This study aimed to evaluate the effect of sulfinic acid sodium salt interposition after acid and sodium hypochlorite treatment (NC treatment) on dentin bonding durability using a mild type one-step self-etching adhesive. Fifteen human third molars were randomly assigned into three experimental groups according to dentin pretreatment before applying the one-step self-etching adhesive: Cont group, without pretreatment; NC group, pretreatment with phosphoric acid and sodium hypochlorite gel; and NC+AC group, additional treatment with sulfinic acid sodium salt followed by the same pretreatment of the NC group. Microtensile bond strength was measured and the pre-treated dentin surface, fracture modes, and bonding interface were observed. The bond strength of the NC+AC group was significantly higher than that of the other groups (p<0.001). The dentin-adhesive interface was degraded after 1 year only in the Cont group. Our results demonstrated NC treatment improves bonding durability and application of sodium sulfinic acid salt after NC treatment improves bonding effectiveness.

Keywords: Sulfinic acid sodium salt, Sodium hypochlorite, Mild type one-step self-etching adhesive, Microtensile bond strength, Dentin bonding durability

INTRODUCTION

Self-etching adhesives, which contain acidic functional monomers to demineralize and infiltrate into dentin substrate simultaneously, are commonly used to prepare dentin surfaces for bonding. These adhesives are thought to require less technical skill than etch-and-rinse adhesives with increased durability1). However, since self-etching adhesive systems do not require rinsing, a smear layer remains on the dentin surface after applying the adhesives. As mild type adhesives cannot completely dissolve the smear layer2), the bonding effectiveness of mild self-etching adhesives to dentin is significantly influenced by the thickness of the smear layer. Belli et al. reported that a thinner smear layer is ideal for higher bonding effectiveness3). Additionally, Suyama et al. found that complete absence of the smear layer significantly improved the bond strength between dentin and resin composite4). Hence, pretreatment to remove the smear layer from dentin surface before applying a self-etching adhesive might be effective to improve the bonding effectiveness.

Since the early 1990s, the use of a total-etching system, which etches both enamel and dentin to remove the smear layer, has gained attention5). However, after total etching, the dentin surface is covered with demineralized collagen, making it inaccessible to complete dentin bonding. Consequently, the durability of resin-dentin adhesion can be decreased. To solve this problem, phosphoric acid and sodium hypochlorite (NaClO) application (NC treatment) was introduced in the 1990s to remove demineralized collagen fibrils from the adhered dentin surface and expose hydroxyapatite on the surface6-8). Although this treatment, which uses both acid and NaClO to remove the smear layer and demineralized collagen fibrils, respectively, is presumed to be efficient for dentin-resin bonding in resin cement systems9), no research has reported the effectiveness of this treatment method using mild type self-etching adhesive systems, which have been widely used in clinical practice.

NaClO is also commonly used as an irrigation solution in root canal treatment. Some studies have demonstrated a negative effect of NC treatment on dentin-resin composite bonding10,11). This negative effect may be due to oxygen production during treatment, resulting in low polymerization rate of the adhesive12). To solve this problem, some studies recommended that additional treatment with antioxidant/reducing agents (e.g., sodium ascorbate, rosmarinic acid, and sulfinic acid sodium salt) can restore the decreased bond strength after NaClO application13-15). Among these agents, sulfinic acid sodium salt has long been used as a chemical initiator16). Hence, we speculated that application of sulfinic acid sodium salt after etching and NC treatment might be effective to increase the bonding effectiveness.

The objective of this study was to determine the effect of sulfinic acid sodium salt interposition after acid
and NC treatment on dentin bond durability using a mild type one-step self-etching adhesive. The null hypotheses were as follows:

1) NC treatment has no positive effect on dentin bonding using a mild type one-step self-etching adhesive.
2) Sulfinic acid sodium salt application after NC treatment has no positive effect to increase dentin-resin composite bonding.
3) One-year water storage has no influence on the bond durability between dentin and resin composite.

MATERIALS AND METHODS

Tooth preparation and resin buildup

Fifteen human third molars, stored in Hank's Balanced Salt solution (HBSS), were used within 6 months after extraction. All teeth were extracted due to periodontal or orthodontic reasons. The experimental protocol was approved by the Ethics Committee of the Osaka University Faculty of Dentistry (No. H26-E6). Mid-coronal dentin surface was obtained by removing the occlusal third of the molar crowns using a low-speed diamond saw (Maruto Instrument, Fukuoka, Japan) under water cooling, and a standard smear layer was prepared with 600 grit SiC paper (Fig. 1a). All specimens were randomly assigned into three experimental groups \((n=5)\) following treatment as described below (Table 1, Figs. 1a, b and 2)\(^7\):

1. Control (Cont) group: The manufacturer’s instructions were followed using the photo cure adhesive (Clearfil Bond SE ONE, Kuraray Noritake Dental, Tokyo, Japan) and the photo cure resin composite (Clearfil Majesty ES-2, Kuraray Noritake Dental). The resin composite was incrementally built up (two layers of about 2 mm each). After applying the adhesive, samples were light cured for 10 s with a cordless light-emitting diode curing light (SATELEC Mini LED 3, Acteon, Merignac, France), which had a maximal light density of 2,200 mW/cm². The composite was also light cured for 10 s per layer, which was considered sufficient to completely cure the resin composite according to the manufacturer’s instructions.

