Synaptic depression enables neuronal gain control

Jason S. Rothman, Laurence Cathala, Volker Steuber & R. Angus Silver

To act as computational devices, neurons must perform mathematical operations as they transform synaptic and modulatory input into output firing rate. Experiments and theory indicate that neuronal firing typically represents the sum of synaptic inputs, an additive operation, but multiplication of inputs is essential for many computations. Multiplication by a constant produces a change in the slope, or gain, of the input–output relationship, amplifying or scaling down the sensitivity of the neuron to changes in its input. Such gain modulation occurs in vivo, during contrast invariance of orientation tuning, attentional scaling, translation-invariant object recognition, auditory processing and coordinate transformations. Moreover, theoretical studies highlight the necessity of gain modulation in several of these tasks. Although potential cellular mechanisms for gain modulation have been identified, they often rely on membrane noise and require restrictive conditions to work. Because nonlinear components are used to scale signals in electronics, we examined whether synaptic nonlinearities are involved in neuronal gain modulation. We used synaptic stimulation and the dynamic-clamp technique to investigate gain modulation in granule cells in acute slices of rat cerebellum. Here we show that when excitation is mediated by synapses with short-term depression (STD), neuronal gain is controlled by an inhibitory conductance in a noise-independent manner, allowing driving and modulatory inputs to be multiplied together. The nonlinearity introduced by STD transforms inhibition-mediated additive shifts in the input–output relationship into multiplicative gain changes. When granule cells were driven with bursts of high-frequency mossy fibre input, as observed in vivo, larger inhibition-mediated gain changes were observed, as expected with greater STD. Simulations of synaptic integration in more complex neocortical neurons suggest that STD-based gain modulation can also operate in neurons with large dendritic trees. Our results establish that neurons receiving depressing excitatory inputs can act as powerful multiplicative devices even when integration of postsynaptic conductances is linear.

The way a neuron transforms signals can be captured by its input–output relationship (Fig. 1a). A modulatory input can change the shape of this relationship, thereby performing a mathematical operation on this transfer function. A shift along the input axis corresponds to an additive operation (+), whereas a change in slope corresponds to a multiplicative operation, or gain change (×). Cerebellar granule cells (GCs) are well suited for studying gain modulation because they have few synaptic inputs. Excitation comes from approximately four mossy fibres (MFs), which can sustain rate-coded signals over a large bandwidth and have STD. Inhibition comes from Golgi cells, most of which is mediated by a modulatable tonic GABA (γ-aminobutyric acid subtype A) receptor (GABAR) conductance. Because it is difficult to activate multiple inputs independently, and because we wanted to compare real synaptic inputs showing frequency-dependent STD with artificial synaptic inputs without STD, we used dynamic-clamp to study synaptic integration.

GCs are ideal for this because their soma and dendrites form a single electrical compartment, allowing dendritic inputs to be mimicked by somatic conductance injection.

We measured AMPA (\(\alpha\)-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptor (AMPA)-mediated excitatory postsynaptic currents (EPSCs) from mature GCs at physiological temperature during Poisson-type stimulation of single MFs at different frequencies. These EPSCs, which showed STD, were then converted to conductance (Fig. 1b, +STD, blue traces throughout). Artificial conductance trains without STD (−STD, red traces throughout) but with identical event timing were constructed by adding a fixed amplitude synaptic conductance waveform at each stimulus time. The effects of STD on synaptic integration were then investigated by injecting the sum of four statistically independent conductance trains with the same mean MF rate into GCs using dynamic clamp and measuring the mean output firing rate with and without STD (Fig. 1c). The resulting steady-state input–output relationships revealed that STD had an almost purely multiplicative effect under control conditions (Fig. 1d). Multiplicative and additive transformations of the input–output relationship were quantified by fitting the data to Hill-like equations\(^{16}\)URTHER.refs_to_gaps\(^{16}\) (Fig. 1d, equation (5) in Methods and Supplementary Table 1) and measuring the change in slope (Fig. 1e, AGain, green) and the shift in the half maximal response (\(Δ\)Offset, orange). In the absence of STD, adding a 500 pS tonic inhibitory conductance (\(G_{inh}\); Fig. 1c) close to the physiological value (438 ± 93 pS (mean ± s.e.m.;\(n = 10\)) produced a modest scaling of the input–output relationship together with an additive shift\(^{13}\) (Fig. 1d,e). In contrast, the same level of inhibition produced a fourfold larger gain change in the input–output relationship when driven with depressing synapses. Moreover, this multiplicative scaling was nearly constant over the entire input range (Supplementary Fig. 1).

