaling $\zeta \to T$ in Eq. (16) gives the correct temperature dependence of the unpolarized result, i.e. a linear term from $q \approx 2k_F$ and a quadratic term from $q \approx 0$. In Fig. 5 we show a comparison between the analytical formula (16) and the numerical results for $\zeta = 0.1$ as calculated from Eqs. (2)-(5). The agreement is clearly excellent in the asymptotic regime $T \ll T\zeta$.

Before concluding, we would like to calculate the high-temperature limit of the spin-drag relaxation rate. In this

FIG. 4: (Color online) Same as in Fig. 3 but for $\zeta = 0.1$.

FIG. 5: (Color online) A comparison between the analytical formula in Eq. (16) (solid line) and the numerical results calculated from Eqs. (2)-(5) (filled squares).
limit the spin-resolved chemical potential is simply given by \( \mu_\sigma(T \to \infty) = k_B T \ln |\sigma| \lambda_{\text{IB}}(T)| \), where \( \lambda_{\text{IB}}(T) = \frac{\sqrt{2\pi \hbar^2/(mk_B T)}}{2} \) is the thermal de Broglie wavelength. Using this result one easily finds

\[
\frac{1}{\tau_{sd}} \to \infty \quad \frac{m}{2\hbar^2 n^2 \pi^{1/2}} \left( \frac{k_B T}{2\varepsilon_F} \right)^{-3/2} \times \int_0^{+\infty} dq \ q v_q^2 \exp \left( -\frac{\varepsilon_q}{2k_B T} \right),
\]

for which \( v_q = g_{1D} \) becomes

\[
\frac{1}{\tau_{sd}} \to \infty \quad \frac{16}{\pi^{1/2}} \left( \frac{k_B T}{2\varepsilon_F} \right)^{-1/2} \frac{\varepsilon_F}{\hbar},
\]

At high-temperature the spin-drag relaxation rate becomes \( \pi \)-independent and identical to the one calculated \( \frac{\varepsilon_q}{2k_B T} \) for a strictly unpolarized system.

IV. CONCLUSIONS

In summary, we have carefully studied within second-order perturbation theory the spin-drag relaxation time of a spin-polarized 1D Fermi gas. We obtain accurate numerical results for \( 1/\tau_{sd} \) as a function of spin polarization and temperature (see Fig. 1), and also an accurate analytical formula for the spin-polarization dependence of \( 1/\tau_{sd} \) in the low temperature regime, which is completely different from what was obtained earlier from an approximate argument.\(^{20} \) These results provide the necessary input for the application of time-dependent current-spin density functional theory to the study of the propagation of spin pulses in the nonlinear regime.\(^{26} \) This in turn will be useful in future comparisons between theory and experiments on spin-pulse propagation in 1D cold Fermi gases.

Note added in proof—Going beyond second-order perturbation theory, one finds to leading order an additional contribution to \( 1/\tau_{sd} \) that arises from intra-species interactions. Such a contribution has a power-law temperature dependence,\(^{20,27} \) and could thus become dominant over the exponential contribution calculated in this work at the lowest temperatures. In Ref. \(^{20} \) it has been shown that this contribution goes as \( T^5 \), and is proportional to \( v_0^2 (v_0 - v_{2k_F})^2 \). This implies that if the interaction range is less than the typical interparticle distance the fourth-order contribution is expected to be suppressed.

In this work we neglect the effect of the weak harmonic potential along the symmetry axis \( x \), which is present in the experiments. Its effect can be treated via a suitable local-density approximation\(^{10,11,22,23}\).