2. NC group: The dentin surface was etched for 15 s using 37% phosphoric acid (K-Etchant gel, Kuraray Noritake Dental), rinsed, and air dried. Then, 10% NaClO-gel (AD gel, Kuraray Noritake Dental) was applied using a rubbing motion for 10 s. After rinsing and air drying for 10 s, the resin composite was light cured for 10 s per layer.

3. Adhesive —

Fig. 2 Experimental groups and treatments. Fifteen human third molars were randomly assigned into three experimental groups: no pretreatment (Cont), dentin pretreatment with phosphoric acid and sodium hypochlorite gel (NC), and additional treatment with sulfinic acid sodium salt followed by the same pretreatment of the NC group (NC+AC). n=5.

Dental) was applied for 60 s and rinsed off. The adhesive and resin composite were then applied as described in the Cont group.

3. NC+AC group: Following the same pretreatment protocol as the NC group, sulfinic acid sodium salt (Accel, Sun Medical, Kyoto, Japan) was applied for 15 s and air dried. The adhesive and the composite were then applied as described in the Cont group.

Microtensile bond strength (μTBS) test
After 24-h water storage, teeth were sectioned perpendicular to the long axis into a series of 1-mm-thick slices under water cooling and 12–16 beams were obtained from each tooth (Fig. 1c). The beams were randomly divided into three subgroups according to the length of water storage (24 h, 6 months, and 1 year) (Fig. 1d). The beams were attached to a jig using cyanoacrylate glue (Model Repair, Dentsply Sankin, Tokyo, Japan) and subjected to tensile force at the crosshead speed of 1 mm/min using a benchtop testing machine (EZ Test, Shimadzu, Kyoto, Japan) (n=15). The cross-sectional area of each beam was measured using a digital caliper (Mitutoyo CD15, Mitutoyo, Tokyo, Japan).

Failure mode analysis
Fractured dentin surfaces were observed using an optical microscope (magnification, 30×). Failure patterns were determined and categorized as cohesive failure in dentin, cohesive failure in the composite, adhesive failure between the composite and the adhesive, adhesive failure between the adhesive and dentin, and mixed failure. Representative specimens were observed using a scanning electron microscope (SEM; JSM-6390, Nihon Denshi, Tokyo, Japan) (Fig. 1e).

Transmission electron microscopy (TEM)
Six 1-mm-thick slices for each group were randomly divided into two groups and stored in water at 37°C for 24 h or 1 year. Slices were serially sectioned perpendicular to the long axis into 400-μm thickness under water cooling. Each slice was then sectioned into...
small blocks including the dentin-bond interface and fixed in 4% paraformaldehyde and 5% glutaraldehyde overnight. Samples were then dehydrated in a graded ethanol series and embedded in epoxy resin (Quetol 812, Nissin EM, Tokyo, Japan). The embedded specimens were sectioned into 70–90-nm thickness using a diamond knife (Nanotome Thick, Sakai Advanced Electron Microscope Research Center, Saitama, Japan) on an ultra-microtome (Ultratome V, LKB, Stockholm, Sweden). The sections were finally mounted on copper grids and observed using a TEM (H-800, Hitachi, Tokyo, Japan) at an accelerating voltage of 200 kV (Fig. 1f).

Pretreated dentin surface observation
Three human non-caries molars were stored in HBSS and used within 6 months after extraction. Mid-coronal dentin surfaces were obtained by removing the occlusal third of the molar crowns using the low-speed diamond saw under water cooling. A standard smear layer was prepared using 600 grit SiC paper (Fig. 1a). The dentin surface was divided into four sections and each surface was treated as follows:

1. No treatment (Cont).
2. Etching: Etch the dentin surface for 15 s using 37% phosphoric acid (K-Etchant gel, Kuraray Noritake Dental), rinse, and air dry.
3. NC: Etch the dentin surface using phosphoric acid, rinse, air dry, and apply 10% NaClO gel (AD gel, Kuraray Noritake Dental) for 60 s.
4. NC+AC: Etch the dentin surface using phosphoric acid, apply NaClO gel and sulfinic acid sodium salt (Accel, Sun Medical) for 15 s, and air dry (Fig. 1g).

Specimens were then observed by SEM (Fig. 1h).