To understand how STD performs multiplicative gain modulation, we examined the frequency-dependence of the time-averaged excitatory conductances (\(G_{exc}\); Fig. 2a, dashed lines). Without STD, the relationship between \(G_{exc}\) and MF input rate (\(f\)) was linear (Fig. 2b). With STD, it became noticeably sublinear above 40 Hz and could be fit with a saturating exponential function (Fig. 2b). To examine how \(G_{exc}\) was integrated postsynaptically, we plotted the mean GC firing rate (\(F\)) as a function of \(G_{exc}\). We found that the \(F_{exc}\) relationships with and without STD overlaid (Fig. 2c), indicating that \(G_{exc}\) was integrated similarly for both cases. Thus, the nonlinearity between \(f\) and \(G_{exc}\) introduced by STD underlies the enhanced gain modulation.

Because neuronal gain can be altered by synaptic noise\(^{11,13}\), we examined how STD transforms GC \(F_{exc}\) relationships generated with noise-free conductance steps (Fig. 2d, inset\(^{13}\)) and noisy synaptic conductances (Fig. 2e, inset). Hill equations were used to mimic \(F_{exc}\) relationships (Fig. 2d, e, insets) whereas linear and exponential functions were used to represent \(G_{exc}\) relationships (Fig. 2b). These were then combined to predict the input–output relationships. In the absence of STD, additive shifts in the \(F_{exc}\) relationship produced a purely additive shift in the input–output relationship (Fig. 2d, e), consistent with conductance performing an additive operation when the noise level is constant\(^2,3\). In contrast, when STD was present, additive shifts in the \(F_{exc}\) relationship produced robust gain changes in the input–output relationship for both noise-free and noisy excitations (Fig. 2d, e). Indeed, the gain change predicted from purely additive shifts in the \(F_{exc}\) relationship accounted for most of that observed experimentally (Fig. 2e). This shows that STD transforms linear, additive modulation of the \(F_{exc}\) relationship into multiplicative gain modulation of the input–output relationship, irrespective of the presence of synaptic noise.

Our experimental results were reproduced in a conductance-based integrate-and-fire model that included short-term synaptic plasticity (Supplementary Fig. 2a, b) confirming the primary role of STD in gain modulation, rather than synaptic noise or other nonlinear synaptic
mechanisms, such as AMPAR activation by means of spillover. Increasing the level of STD increased the inhibition-mediated gain reduction (Supplementary Fig. 2c, d). Conversely, increasing the level of tonic inhibition increased the size of the gain reduction at all levels of STD. We also observed gain modulation with phasic inhibitory conductances, which are widespread in the central nervous system (Supplementary Fig. 3), confirming that STD-mediated gain modulation operates effectively with both phasic and tonic inhibition.

NMDA (N-methyl-D-aspartate) receptors (NMDARs) contribute to transmission at many central synapses and show a nonlinear voltage dependence. To examine experimentally how this synaptic component interacts with STD-based gain modulation, we measured the NMDAR component during Poisson stimulation of a single MF input and added it to the AMPAR conductance trains from the same GCs (Fig. 3a). The $G_{exc}/rel$ relationships for the combined AMPAR and NMDAR components (Fig. 3b) were similar in shape to the AMPAR-only cases with and without STD (Fig. 2b), because the relationship between the mean NMDAR conductance and MF frequency was approximately linear (Fig. 3b, inset, and Supplementary Fig. 4). In the absence of AMPAR STD, 500 pS inhibition produced a slightly less gain modulation than the AMPAR component alone (Fig. 1d, e, 12.6%), as assessed by means of spillover23. The $G_{exc}/rel$ relationships accounted for most of the inhibition-mediated gain change (Supplementary Fig. 5), confirming that it was mediated predominantly by STD.

Several factors complicate the implementation of multiplicative operations in neurons with extensive dendritic trees. The large voltage fluctuations required for noise-based gain modulation24,25,26,27 are difficult to achieve with many inputs and heavy dendritic filtering, without precisely balanced excitation and inhibition. Moreover, multiplication by means of nonlinear dendritic integration28 or a combination of noise and dendritic saturation29 requires spatially localized activation of synapses on a single dendritic branch, but these are usually distributed over the tree, making linear synaptic integration more likely25. To test whether the STD-mediated gain modulation can operate effectively in more complex neurons than GCs, we simulated synaptic integration in a neocortical layer 5 neuron model with hundreds of synaptic inputs, randomly distributed over the network.

Because EPSC depression occurs rapidly in GCs (most effective when synaptic depression has reached steady state. Integration to be matched to the operational frequency of the inputs. NeuroConstruct (http://www.NeuroConstruct.org) and run on the NEURON connected to 400 excitatory neurons and 30 inhibitory neurons using division and the lack of dependence on synaptic noise indicate that modulatory inputs once depression has occurred. Transient enhancement of the gain of dynamically changing inputs perform distinct multiplicative operations on different time scales: multiplication of driving and modulatory input conductance is most effective when synaptic depression has reached steady state. Because EPSC depression occurs rapidly in GCs (τ defending = 1.5 pulses), gain modulation will only require a 4–7 ms settling time (2τ defending/frequency; 40–800 Hz), but at cortical synapses where STD occurs at lower frequencies gain modulation will be slower. STD-mediated gain modulation allows a modulatory conductance to scale a neuron’s sensitivity to all of its driving inputs. This is distinct from the transient synaptic responses to changes in input rate, which allows signalling independent of absolute rate. STD can therefore perform distinct multiplicative operations on different time scales: transient enhancement of the gain of dynamically changing inputs before STD has developed, and multiplication of all driving and modulatory inputs once depression has occurred.

Our findings show that the mathematical operation performed by a modulatory input on a particular set of driving inputs depends on their STD characteristics. This could allow input-configuration-specific, and thus context-dependent, computation at the level of a single neuron. The widespread incidence of STD, its compatibility with linear synaptic integration and the lack of dependence on synaptic noise indicate that this cellular mechanism for gain modulation could be used to multiply inputs together in many different neuronal types in the brain.

METHODS SUMMARY
Whole-cell recordings were made from GCs at 35.3 ± 0.1 °C (n = 62) in rat cerebellar slices (postnatal day 30–40). EPSC trains for conductance clamp were recorded during stimulation of a single MF input at random Poisson intervals (mean rate f = 6–138 Hz). The NMDAR EPSC component was isolated by recording in 5 mM 2,3-dioxo-6-nitro-1,2,3,4-tetrahydrobenzo[f]quinoxaline-7-sulphonamide (NBQX). The AMPAR EPSC component was obtained by subtracting control and NBQX recordings. Conductance trains at each frequency were constructed by averaging ten responses, subtracting stimulus artefacts, dividing by the driving force, and averaging responses from four different GCs. AMPAR, NMDAR and tonic GABAR conductances with reversal potentials of 0 mV, 0 mV and −75 mV, respectively, were injected into GCs using a dynamic clamp amplifier. Inhibition was blocked with 100 μM SR95531. Direct activation of GC firing was achieved with single MF excitation using a 15-pulse Poisson stimulation (25–800 Hz). To minimize the effects of any time-dependent changes in excitability, MF excitation was randomized, control and tonic inhibition measurements interleaved, and experiments were carried out within 15 min of obtaining intracellular access to the GC. The cortical layer 3 neuron model27 was connected to 400 excitatory neurons and 30 inhibitory neurons using neuroConstruct (http://www.NeuroConstruct.org) and run on the NEURON simulator (http://www.neuron.yale.edu). Data are presented as mean ± s.e.m.