Statistical analyses
The μTBS data were analyzed by two-way repeated-measures ANOVA and Scheffé’s multiple comparison test. Additionally, the aging time effect was analyzed by one-way ANOVA and Scheffé’s test. Differences were considered to be statistically significant at a level of 5%.

RESULTS

μTBS test
Mean bond strengths are summarized in Table 2 and Fig. 3. Two-way repeated-measures ANOVA revealed a significant effect of pretreatment ($p<0.001$, $F=23.4$) and aging time ($p=0.008$, $F=5.0$), but not for the correlations between individual factors ($p=0.822$). Scheffé’s multiple comparison test showed that the bond strength was significantly higher in the NC+AC group than in the other two groups ($p<0.001$). However, no significant difference was observed between the Cont group and the NC group ($p=0.923$). According to one-way ANOVA, a significant influence of aging time was observed in the Cont group ($p=0.012$). In the Cont group, Scheffé’s

Table 2  Microtensile bond strength and failure analysis

| Group   | 24 h       | Aging Time          | 1 year       |
|---------|------------|---------------------|--------------|
|         | 38.4 (10.5) a | 35.9 (10.6) a,b     | 28.1 (11.1) b |
|         | (2/4/0/3/6)   | (0/2/2/0/11)        | (0/2/2/0/11) |
| NC      | 39.3 (15.6)   | 33.2 (11.7)         | 33.0 (13.4)  |
|         | (0/2/2/0/11)  |                    | (0/7/1/0/7)  |
| NC+AC   | 53.3 (9.7)    | 50.0 (11.8)         | 45.8 (12.9)  |
|         | (0/1/2/0/12)  |                    | (1/5/1/0/8)  |

Numbers in parentheses in the upper line refer to ±standard deviation and numbers in parentheses in the lower line refer to number of beams per failure mode as follows: cohesive in dentin/cohesive in the composite/interface between the adhesive and dentin/interface between the composite and the adhesive/mixed. Within Cont group, means with same letters are not statistically different.
Fig. 4  Representative SEM photomicrographs of the dentin surface.  
(a): The dentin surface in the Cont group is covered by a smear layer. (b): After phosphoric acid treatment. Complete absence of the smear layer and collagen fibrils is observed. (c): In the NC group, collagen fibrils are removed and dentin tubules are observed. (d): The dentin surface in the NC+AC group is similar to that in the NC group.

multiple comparison test showed a significant difference between 24-h and 1-year subgroups ($p=0.012$).

Pretreated dentin surface observation
The dentin surface was covered by the smear layer in the Cont group (Fig. 4a). However, the smear layer was removed by phosphoric acid processing and a collagen fiber layer was observed on the surface during the etching process (Fig. 4b). The collagen fiber layer was then removed and the diameter of dentin tubules increased after applying NaClO (Fig. 4c). After sulfinic acid sodium salt application, obvious changes were not observed (Fig. 4d).

Failure mode analysis
Mixed failure predominantly occurred in all groups, followed by cohesive failure in the composite except for the NC+AC group at 24 h (Table 2). Interface failure between the composite and the adhesive was observed only in the Cont group at 24 h (Table 2, Fig. 5a). Concerning mixed failure in the Cont group, the adhesive-dentin interface was seldom observed in the 24-h subgroup, though the adhesive-dentin interface was more frequently observed in the 1-year subgroup (Fig. 5b). The NC group and the NC+AC group demonstrated a similar trend in that there was no clear difference between 24-h and 1-year subgroups except cohesive failure in the composite was increased (Table 2). SEM observation of the fractured surface showed a similar

Fig. 7  Representative TEM photographs of the adhesive interface.
(a): The Cont group at 24 h. (b): Magnified image (15,000×) of (a). The smear layer (SL) is observed below the adhesive layer, and a smear plug (SP) is observed in a dentin tubule. (c): The Cont group at 1 year, magnified image (15,000×). A gap (white arrow) is observed between the adhesive layer and the dentin layer. (d): The NC group at 24 h. Dentin tubules are open and the adhesive fills dentin tubules, forming resin tags. (e): Magnified image (15,000×) of (d). Collagen fibrils (1 μm) are observed. (f): The NC group at 1 year, magnified image (15,000×). No gap is observed between the adhesive layer and the dentin layer. (g): The NC+AC group at 24 h. (h): Magnified image (15,000×) of (g). No smear layer (SL) and no smear plug (SP) is observed. Resin tags are observed. (i): The NC+AC group at 1 year, magnified image (15,000×). No gap is observed between the adhesive layer and dentin layer. ad: adhesive, co: composite, de: dentin, SL: smear layer, SP: smear plug. Black arrowheads indicate dentin tubules, white arrows indicate gaps, and double-headed white arrows indicate the smear layer.
Some studies reported that NC treatment could improve bond strength and durability, whereas other studies reported that it decreased bond strength and caused microleakage. In this study, the application time of phosphoric acid and NaClO gel was 15 and 60 s, respectively. Wakabayashi et al. reported a sufficient bonding effect of 15-s phosphoric acid application and 60-s NaClO gel application. After NC treatment, the smear layer and collagen fibrils on the dentin surface appeared to be removed completely under SEM observation as mentioned above. However, TEM observation revealed a decalcified collagen layer remained in some areas in the NC group, indicating that the effect of NaClO gel may vary. As the decalcified collagen layer has been thought to create a weak area, we speculate that this layer influenced the mean bond strength of the NC group. In the present study, the flat dentin surface was considered to be an easily removable collagen layer rather than the dentin surface in clinical settings, which is thought to be more difficult to manipulate. Therefore, a negative effect of NC treatment may be readily observed when phosphoric acid and NaClO gel are used in dentin in clinical settings.