METHODS

Parasagittal slices (200–250 μm) of the cerebellar vermis were prepared from Sprague-Dawley rats (P30–40) in ACSF solution containing (in mM) 125 NaCl, 2.5 KCl, 1.25 NaHCO3, 1.25 NaH2PO4, 2 CaCl2, 1 MgCl2, 25 glucose and 0.5 ascorbic acid (pH 7.4 when bubbled with 95% O2 and 5% CO2), or in a low-sodium sucrose solution containing (in mM) 85 NaCl, 2.5 KCl, 26 NaHCO3, 1.25 NaH2PO4, 0.5 CaCl2, 4 MgCl2, 25 glucose, 63.4 sucrose and 0.5 ascorbic acid. In some preparations 1 mM kynurenic acid or 10 μM d-(-)-2-amino-5-phosphonoheptanoic acid (d-APV) was added to block glutamate receptors. After ~30 min incubation at 32 °C, slices were transferred to ACSF solution at room temperature (~20 °C). Whole-cell recordings with a series resistance of 27.9 ± 1.3 MΩ (n = 62) were made with an Axopatch 200B amplifier, filtered at 7–10 kHz and digitized at 33–100 kHz using an InstruTech ITC-18 board and Axograph and NeuroMatic software (http://www.neuromatic.thinkrandom.com). GCs had a cell capacitance of 3.2 ± 0.1 pF (n = 62) and a resting membrane potential of −78.5 ± 0.9 mV (n = 52). Data were analysed using NeuroMatic within the Igor Pro environment (WaveMetrics).

Synaptic conductance trains and dynamic-clamp. Whole-cell recordings were made from GCs perfused with ACSF containing 0.3 μM strychnine and 10 μM SR95531 (Gabazine) to block inhibitory receptors, and 3 μM glycine to ensure NMDAR activation. Recordings of EPSCs used to be made for dynamic-clamp were made at −54 mV or −60 mV, using fire-polished borosilicate micropipettes (in mM) 110 KmeSO3, 4 NaCl, 1.78 CaCl2, 0.3 Na-GTP, 4 Mg-ATP, 40 HEPES and 5 EGTA (pH 7.3), or in some cases 90 CaCl2, 10 NaCl, 1.78 CaCl2, 0.3 Na-GTP, 4 Mg-ATP, 40 HEPES and 5 EGTA (pH 7.3). EPSCs were evoked by extracellular stimulation of a single MF input using Poisson stimulation trains (PSTs) of 250–2,500 ms duration with a 1-ms minimum refractory interval. Ten repetitions of four statistically different PSTs were recorded from each MF–GC synapse at each frequency. Stimulus artefacts were removed by convolving a single stimulus artefact with the PST, and subtracting the resulting waveform from the averaged data. Dynamic current trains were converted to conductance trains by dividing by the holding potential, after correcting for the liquid junction potential. Conductance trains with the same conductance from four different GCs were aligned and averaged, and had a mean conductance close to the population mean. To create non-depressing AMPAR conductance trains, the first AMPAR response of each train was fit with the following multiplicative-exponential function:

$$G(t) = (1 - e^{-t/\tau_A})^n [a e^{-t/\tau_A} + a_0 e^{-t/\tau_0} + a_0 e^{-t/\tau_0}]$$

where $\tau_A$ is the base of the natural logarithm, $\tau_A$ and $\tau_0$ are the time constants of the rising and decaying components, respectively, $a_0$ are the amplitude components and $t$ is the time. The resulting fit was then convolved with the given PST to create a non-depressing train (Fig. 1b, red trace).

Dynamic-clamp recordings and spike analysis. Slices were perfused with ACSF containing 10 μM SR95531 to block tonic GABAR currents. Dynamic-clamp recordings were made from GCs using fire-polished borosilicate micropipettes containing (in mM) 114 KmeSO3, 6 NaOH, 3 MgCl2, 0.02 CaCl2, 0.3 Na-GTP, 4 Na-ATP, 40 HEPES and 0.15 BAPTA (pH 7.3). A liquid junction potential of +6.3 mV (n = 5) was corrected before gaining whole-cell access. During recordings, the resting membrane potential ($V_{rest}$) was maintained near −80 mV using small amounts of holding current. Conductance trains were injected with a three-channel SM1 amplifier (Cambridge Conductance). Because GCs receive an average of four MF inputs, and often require more than one input to fire^25,26, AMPAR conductance trains (and NMDAR conductance trains) from four statistically different PSTs were summed together at each input frequency (F) before injection into GCs by means of dynamic-clamp as described below.

Unlike the AMPAR component, which follows a simple linear Ohmic relationship with voltage, the NMDAR component introduced by the SM1 amplifier has a Boltzmann-like nonlinearity that mimics the voltage-dependent Mg2+ block of the NMDA conductance measured in GCs (Supplementary Fig. 4). This nonlinearity introduced by the SM1 amplifier scaled the NMDA conductance waveforms so that the final peak value, after leaving the SM1 amplifier, matched that of GCs, as described by the following Boltzmann function:

$$G_{inh}(V) = \frac{G_{max}}{1 + e^{-(V - V_{inh})/k}}$$

where $G_{inh}$ = 367.9 pS, $V_{inh}$ = −12.8 mV and k = 22.4 mV (n = 6 cells; curve fit to data in Supplementary Fig. 4a). During the experiments, conductance trains at various F were injected in a random order, and conditions with and without tonic inhibition ($G_{inh}$ = 500 pS; steps began 10 ms before onset of the synaptic input) were presented consecutively at each F. Some GCs were excluded because their output spike rate was too low or absent in the presence of STD and tonic inhibition (13 out of 36 cells), preventing an accurate measurement of a gain change. This will tend to underestimate the gain change we report. Cells were also discarded if the heights of their action potentials changed more than 10% during the experiment (3 out of 36 cells). For dynamic-clamp experiments, GC output firing rate (F) was calculated from 100 ms after the onset to the end of the stimulus train. Action potentials were detected using a threshold-level detection set at 0 mV.

Granule cell excitation with mossy fibre stimulation. GCs were directly activated by stimulating single MF inputs with burst PSTs (F = 25–800 Hz; 1 ms minimum refractory interval) to mimic in vivo MF activity^27,28. Bursts lasted for a period T = 15/f seconds, consisting of approximately 15 stimuli. Average conductance and output spike rate were computed over the same period T, but starting from the time of the fourth stimulus, when STD reached approximate steady-state levels. Recording conditions were the same as those described for the dynamic-clamp recordings, except $V_{rest}$ was maintained at −75 mV rather than −80 mV because most GCs (69%; n = 22 of 32) either did not fire action potentials when stimulated from their resting potential or did not produce enough output spikes to compute an input–output relationship in the range 25–800 Hz. Tonic inhibition was applied with dynamic-clamp ($G_{inh}$ = 500 pS; steps began 75 ms before onset of the synaptic stimulation) and was alternated with control conditions at each F.

Data analysis. Plots of average excitatory conductance ($G_{exc}$) versus MF input rate (F) (GABAR relationships; Figs 2b and 3b) were fit with a linear equation for AMPAR conductances with STD:

$$G_{exc}(f) = mF + b$$

and an exponential function for AMPAR conductances with STD:

$$G_{exc}(f) = mF |1 - e^{-f/f_0}|$$

where $\alpha$ is a frequency constant and $\beta$ is a shared slope factor. At low frequencies ($f < \lambda$), these two equations are approximately equal. Plots of GC firing rate F versus $G_{exc}$ ($G_{exc}$ relationships) were well described by a Hill equation of the form:

$$F_{max}(G_{exc}) = \frac{F_{max} \cdot G_{exc}^{n_d}}{G_{exc}^{n_d} + K_{d}}$$

where $n_d$ and $K_{d}$ are the time constants of the rising and decaying components, respectively, $a_0$ are the amplitude components and $t$ is the time. The resulting fit was then convolved with the given PST to create a non-depressing train (Fig. 1b, red trace).

Neuronal models. A GC-like conductance-based integrate-and-fire model was implemented in the NEURON simulation environment and was described by the following equation:

$$\frac{dV}{dt} = \frac{(V - E_L) - D(G_{AMPAR}(V - E_{AMPAR}) + G_{GABAR}(V - E_{GABAR}))}{R_m}$$

where $C_m$ = 3.1 pF, the reversal potentials for the leak $E_L = -75$ mV, AMPARs $E_{AMPAR} = 0$ mV and GABARs $E_{GABAR} = -75$ mV, and a membrane resistance $R_m = 2.6 \Omega$. Spikes were generated when the model reached a threshold of −49 mV, at which time the voltage was set to 10 mV for one integration time step, and then clamped to −75 mV for a refractory period of 2.5 ms. The AMPAR conductance was described by equation (1), using the following values computed to our GC AMPAR conductance data: $n = 11$, $t = 0.1$ ms, $a_0$ = 2.23 mV, $t_a$ = 0.45 ms, $a_0$ = 0.29 mS, $a_0$ = 2.88 mS, $a_0$ = 0.08 mS and $t_a$ = 21.67 ms. For simulations with STD, whenever the integrate-and-fire model received an excitatory input, the amplitude of the postsynaptic AMPAR
response was multiplied by a scale factor $\delta$ ($D\to D\delta$)\textsuperscript{36}. Between inputs, $D$ recovered exponentially back to its initial value of 1.0 with a time constant $\tau_{D} = 40$ ms. For simulations with phasic inhibitory input (Supplementary Fig. 3) the synaptic GABAR conductance was described by equation (1) using the following values: $n = 8.34$, $\tau_{r} = 0.14$ ms, $a_{1} = 53.02$, $a_{2} = 0.05$ ms, $a_{3} = 0.53$, $a_{4} = 6.90$ ms and $a_{5} = 0$. The peak conductance was set to 663 pS to give a time-averaged conductance of 500 pS at 100 Hz. Mean input rates were 50–150 Hz.