Between the NC+AC group and the NC group, a significant difference in bonding effectiveness was observed. Therefore, the second null hypothesis—there is no positive effect on dentin bonding by sulfinic acid sodium salt interposition—was rejected. This outcome corroborates a previous report which demonstrated bond strengths of NaClO-treated dentin could be restored by application of sodium sulfinic acid. The authors concluded that the application of Accel for 5 or 10 s improved bond strengths of NaClO-treated dentin. Ascorbate acid and sodium ascorbate are also used as reducing agents in clinical practice. Yiu et al. reported additional treatment with sodium ascorbate restored bond strengths after NaClO treatment. Additionally, Morris et al. found that NaClO and EDTA agents produced significantly large reductions in resin-dentin bond strengths, which could be completely reversed by application of either 10% ascorbic acid or 10% sodium ascorbate. Prasansuttiporn et al. also reported that application of Accel after NaClO treatment could obtain higher bond strengths than application of sodium ascorbate. Taken together, the effectiveness of sodium sulfinic acid was not inferior to that of other reducing agents. Because sodium sulfinic acid can be stored for prolonged periods, it is preferred in clinical settings.

This study evaluated not only immediate bond strength, but also bonding durability. In the Cont group, there was a significant difference between the 24-h and 1-year subgroups. However, no significant effect of water aging was observed in the NC group and the NC+AC group. Therefore, the third null hypothesis—1-year water storage has no influence on bonding ability—was accepted for the NC and NC+AC groups and rejected for the Cont group. In the Cont group, bond strengths significantly decreased by water aging and failure in...
the dentin-adhesive interface, including specimens counted as mixed failure, was more frequently observed in the 1-year subgroup than in the 24-h subgroup. Moreover, a clear gap in the smear layer and degradation at the bottom of the smear layer were observed in the Cont group at 1 year by TEM. Conversely, in the NC group and the NC+AC group, bond strengths significantly decreased and remarkable morphological changes were not detected by TEM and SEM. Kodama evaluated the effect of NC treatment using Panavia 21, a conventional dual-cure resin cement, and concluded that NC treatment improved resin-dentin bond durability20). Degradation of collagen fibers is one of the main factors associated with bonding durability. Thus, the removal of collagen at the bonded interface seems to be effective. These factors are responsible for a greater infiltration of adhesive systems in dentin23). The findings of the present study, which used a mild type one-step self-etching adhesive, suggest that the remnant smear layer has a negative effect on bond durability. In clinical practice, the dentin surface would be covered by temporary cement, dental plaque, and/or saliva, and some bacteria may be trapped in the smear layer. NC treatment can remove not only the smear layer and decalcified collagen, but also these chemical and biological contaminants. Therefore, NC treatment might be more effective in clinical practice than in vitro conditions.

The simplified one-step system is gaining attention in clinical practice19). However, this adhesive system has inadequate decalcification ability, thus the smear layer is not completely removed. The present study showed that the bond strength of the Cont group, which used a mild type one-step system adhesive containing 10-MDP that was thought to be resistant to degradation, was significantly decreased after water aging. NC treatment was anticipated to resolve this shortcoming. However, some studies reported that NC treatment performed better in dual-cure cement systems17,20) but was unsuitable for 4-META/MMA-TBB resin cement. Moreover, the application of antioxidants can increase bond strengths18). These results suggest that the deproteinization effect of NC might be adhesive-dependent and the application of antioxidants after deproteinization may be beneficial only in select adhesive systems. Thus, further studies evaluating various adhesive systems are needed to validate this technique.

CONCLUSION

According to the results of this study, we confirmed the effectiveness of the following steps before application of mild type one-step adhesive to dentin: 1) application of phosphoric acid and NaClO to improve bonding durability and 2) application of sodium sulfinic acid salt after NC treatment to improve bonding effectiveness.