A model of a cortical layer 5 neuron\textsuperscript{27} was synaptically connected to 400 excitatory neurons and 30 inhibitory neurons using neuroConstruct\textsuperscript{39} (http://www.NeuroConstruct.org) and the code was automatically generated for the NEURON simulator\textsuperscript{37}. Each excitatory synaptic cell had three synaptic contacts (to model six contacts with intermediate release probability)\textsuperscript{40} and inhibitory contacts had five synaptic contacts (to model ten synaptic inputs)\textsuperscript{41}. Both input types were distributed randomly over the basolateral dendritic tree and soma to mimic layer 5–layer 5 connectivity. Excitatory synaptic inputs had a conductance time course described by two exponential functions ($\tau_{\text{rise}} = 3$ ms, $\tau_{\text{decay}} = 3$ ms) and a peak conductance of 3 nS\textsuperscript{39} (that is, 1 nS at each of the three synaptic contacts). Each presynaptic excitatory neuron was driven to fire an independent Poisson spike train (1–70 Hz) and the synaptic conductance was scaled by the level of STD, which was implemented as described previously using experimentally measured values for layer 5 pyramidal cell connections (where the fraction of synaptic resource used, $U_{\text{net}}$, was equal to 0.5, and the time constants of inactivation and recovery were $\tau_{\text{inact}} = 3$ ms and $\tau_{\text{recov}} = 500$ ms, respectively)\textsuperscript{42}. Inhibitory synaptic inputs had fixed conductances with a dual exponential time course ($\tau_{\text{rise}} = 0.3$ ms, $\tau_{\text{decay}} = 10$ ms) and a peak conductance of 3.5 nS\textsuperscript{41}. Presynaptic inhibitory neurons were driven with independent Poisson trains with mean rates 30–150 Hz. Reversal potentials for excitatory inputs had a conductance time course $V_{\text{rest}} = 0$ mV and $V_{\text{rest}} = 275$ mV, respectively. Because the excitatory drive for non-depressing synapses was much higher than the more physiological depressing inputs, we carried out simulations with two different synaptic conductances (3 nS and 0.5 nS) for the non-STD case. 50 Hz inhibition produced a similar gain change for the two conductances (−11.7% and −10.9%, respectively), but the larger conductance gave a bigger gain change at 150 Hz as expected for noise-based gain modulation (−28.6% versus −22.9%). The 0.5 nS value was chosen for comparison because the excitatory input drive (0–70 Hz) better matched that of the STD case (0–60 Hz; Fig. 3b, d) than for 3 nS inputs, which saturated firing at input rates of only 12 Hz. Output firing rate was measured at steady state. Input–output relationships were fit with a simple Hill function similar to equation (5), but with input frequency ($f$) substituted for $G_{\text{net}}$, owing to difficulty in defining the effective $G_{\text{net}}$ for a distributed input. $\Delta$Gain and $\Delta$Offset were calculated assuming a maximum rate of 100 Hz. Because the model\textsuperscript{37} had an input resistance in the absence of synaptic input (11.5 MΩ) at the low end of that measured experimentally 9–123 MΩ (mean 36 MΩ)\textsuperscript{41}, we repeated the simulations with a different model\textsuperscript{44} with a high-input resistance (79 MΩ), which we modified to fire repetitively. We obtained similar results for the effects of inhibitory synaptic input on the input–output relationship in the presence and absence of STD in the excitatory input (data not shown), although fewer presynaptic cells (100 excitatory and 20 inhibitory) were required to drive the model over a similar range of frequencies.
